Foreword

Birding Past, Present and Future—a Global View

For Max Nicholson, who made us all into birders.

Introduction

> *For those who practise it bird-watching is not only a sport and a science, but also something near a religion, and after all its externals have been inventoried the essence stays incommunicable.* **[1]**
>
> Max Nicholson, 1931

Today, in the first decade of the third millennium, birding is a truly global leisure activity, carried out by millions of people throughout the developed and developing world. Yet just a century ago it was a minority pastime, practised by a small number of people, and virtually confined to Britain, North America and parts of the British Empire.

This essay aims to show how, in barely one hundred years, birding went from being the preserve of a few eccentric enthusiasts to the mass-participation leisure activity of today.

Following a brief summary of the history and development of birding during the 20th century, I shall review the current state of birding in a number of contexts: including changes in the demographics of who watches birds, how birding contributes to conservation, the influence of new technology, and the economic impact of birding.

Finally, I venture a number of predictions as to how birding might develop in the next fifty years or so, given the potential impact of global climate change, technological, social and political developments, and the nature of leisure.

Inevitably I have had to be selective in my approach: it is simply impossible to do full justice to the massive topic of the history, development and possible future of birding in such limited space. I have therefore chosen to concentrate on the following broad themes:

- How birding emerged from the disciplines of museum-based ornithology and the collecting of specimens in the field; and how some of that 'hunting and collecting' ethos was retained in modern practices such as twitching and listing.
- How the need to protect birds and conserve their habitats helped recruit people into the pastime of birding: initially through the Royal Society for the Protection of Birds (RSPB) in Britain, and the National Audubon Society in the United States, and later elsewhere in the world.
- How ornithology and birding have developed in parallel: with ornithologists providing birders with 'scientific justification' for their hobby, while birders provide scientific data used by ornithologists in their work, through participation in 'Citizen Science' projects.
- How an expansion in global travel has changed the way we watch birds, both in the developed and developing world, and the resulting impacts (both positive and negative) on the conservation of habitats and species.
- How the economic value of birding has emerged as a key factor in its development as a mass-participation activity, both in the developed and the developing world.
- How new technology, especially in the field of communications and the Internet, has revolutionised the way we watch birds.
- How the demographics of birding have changed: from being the pastime of educated, white, middle-class males into one pursued by a more broadly-based cross-section of humanity.
- How radical changes in the global environment—most notably climate change and its consequences—are likely to affect birds and birding in the 21st century.

Although the practice of watching birds primarily for pleasure goes back at least to the late 18th century (as depicted in *The Natural History and Antiquities of Selborne* **[2]** by Hampshire vicar Gilbert White, 1789), and arguably even further, I have chosen to concentrate mainly on the period from the beginning of the 20th century to today.

During this period—barely longer than a single human lifetime—birding underwent a profound series of social changes which laid the foundations of the way we watch birds at the beginning of the 21st century.

For a more detailed discussion of the early development of birding, including the way birds were perceived in the era before birdwatching became a recognised leisure activity, I refer the reader to my earlier work, *A Bird in the Bush: a Social History of Birdwatching* (Stephen Moss, 2004) **[3]**.

Note:
Readers of this essay may find the material and examples too focused on the United Kingdom and United States. In my defence, I must point out that virtually all the published surveys, analyses and histories of birding emanate from those two countries; and that even when I have quoted examples of more global initiatives, such as bird tourism, conservation programmes or bird clubs and societies, the impetus behind these—and often the people involved—tend to be either British or American.

There are many reasons for this. First, there is the long and distinguished history of birding and ornithology in those two nations. Second, the far higher participation rates in the UK and US, meaning that in terms of sheer numbers a vast proportion—perhaps 90% of the world's birders—either live in or come from there. Finally, the social and economic pressures, especially in developing countries, that make birding beyond the aspirations of the majority of the population.

I sincerely hope that over the coming century this situation will change; and that the foundations laid by British and American birders—and many others—around the world will lead to a truly global community of birders. This may already be happening—the wide representation at the annual British Birdwatching Fair certainly gives a basis for optimism—but as I examine in Part 4, there are factors which may stop such progress in its tracks.

Part 1: Birding Today

> *The entry-level birder... is probably between 40 and 59 years old and is white. She puts in about 10 birding days or fewer per year, trying to squeeze birding into a busy life... This female birder lives in the South in a suburban area, has a modest-to-middle income standard of living, and may not have a college degree.* **[1]**
>
> Ken Cordell and Nancy G. Herbert, 2002

According to the statistics, from a US Fish & Wildlife Service study carried out in 2001 **[2]**, there are approximately 46 million birders in the United States. These represent a substantial minority—more than one in five—of the adult population (those over 16 years old).

Most of these—at least 40 million—are what Americans call 'backyard birders', watching birds in and around their homes. But a significant proportion—18 million individuals, representing almost 40% of those surveyed—travelled at least one mile from their home specifically in order to watch birds.

In the United Kingdom, a recent RSPB survey **[3]** found that there are 2·85 million 'active birders', while the number of people who feed birds in their garden has been estimated at almost 30 million—about two out of three of the adult population, and roughly the same as the number who use the Internet. The RSPB boasts well over one million members; television programmes featuring British birds regularly top the ratings on terrestrial channels; while the number of bird books has increased exponentially, with hundreds of titles now published each year.

If one event can be said to epitomise the popularity of birding—not just in Britain but throughout the world—it is the British Birdwatching Fair. Described as "a cross between the Chelsea Flower Show and the Glastonbury Music Festival" **[4]**, the Birdfair is held annually, on a site alongside Rutland Water in the heart of the English countryside.

Since it first began in the late 1980s, the Birdfair has grown into the biggest event in the British birding calendar. Vast marquees house hundreds of exhibitors, selling all manner of birding products and services ranging from optics to books and clothing to exotic foreign holidays. Thousands of people attend the three-day event, coming from all over the world to make the Birdfair truly global in scope. Most importantly, at a

time when bird populations and habitats are under threat everywhere, the Birdfair has donated over £1·5 million to global bird conservation projects, making a significant impact on the welfare of birds.

The original Birdfair has, thanks to the efforts of its founders, spawned a number of similar events around the world: in places such as the Netherlands, Israel, India, Taiwan and Australia, as well as many state-based events around the US. Each event helps to encourage birding and conservation in the country where it takes place; and each, too, forms another link in the rapidly growing global birding network.

This is the most significant aspect of the Birdfair: that it provides a central, physical meeting place for the global birding community. Of course not everyone can attend; but at some time or another, a significant proportion of the key people in the birding world do so. Writers, artists, tour leaders, business people, identification experts, publishers, conservationists and amateur enthusiasts can meet each other, exchange ideas, discuss projects, and in doing so help to strengthen and develop birding as a truly global activity.

Elsewhere in the world, birding is thriving as never before:

- In Australia, Sean Dooley's book *The Big Twitch* **[5]**—an account of the author's successful attempt to break the Australian 'Big Year' record—became an unexpected bestseller, turning the young birder and comedy writer into a national celebrity.
- Off the coast of California, Debi Shearwater (a woman who loves seabirds so much she changed her name to one!) runs a series of offshore boat trips, known as 'pelagics', allowing birders from all over North America and beyond to see rare and elusive seabirds **[6]**.
- In October 2004, the 7th annual Turkish Bird Conference was held in Izmir, on the edge of the Aegean Sea. Unlike similar conferences held in Britain and the US, most of the birders who attended were under 30 years old, and about one in three were women.
- The Internet now hosts many 'bird forums', where birders can discuss sightings, exchange news and views, etc. One such example is that of the Nature Society (Singapore) **[7]**.
- Conservationists around the world, often aided by local and visiting birders, have saved at least 31 species from extinction during the past three decades. Birds brought back from the brink include Mauritius Kestrel (*Falco punctatus*), Chatham Island Robin or Black Robin *(Petroica traversi*) and California Condor (*Gymnogyps californianus*).
- Bird tours, mainly run by companies based in Britain and the US, continue to visit virtually every country and region of the world, where by employing local guides and using local facilities they make a significant contribution to national and regional economies.
- In Britain, birding is one of a range of 'life skills' (also including cookery and financial literacy) which are set to become part of the school curriculum for children aged from eleven to 14, in an attempt to combat disaffection and social problems.

From this eclectic list, it can be seen that birding is no longer simply a pleasant and enjoyable hobby, practised in isolation from the rest of society. Arguably it never was: birding and changes in society have always gone hand-in-hand, and Max Nicholson, amongst others, commented on the 'classless' nature of birding as long ago as the 1920s.

But today, as never before, birding is becoming incorporated into a much broader range of activities and lifestyles. This is largely, I believe, because of the nature of modern society, in which the old boundaries between social classes, activities and ways of living are breaking down.

Before I examine the wider implications of this change on birding, in the next section I shall briefly survey the ways in which birding and society developed during the 20th century.

Part 2: Birding Past

> *Birdwatching is not only an intense aesthetic experience, but also a stimulus to the mind and to the imagination, as one tries to understand the nature of a bird's world.* **[1]**
>
> H. G. Alexander, 1974

The contrast between the global, multi-faceted and pluralist way in which we watch birds today, and the fragmented, insular and parochial nature of birdwatching which prevailed during most of the 20th century, could hardly be greater. At least until the 1980s, which saw a sea-change in the way we watch birds (mainly, though not exclusively, due to changes in communications, technology and travel), birdwatching remained the preserve of a relatively closed community of like-minded souls. Even as recently as the 1970s, the pastime was largely confined to white, educated males, almost all of whom lived in the English-speaking world.

A generation ago birdwatchers relied on a handful of identification books, mainly illustrated by the great American bird artist Roger Tory Peterson. They used fairly basic optical equipment: a pair of old-fashioned 'Porro-prism' binoculars, whose design had remained virtually unchanged since the First World War, and rarely carried telescopes, which were primitive in design and difficult to use.

Feeding garden or backyard birds was limited to putting out a few kitchen scraps or peanuts onto a bird table, while going abroad to watch birds was still in its infancy. Most Britons never even crossed the English Channel, and even the most intrepid travellers rarely ventured beyond the boundaries of Europe. In the US, birders did travel within the lower 48 states, but few went much farther afield.

Half a century before that, in a world recovering from the devastation of the First World War, birdwatching was even less significant. When a young man named Max Nicholson went up to Oxford in the early 1920s, his fellow students were more interested in hedonism and drunken japes than in wholesome, outdoor pursuits such as watching birds. Despite the lack of interest amongst his peers, Nicholson joined the embryonic Oxford Ornithological Society, and went on to become the most influential figure in the development of birdwatching in Britain before his death in 2003 at the age of 98.

During his lifetime, Max Nicholson witnessed the many social changes that together created the world of birding we know today; a process—or series of processes—which I document in this chapter.

The 'invention' of birdwatching

Human beings have been aware of birds—from a religious, cultural and often practical point of view—since civilisation began. Peoples as varied as the Aztecs of Mexico, the ancient civilisations of the Far East, and the indigenous peoples of Australia, all had birds at a central place in their culture.

But there is a world of difference between these ways of looking at birds—the cave-paintings made by prehistoric European hunters, the early quasi-scientific studies by men like Aristotle and Pliny, and the wealth of folklore associated with birds in all the world's cultures—and the leisure activity we now call birdwatching or birding. Indeed, the very term 'birdwatching' is a coinage barely a century old.

In 1901, 'bird watching' appeared in print for the very first time, as the title of a book **[2]** by British naturalist Edmund Selous. Selous himself was something of a recluse, living in the shadow of his more famous brother, the big game hunter F. C. Selous. In some ways he typified a public image of the birdwatcher as a solitary eccentric; an image that persisted until at least the end of the 20th century, and lingers on in some places even today.

At the time Selous's book was published, birdwatching was struggling to emerge from the influences of scientific ornithology and collecting. Both Britain and the United States had a long history of both disciplines, going back at least to the 18th century, and arguably even earlier.

Indeed the two were inextricably intertwined: most early ornithologists were also 'collectors', at least in the sense that they either shot birds themselves, or sent someone else to obtain specimens for them. This was not the blood-lust it has often been depicted: in the main, the collectors of the 18th and 19th century were serious men

(and the occasional woman) pursuing a genuine interest in extending the frontiers of scientific knowledge **[3]**.

What Max Nicholson called "the Victorian leprosy of collecting" did have its downside: although it greatly increased our understanding of subjects such as bird classification, distribution and plumage details, it also created a climate where field observation was for long regarded as a second-class substitute for studying a bird in the hand—summed up in the oft-quoted mantra, "What's hit is History, what's missed is Mystery".

Yet there is no doubt that between them, the museum-based ornithologists and field collectors laid the foundations for the unprecedented development, during the 20th century, of birding as a leisure activity. One example is Elliott Coues (1842–1899), author of the *Key to North American Birds* (1872) **[4]**, which ran to four editions, and was later published in Britain as the *Handbook of Field and General Ornithology* (1890) **[5]**.

Coues's approach can be summed up in a quote from that work: "How many birds of the same kind do you want? All you can get". As a committed collector, Coues may appear to have little in common with the birders who came to prominence in the following generation, yet he was one of the three founders of the influential American Ornithologists' Union (AOU) and editor of its quarterly journal, *The Auk*. Moreover, his unbounded enthusiasm for the pursuit of birds was not very different—in both the impulse behind it and the determination with which it was pursued—from the modern twitching ethos.

The gradual shift between collecting and birding is personified in the life and career of one of Elliott Coues's disciples, Frank Chapman (1864–1945). Although Chapman learnt about birds primarily through collecting expeditions (even taking his wife collecting on their honeymoon!) he later found fame as a campaigner for the protection of wild birds.

As well as writing a number of popular bird books, in 1899 he founded *Bird-Lore*, the official magazine of the Audubon movement; a publication which perhaps did more than any other to stimulate and encourage the new-found hobby of birding.

Another driving force behind this new and more benevolent approach to birds had come from a campaign, in both the US and Britain, against the use of bird feathers and skins in women's fashion. Led mainly by women—mostly from the upper echelons of society—this resulted in the founding of the National Audubon Society in 1886 (and soon afterwards the various local Audubon chapters), and the Society for the Protection of Birds (later the RSPB) in 1889. In the following century these two organisations would have a major impact on the numbers of people taking up birding as a pastime.

Soon afterwards, similar bird protection groups would emerge elsewhere, such as La Ligue pour la Protection des Oiseaux (LPO), founded in France in 1912; Aves Argentinas, founded in Buenos Aires in 1916; and the Royal Forest and Bird Protection Society, founded in New Zealand in 1923.

A further impetus to the new hobby came from a revolution in optics. In 1854, the Italian inventor Ignatio Porro had registered a patent for an optical system using prisms; the forerunner of compact binoculars and telescopes we use today. Forty years later, in 1894, the German firm Carl Zeiss brought out the first truly effective pair of prismatic binoculars, following Porro's original design. By the first decade of the 20th century this type of binoculars—virtually identical to the kind many birders still use today—had become widely available.

So by 1901, when Edmund Selous's book *Bird Watching* was published, the scene was set for a new, more benign way of studying birds—using an optical lens to watch them, rather than a double-barrelled shotgun to kill them. A new era—during which birdwatching would develop many of the characteristics by which we know it today—was about to begin.

The early years of birdwatching: 1900–1939

On Christmas Day, 1900, 27 observers—led by the new editor of *Bird-Lore*, Frank Chapman—took part in the very first Christmas Bird Count in the US. From its humble beginnings, this has since become a national institution, with more than 50,000 people now taking part in over 2000 separate counts from Alaska to Hawaii and from Florida to California, as teams compete to record the greatest number and variety of birds in their local area.

In Britain, too, 'listing'—so characteristic of the sporting side of birdwatching—was also taking root. Pioneering birder H. G. Alexander and his brother Christopher were the first to document the practice near their home in Kent on New Year's Day 1905; with H. G. continuing until his death in Philadelphia, in 1989, in his 101st year.

Other aspects of modern birding which either began, or became established practice, in the first two decades of the 20th century were bird ringing (known in North America as 'banding'), migration studies, and close observation of breeding bird behaviour.

The first official ringing scheme began in Britain in 1909, coincidentally the very same year that banding began in North America. Migration studies had begun with Heinrich Gatke's visits to the German island of Helgoland in the mid-19th century, but it was the work of English ornithologist William Eagle Clarke and his followers on Fair Isle, from 1905 onwards, that finally solved so many mysteries about the origin and appearance of migrating birds.

Soon afterwards, British birdwatchers turned their attention to breeding birds: studies of warblers (Sylviidae) and the Common Moorhen (*Gallinula chloropus*) by Eliot Howard, the Great Crested Grebe (*Podiceps cristatus*) by Julian Huxley, and of the Common Cuckoo (*Cuculus canorus*) by Edgar Chance, revealed extraordinary secrets about common—and previously largely ignored—birds.

With the establishment of *Bird-Lore* in the US in 1899, and *British Birds*, founded by H. F. Witherby in 1907, the stage was set for a boom in birding as a popular pastime. Birdwatching was by now becoming popular amongst all walks of life, including the very top: as revealed when, one fine morning in June 1910, former US President Theodore Roosevelt and British Foreign Secretary Edward Grey went for a day's birdwatching in rural Hampshire. Four years later, in August 1914, the progress of the pastime—and indeed many other aspects of normal life—came to an abrupt halt, with the start of the First World War.

In many ways the Great War stopped the development of birdwatching in its tracks; not least because it killed so many promising young ornithologists and birdwatchers. But in other ways it had a profound and lasting effect on the way in which birdwatching would develop during the years between the end of the conflict in 1918 and the start of the Second World War in 1939. These years would see another surge in the popularity of watching birds for pleasure, on both sides of the Atlantic and throughout the British Empire.

The key factors which shaped the development of birdwatching during the 21 years between the two world wars were very much the product of that remarkable era. This was a time of global uncertainty, during which the horror of the legacy of war, then worldwide economic depression, and finally the impending onset of a new conflict, created a very different world from the essentially stable society of the 19th and early 20th centuries.

In addition, technological changes—especially in the fields of transport, optical equipment and publishing—all had an impact on birding, by providing access to birdwatching sites, better quality binoculars and the first truly portable bird identification books. Finding, watching and identifying birds—at least if your income permitted—had never been easier.

In 1934, a young American bird artist named Roger Tory Peterson published his original *A Field Guide to the Birds* **[6]**, which has since sold more than three million copies. This book encouraged millions of Americans to take up the pastime by providing them with the means to identify the birds they saw.

The original Peterson guide is, by today's standards, a somewhat modest volume, with a brief text and a series of rather formalised plates depicting the birds of the eastern US. The revolutionary aspect of this work, however, was not the content—there had been field guides before—but Peterson's approach. He depicted families of birds in stylised positions, with arrows showing key field marks, allowing direct comparison between similar species. It proved a winning formula, and today Peterson guides are still available for a myriad of subjects, from clouds to beetles and mammals to urban wildlife.

Peterson was not just a great bird artist, but an active birder, encouraging major advances in field identification (rare birds no longer needed to be shot to prove their identity) and our knowledge of North American birds as a whole. The breadth of his influence on birding in North America was summed up by his old friend Elliott Richardson, in 1977:

> It has been said that... Roger Tory Peterson has done more than any other person to make the field identification of birds a science. I am sure that is true. But it is fair to say that Roger Tory Peterson has also done more than any other man to make field identification a sport. **[7]**

On May 19, 1984, at the age of 75, he was still fit and keen enough to take part in an event which sums up his legacy, the first annual World Series of Birding, a race to see

as many different species as possible in 24 hours, held in the state of New Jersey. And yes, with a total of 201 species, Peterson's team won!

Despite the lack of a decent field guide to British birds until after the Second World War, birding continued to develop in Britain. It did so largely under the guidance of a handful of gifted, dedicated and far-sighted individuals.

The 'godfather' of British birding was H. F. (Harry Forbes) Witherby, who, on top of founding *British Birds* two years earlier, started the official bird ringing scheme in 1909, and was to be the main editor of the seminal *The Handbook of British Birds* **[8]**, published in five volumes from 1938 to 1941, which had a profound and lasting influence on generations of birdwatchers for several decades afterwards.

His trusty *consigliere* was Bernard Tucker, an early member of the Oxford Ornithological Society, who collaborated with Witherby on the *Handbook* before his untimely death in 1950, aged just 49. Then there was the charismatic, mercurial polymath Tom Harrisson, who instigated the earliest bird surveys, later using what he had learned about observing birds to study the ordinary lives of people, in the Mass-Observation movement of the 1930s.

But the key figure, not just between the wars but well beyond, was Max Nicholson. During a long and distinguished career this extraordinary man either founded or ran most of the key ornithological and conservation organisations in Britain today, including the British Trust for Ornithology (BTO), the Edward Grey Institute at the University of Oxford, the Nature Conservancy Council (now part of Natural England) and the World Wildlife Fund (now the World Wide Fund For Nature). He was that rare being, a practical visionary, able to envisage the future and work to bring it about. And like Peterson, he was also a keen and active birdwatcher, whose view of birding encompassed not only the scientific and competitive aspects of the pastime, but the spiritual ones as well, as the quotation at the top of this essay shows.

Between them, these men took birding by the scruff of the neck, shook off the baggage left over from the Victorian and Edwardian eras, and embraced a new, modern and scientific approach to the observation, study and recording of birds. Without them, it is unlikely that birding would ever have developed into the global, mass-participation and multi-faceted activity of today.

What allowed all this to happen, more or less simultaneously, in Britain and the US, was that a major social shift was taking place; one which would have a profound impact not just on birdwatching, but on hobbies and interests in general. This was the much greater availability of leisure time—no longer just for the monied classes, but for more or less everybody.

As American sociologist Steven M. Gelber has shown **[9]**, by 1920 industrial workers in the US had eight hours more 'free time' per week than their counterparts in 1900. As a result, the concept of having one or more 'hobbies' arose for the first time. The combination of increased leisure time and the need to fill it (driven, presumably, by the Protestant work-ethic that dominated US and British society) led to a major upsurge in what became known as leisure activities, of which birding was just one.

By the end of this period, at the start of the Second World War, George Orwell was able to gently mock his compatriots' addiction to hobbies:

> Another English characteristic which is so much a part of us that we barely notice it, and that is the addiction to hobbies and spare time occupations… We are a nation of flower-lovers, but also a nation of stamp-collectors, pigeon-fanciers, amateur carpenters, coupon-snippers, darts-players, crossword-puzzle fans… **[10]**

To which he could, of course, have added 'birdwatchers'. By the start of the Second World War birdwatching had become a socially acceptable and reasonably widespread leisure activity both in Britain and the US. And although it might be imagined that another major global conflict would once again stop the progress of the pastime in its tracks, strangely the very opposite was the case.

War, peace and the birdwatching boom: 1939–1975

Unlike the First World War, which effectively set the progress of birdwatching as a pastime back at least a decade, the Second World War appears to have had a quite different effect.

Many keen young birdwatchers in Britain and North America found themselves posted abroad—for the vast majority, this was the very first time in their lives they had ever left their home country. Moreover, the arenas of conflict were far wider than

in any previous war, including North Africa, the Middle East, India, the Far East and the Pacific, giving birdwatchers—and potential birdwatchers—access to exotic habitats and species beyond their wildest dreams.

There is clear evidence that many people took the opportunity of being posted abroad to extend their interest in watching birds. As has often been said, war consists of 5% fear and excitement, and 95% boredom; and if that is the case, then birdwatching certainly provided at least something of an antidote.

What are perhaps the most fascinating accounts of wartime birdwatching come from a single prisoner-of-war camp, Eichstätt in Bavaria. Here, three men who were later to have a distinguished career in the British ornithological establishment—John Buxton, Peter Conder and George Waterston—all used their enforced 'leisure time' to make detailed studies of the local birds. After the war, Buxton published his findings in one of the early Collins New Naturalist monographs, *The Redstart* **[11]**.

But the real legacy of the Second World War was the way in which it broadened people's horizons, and clarified their needs, wishes and desires. Whether or not one was posted abroad or forced to spend years confined to a restricted local neighbourhood, the desire following the ending of hostilities was the same: to make the most of one's life.

This manifested itself in a hunger for education; a keenness to explore one's own country and, if possible, the world; and what Sir Dudley Stamp, writing almost a quarter century after the end of the war in 1969, called "the satisfaction of the less obvious demands of the spirit" **[12]**.

In the decade or so following 1945, birdwatching underwent a major rise in popularity and participation on both sides of the Atlantic. Better—and cheaper—optics, and the first comprehensive field guides (including Roger Tory Peterson's co-operation with two British ornithologists, Guy Mountfort and Philip Hollom, to produce *A Field Guide to the Birds of Britain and Europe* **[13]**, in 1954) allowed tens of thousands of people to take up birdwatching for the very first time.

From 1950, petrol was no longer rationed in Britain, while in the oil-rich, gas-guzzling US it had never even been contemplated; allowing birders on both sides of the Atlantic to travel further afield in search of their quarry. Access to the British countryside was also made much easier than it had been before the war.

The war brought another, unexpected side-benefit: the use of radar—originally, of course, a military invention—to track the journeys of migrating birds. The 1950s saw a boom in migration studies, as observatories opened on remote islands and headlands all round the coasts of Britain and Ireland.

During the late 1950s and early 1960s, as restrictions on foreign travel were gradually removed, British birdwatchers headed abroad on organised expeditions or private holidays in much greater numbers than before. Others were forced to do so: compulsory National Service continued in Britain until the early 1960s, with many young men spending two years in far-flung corners of the British Empire. Like their Victorian predecessors, some of them forsook the temptations of women and strong drink and spent their spare time watching birds.

In North America, once again Roger Tory Peterson was at the forefront of encouraging people to take up birding, and giving established birders the impetus to broaden their horizons beyond their immediate neighbourhood, county or state.

In 1953, Peterson and his British counterpart James Fisher travelled the length and breadth of North America north of the Rio Grande, racking up 30,000 miles in just 100 days, and seeing 572 species along the way—at the time a record annual total. The book and film of the journey, *Wild America* **[14]**, were both released in 1955, to great popular and critical acclaim. Suddenly, it seemed, there was no limit to the distances a keen birder might travel in pursuit of North America's birds.

In the following two decades, the sporting nature of birding—largely suppressed since the days of the Victorian collectors—really took hold. The Christmas Bird Count hugely increased in popularity, while North American listers competed to be the first person to break the 600 species barrier in a single calendar year.

This landmark had almost been reached by Englishman Stuart Keith in 1956 (598 species), and amongst birders had gained iconic status, rather like breaking the four-minute mile or the sound barrier. After several people had tried and failed, the 600 mark was finally shattered in 1971, when an 18-year-old college student from Pennsylvania named Ted Parker saw a staggering total of 626 species.

As the number of birders on both sides of the Atlantic grew, so a kind of 'positive feedback loop' was established. The more birders there were in a particular community, the more people they were likely to recruit to their interest, in turn spreading the word amongst non-birders.

Birding has always suffered from something of a poor image amongst the general public, with derogatory terms such as 'anoraks', 'nerds' and the more creative 'organic trainspotters' being used to describe its adherents. But from the 1960s onwards, there was strength in numbers: a kid at school or starting college, or someone changing jobs or moving into a new neighbourhood, was likely to simply bump into fellow enthusiasts at local birding sites, or be given details of 'a friend of a friend' who was a birdwatcher **[15]**.

Bird-finding guides were also beginning to be published, pioneered by Olin S. Pettingill in the US, whose ground-breaking *A Guide to Bird Finding East of the Mississippi* **[16]** appeared in 1951. Once again, Britain soon followed the American example, with John Gooders' *Where to Watch Birds* **[17]** first published in 1967, and rapidly becoming a best-seller.

As horizons broadened, so the opportunity to travel farther afield arose, thanks to the widespread ability of cheap 'package tours' from the mid-1960s onwards. By a convenient coincidence, many of the destinations for these trips were also excellent places to watch birds.

So, as the package holiday phenomenon took off, British birders headed beyond their nation's shores, many for the first time. The most popular destinations were the Mediterranean island of Mallorca, and the Spanish Costas, soon followed by the Algarve in Portugal, and islands in the eastern Mediterranean such as Cyprus, Crete and Rhodes.

In the US, the increased popularity of Florida as a cheap holiday destination also attracted millions of visitors—not just from within North America, but also from Europe, especially the UK. Perhaps because of the relatively recent development of the state, Florida's birds are exceptionally approachable—so much so that early visitors to Walt Disney World often assumed that they were looking at captive rather than wild birds!

Meanwhile, in various parts of the globe national birding and bird protection organisations were being set up, such as La Lega Italiana Protezione Uccelli (LIPU) in Italy, founded in 1965; and the Hong Kong Bird Watching Society, founded in 1957. These joined the more established organisations such as the Bombay Natural History Society, a 19th century foundation, to provide a focus for birders in their respective countries to meet, socialise and exchange information.

Birding joins the mainstream: 1975–2000

During the period from the mid-1970s to the turn of the new millennium, birding underwent a series of important changes, including:

- The use of surveys, initiated by professional scientists but largely carried out by amateur birders, to highlight changes in population and range of the birds of a particular country or region.
- A revolution in communications, from an informal telephone 'grapevine', via premium rate phone information lines and portable pagers, to the widespread use of the Internet.
- A great improvement in the standard of optical aids; and a parallel boom in bird books, especially field guides.
- A much broader information base, firstly via books (especially site guides) and later using the Internet.
- A major increase in travel to watch birds, leading to a global network of birding areas, sites and local guides, and the huge growth in the desire to see rare birds—resulting in a boom in national twitching and, for a rich minority, world listing.
- In the latter part of this period, a broadening of the demographic base of birding, to become more socially inclusive than before.

Looking back just a single generation, to the early 1970s, it is clear that much of this could never have been predicted. Nevertheless, the seeds of this phenomenal growth and change were already being sown; and with hindsight we can analyse how these changes came about.

Surveys

Although formal bird surveys had been carried out in Britain since the late 1920s—and indeed could be said to have begun with a survey of spring migrants carried out by the Finnish professor Johannes Leche as early as 1749 **[18]**—the very first comprehensive attempt to document the distribution of an entire breeding avifauna did not take place

until the late 1960s. The original *Atlas* survey **[19]**, carried out by the BTO and the Irish Wildbird Conservancy, was very much the triumph of hope over experience.

The organisers, many of whom had serious doubts about the success of the enterprise, had underestimated the sheer dedication of the 10,000 or so amateur fieldworkers, who between them covered almost 4000 10-kilometre squares and produced more than a quarter of a million records of over 200 breeding bird species. As in the 1930s, when the BTO's earliest surveys of single species had been carried out, the end result was that birding, conservation and science joined forces to create something much greater than the sum of the parts.

During the subsequent decades, the *Atlas* format was successfully duplicated all over the world, with national and regional surveys of breeding, wintering and migratory birds appearing by the dozen. Each had the welcome by-product of giving thousands of ordinary birdwatchers a sense of purpose and collective achievement in what has become known as 'Citizen Science' (see Part 3).

The communications revolution: twitching and world listing

As recently as the 1950s and early 1960s, if a rare bird was sighted in Britain, the finder would often communicate the news to his fellow birdwatchers by sending them a postcard! By the 1970s, almost every home had a telephone, and as a result rare bird enthusiasts organised informal 'grapevines'—networks of people who would telephone each other to pass on the news of a rarity. The instantaneous nature of this new form of communication gave rise to the twitching boom of the 1970s and 1980s, during which time groups of like-minded enthusiasts travelled hundreds of miles every weekend to add vagrant birds to their 'British List'.

But the domestic telephone had one major drawback: it was not portable. Then, in the mid-1980s, a revolution in communications created three new ways of obtaining information about rare birds while out in the field.

First, the premium-rate telephone information line, by which twitchers could dial up to get up-to-the-minute news of a rare bird. Second, the portable pager—a device originally designed to alert medical staff about an emergency—was appropriated to send rare bird information, some of which could be personalised to the individual recipient. Finally, the widespread availability of mobile telephones allowed instant communication between fellow birders.

The impact of these new technologies on the way in which birding developed during this period was immense. It is hard to imagine that twitching would have become quite so popular with so many people if the means by which the latest news of a rare bird's arrival—or just as important, its departure—had not been available.

At its height, in the 1990s, twitchers vied with each other to travel ludicrously long distances—and spend even more ludicrous amounts of money—to see a single rare bird. Return trips from the Isles of Scilly to Shetland, costing hundreds of pounds and involving the chartering of a private aircraft, were not uncommon during this period.

In North America and Australia, the far longer distances involved led to even more bizarre stories, many of which have been documented for posterity in books such as Mark Obmascik's *The Big Year* **[20]** (a gripping account of a three-way attempt on the North American record for the number of species seen in a calendar year), and Sean Dooley's *The Big Twitch* **[21]**, a similar story of individual persistence in Australia.

But for truly epic stories of human endeavour, we must look to a tiny sub-group of truly obsessive individuals: those who spend their lives—and copious amounts of money—pursuing the ultimate goal of the global birder, the 'world list'.

World listing is the logical consequence of the habit of most birders of keeping a record of the different species they see. Until the late 20th century, before frequent foreign travel became the norm rather than the exception, most birders kept a series of lists ranging from the birds seen in their garden or backyard, via a list of those seen in a particular county or state, to their national list, of all the species seen in the wild in their home country (or in the case of many North American birders, their continent north of the Mexican border).

From the 1960s onwards, an elite group of well-travelled birders (mostly professional bird tour guides or international businessmen) began to tally their world list. At the time, only a tiny minority had seen over 2000 of the then estimate of about 8600 species; and just two or three could boast a list of over 3000 species. In 1973, expatriate British birder Stuart Keith, by then based in New York, became the very first person to see 4300 species—half the world total, then considered a seemingly unassailable achievement.

But as global air travel became cheaper and more accessible, and the incomes of the very rich rose exponentially, so a new breed of global birders emerged. Some were top birders themselves; others simply paid local experts to find their birds for them. By the end of the century a handful of these obsessive travellers had reached the 8000 mark (though by then, because of advances in taxonomic knowledge, the total number of species was nearing 10,000).

The best-known of all the world birders was the American heiress Phoebe Snetsinger, who tallied an incredible 8400 species. Having won a long battle against apparently terminal cancer, as told in her posthumously published autobiography *Birding on Borrowed Time* **[22]**, it was ironic that Snetsinger died in a freak road accident while birding in Madagascar, in 1999.

The technological and communications revolutions: optics, books and the Internet

For the ordinary birder, such feats of global listing were very far from their normal experience. Nevertheless, the wider aspects of the technological and communications revolutions had an important affect on their chosen pastime too.

Perhaps most important was the massive improvement in optics during this period. Back in the early 1970s, the binoculars used by most birders had hardly changed since the Second World War, and the use of telescopes was confined to a hard core of serious enthusiasts. Less than two decades later, it seemed that virtually every birder in the developed world was sporting a pair of high-specification, roof-prism binoculars made by one of the leading manufacturers such as Zeiss, Leica or Swarovski. Even at the lower end of the market, standards had improved radically, with excellent optics available for less than £150 in Britain or below US$200 in the US. The rapid turnover rate as birders vied with each other to sport the latest models had an unexpected knock-on effect to birding in the developing world, as travelling birders began to donate their old (but perfectly workable) models to local guides.

Telescope technology also advanced by leaps and bounds during this period. The old draw-tube brass instruments had been consigned to history, to be replaced by telescopes of astonishing quality, using the latest in optical technology to allow birders to see plumage detail they could only have imagined previously.

During the same period, the number of bird books—especially field guides—increased exponentially. Today, modern, well-researched and up-to-date field guides are available for virtually every region in the world; a result of a combination of greater ease of travel and the improvement in optics which has allowed the authors and artists to study their subjects in forensic detail in the field.

This culminated in the appearance of a definitive series of volumes, one of which you are currently reading. The first volume of the *Handbook of the Birds of the World* **[23]**, covering the ratites to wildfowl, appeared in 1992, and the publishers have achieved a commendable strike rate since then, with the sixteenth and final volume due to appear in autumn 2011. The standards achieved—in research, writing, photography and illustration—have been quite phenomenal, with reviewers running out of superlatives to describe each new volume. The series has not only provided ornithologists and amateur birders with an indispensable reference tool, but is also contributing to our understanding and conservation of some of the world's rarest and most endangered species.

Site guides have also enjoyed a boom, with books covering most of the world's regions, including a recent guide—aimed largely at regular business travellers—to watching birds in and around more than 60 of the world's major cities, from Addis Ababa to Zurich **[24]**.

But for information on where to find, see and watch birds, most birders now log onto the World Wide Web, where up-to-date information written by birders for their fellow enthusiasts can be downloaded in a matter of seconds, obviating the need to spend time and money tracking down a book. This is, of course, just one aspect of the impact of the Internet, which I shall examine in Part 3 of this essay.

Birding in the developing world

In those parts of the world which had once been ruled by the British, under the Empire "on which the sun never set", expatriate and local birders were building on the legacy of the departed colonial administrators. In former colonies such as India, Hong Kong and Singapore birding continued to thrive, supported by organisations such as the Bombay Natural History Society, the Hong Kong Bird Watching Society and the Malayan Nature Society, whose very names reflect their colonial past.

In most cases expatriate Britishers dominated, including British servicemen and business people based abroad. In Singapore, the withdrawal of British forces in 1971

led to a major downturn in membership of the local nature society; but from the 1980s onwards birding began to boom again, as ornithologist Lim Kim Seng has noted:

> The 1980s through to the end of the 1990s marked a period of phenomenal growth in interest in birding. This was the result of the Malayan Nature Society's very active Bird Group, which increased its monthly birding trips to twice a month, initiated an annual bird race and started involving members and the public in bird censuses... Membership grew more than six-fold from 300 in 1980 to over 2000 by 1999, by which time the MNS had changed its name to better reflect its objectives to Nature Society (Singapore). **[25]**

Elsewhere in the world, too, birding has made rapid progress. In a chapter written for the new book, *The Birds of Turkey* **[26]**, British ornithologist and expert on the birds of the Middle East Richard Porter lays out the recent, but quickly developing, history of Turkish ornithology. In a personal note he describes the major changes that have taken place since his first visit to the country in the late 1960s:

> In October 2004 I attended the 7th Turkish Bird Conference, which has now become an annual event. It was held in Izmir, on the edge of the Aegean, with two days of talks followed by two days of trips to marsh and mountain.
>
> I gave a talk on Turkey in the 1960s, when I first visited the country there was just one, or possibly two, birdwatchers. In 2004, there were over 150 Turkish birders at the talks, and on the outings even more...
>
> Most of the birdwatchers at the conference were under 30 (and about one-third were female). Compare this with the mix at the annual BTO conference! At the last one I attended, two years ago, there was hardly anyone below 30...
>
> I happened to ask a young girl, who was active in conservation, what changes she would like to see to help wildlife in Turkey. Her reply? "I wish we were all 20 years older—then decision-makers would take our views more seriously." The good thing is they will be one day. **[27]**

The changes witnessed by Porter in a single generation in Turkey have been replicated throughout the developing world. A felicitous combination of visiting birders from Europe and North America, and the efforts of local birders, has led to extraordinary progress.

Other examples include Israel, a favourite destination for British and Scandinavian birders since the early 1980s, where in 1996 the young ornithologist Hadoram Shirihai produced a monumental book, *The Birds of Israel* **[28]**, a comprehensive avifauna of breeding, wintering, migrant and vagrant birds which matched anything published for more developed nations. Shirihai acknowledged the debt of previous writers on the birds of the Middle East, going back to the anonymous authors of the Old Testament, who had made some of the earliest ever written observations of birds.

Birding in the Middle East developed rapidly during the 1980s and 1990s, thanks partly to talented and committed individuals such as Shirihai, and partly to the support and expertise of visiting birders—including those from the new birding hotspots of Scandinavia and the Netherlands. This relationship was formalised by the founding, in 1978, of the Ornithological Society of the Middle East (OSME), the successor to the Ornithological Society of Turkey. Today this thriving society has expanded to include the Caucasus and Central Asia as well as its more traditional region.

OSME was swiftly followed by the Oriental Bird Club (OBC) in the mid-1980s, and the Neotropical Bird Club (NBC) and African Bird Club (ABC) in the mid-1990s. Given the long tradition of British interest in these regions, it is hardly surprising that all these organisations originated in the United Kingdom, and were, initially at least, largely run by British birders; though there was also an active network of country representatives. As membership expanded to reflect international interest in these regions, so the focus of the bird clubs broadened too: with the OBC holding meetings in the Netherlands, Sweden, Denmark and Malaysia.

Much of the work of the bird clubs has been focused on the conservation of key habitats and species: such as Gurney's Pitta (*Pitta gurneyi*) in Thailand and Myanmar, Cerulean Warbler (*Dendroica cerulea*) in the Americas, and Congo Peafowl (*Afropavo congensis*) in Africa. Money is raised via sponsors and events, and grants and bursaries are given to conservation organisations and individuals within the region.

The rise of the bird clubs has gone hand in hand with two other factors. On the positive side, the period also saw a massive growth in birding tourism, with specialised trips now taking birders to visit virtually every part of the world.

More worryingly, the period has also seen two negative factors emerge: the rapid decline of many rare and endangered bird species; and the growth in global political

(and now economic) instability that has accompanied (and in many cases, helped to cause) these declines.

The role of the bird clubs in alerting governments and other organisations to problems and potential disasters is now crucial; fortunately the individuals involved in the clubs are often also working for BirdLife International and/or national conservation organisations **[29]**.

Part 3: Birding Present

> *There has been a tremendous renaissance in nature study in recent years; it has been called a form of escapism, and perhaps it is in a way, but not an escape from reality; but rather, a return to reality.* **[1]**
>
> Roger Tory Peterson, 1957

In this section I examine and analyse the current global birding 'scene' from a thematic, rather than historical, point of view. This inevitably leads to some overlap, but so it should: none of the subjects covered here exists in isolation, and all impinge, to a greater or lesser extent, on each other.

The subject areas I have chosen to cover are:

- **Who watches birds?** Using a combination of statistical surveys (where they exist), and anecdotal evidence (where they do not) I have examined the demographics of birding in the developed and developing world. I also look at the ways birding relates to specific groups in society, such as women, ethnic minorities, gay and disabled people.
- **Birding, ornithology and conservation**. How birding continues to interact with the scientific discipline of ornithology, with both groups gaining strength and depth from this relationship. This includes atlases and surveys, 'Citizen Science' projects, global and local conservation work, and how new developments in science (notably techniques to analyse the DNA of living creatures) are changing the way we watch and think about birds.
- **Birding and the media**. How television, radio and newspapers report birding stories.
- **New technology**. How the most recent developments in technology, including palmtop PCs, mobile phones and the Internet, are affecting the way we watch birds.
- **The economic importance of birding**. How birding contributes to local, regional and national economies, through expenditure on travel, equipment, etc., job-creation, taxes and overall economic benefits.

Who watches birds?

At the start of the Second World War, British ornithologist James Fisher made a random list of the people he knew who enjoyed watching birds:

> Among those I know of are a Prime Minister, a President, three Secretaries of State, a charwoman, two policemen, two Kings, two Royal Dukes, one Prince, one Princess, a Communist, seven Labour, one Liberal, and six Conservative Members of Parliament, several farm-labourers earning ninety shillings a week, a rich man who earns two or three times that amount in every hour of the day, at least forty-six schoolmasters, an engine-driver, a postman, and an upholsterer. **[2]**

Apart from the rather dated language used, a similar list could easily be compiled today. What both would show is that birding is by no means confined to a single social class. In an era when Western societies, at least, appear to be fragmenting into ever-narrower special interest sectors, birding is refreshingly eclectic in its participants.

Certain groups have always been prominent, however. Politician-birders have a long pedigree, going back as far as Teddy Roosevelt and Edward Grey at the turn of the 20th century, and including at least one Prime Minister of the United Kingdom (Sir Alec Douglas-Home, later Lord Home), another US President (Jimmy Carter) and a British Chancellor of the Exchequer (Kenneth Clarke). Maybe it is the relief from the pressures of the offices of state that impels politicians to seek solace in birds!

Royals, too, have taken a keen interest. Prince Philip became so keen on photographing seabirds on his royal voyages that he published a book on the subject, *Birds*

from Britannia **[3]**. Until 2004, Queen Noor of Jordan was the President of Birdlife International, after which the role was taken over by Princess Takamado of Japan. Another Asian royal, Princess Sirindhorn of Thailand, has even had a bird named after her: the White-eyed River Martin, (*Pseudochelidon sirintarae*). Sadly, since its original discovery in 1968 the bird has rarely been seen, and may now be extinct.

While these royal personages may not qualify as 'birders' in many people's eyes, their involvement—and the symbolic value to their subjects—is certainly vital to the continued survival of many of the world's most threatened birds.

Comedians also have a distinguished track-record as birders, and include in their ranks the best-known British birder, Bill Oddie, and the late Eric Morecambe. Rock stars, too, seem particularly attracted: Jarvis Cocker of Pulp, the late Billy Fury, and new bands such as British Sea Power and the Guillemots all profess an interest. And Jim Crace in Britain, Jonathan Franzen in the US and husband-and-wife Graeme Gibson and Margaret Atwood in Canada all seek escape from the solitary life of the writer by going birding.

In fact almost any profession or calling contains at least some birders; perhaps because the impulse to watch birds is, some would argue, as innate as a love of music or art. Even Saddam Hussein, during his final days in captivity, was reported to have saved crumbs from his meals to feed the birds—an echo of the famous story of the 'birdman of Alcatraz'.

On a broader scale, there is, unfortunately, very little information on the demographics of birding. Indeed the only full-scale national surveys are those carried out in the US.

The US Fish & Wildlife Service survey carried out in 2001 **[4]** inevitably produces a broad-brush picture of birding demographics, not least because it includes all those describing themselves as 'wildlife-watchers' and not just birders. Nevertheless, it does reveal some fascinating results, summarised here:

- **Age**: perhaps not surprisingly, birders tend to come from the older age-groups, with the 'participation rate' highest in the 55–64 group (28%, compared with a US average of 22%), closely followed by the 45–54 (26%), 35–44 (24%) and 65 plus (24%) age-groups. The average age for backyard birders was 50, while that of those who took trips away from home to watch birds was slightly younger, at 45.
- **Income**: US birders tend to be better-off, financially, than their non-birding counterparts. The income-groups with the highest percentage of birders were those earning US$75,000 or more per annum (27%); while the lowest percentage were amongst those earning less than US$20,000 per annum (19%). This reflects the fact that while birding is hardly an expensive hobby, compared for instance to skiing or photography, it does require some investment in optical equipment, books and travel. Lower-income groups also tend to have less access to transport such as private cars, and are less likely to use commercial flights, restricting their birding horizons.
- **Education**: US birders also tend to be more educated than non-birders. Here the statistics were even clearer than for income, with the participation rate ranging from 33% for those with five or more years college education, to just 17% for those who only attended high school.
- **Gender**: 54% of those surveyed who described themselves as birders were female, while 46% were male; an interesting contrast to Britain, where the vast majority of active birders are men. However, given that backyard birders make up a high proportion of those surveyed, this figure is perhaps less surprising.
- **Marital status**: A significant majority—72%—of birders are married, while 13% have never married, 9% are divorced or separated, and 7% are widowed. This suggests that birding and marriage are highly compatible, given that the percentage of people married in the US is about 66%.
- **Ethnic and racial distribution**: As the report notes, "Excepting Native American participation, birders are not a racially or ethnically diverse group". Indeed participation rates are dramatically lower in non-white sections of the community: 9% amongst Hispanics, 6% for African Americans, and 6% for those of Asian origin—compared with 24% amongst white Americans and 22% for Native Americans. This is broadly similar with the lack of ethnic diversity amongst birders in the UK, and cannot simply be explained by socio-economic differences between groups. Given that white Americans number roughly 181 million out of the adult population of about 235 million, the figures suggest that there are fewer than four million non-white birders in the US.

Evidence from another source suggests that not only is birding in the US very popular, but that its popularity is growing even faster than other outdoor leisure activities such as hiking, backpacking and snowboarding. The National Survey on Recreation and the Environment **[5]** is a regular snapshot of participation in outdoor activities in the US.

By comparing data from 1983 and 2001, it was found that the number of active birders (defined as those who have watched birds away from their home) increased by more than 230% during the period, and that one in three adult Americans "participated at least at a mild level in outdoor birding at least once in the last year". In absolute terms, the survey suggests that the number of birders has grown from 21 million in 1983, through 54 million in 1995 to over 70 million in 2001. Of these, 28%, or almost 20 million people, can be defined as 'enthusiasts', meaning that they go birding at least 50 times a year.

Although birding is far from the most popular outdoor leisure activity in the US (coming 15th in the survey's 'league table'), the rapid rate of increase in participation means that "birding continues to move toward attaining the status of being among Americans' most-favored activities".

As birding has increased in popularity, so it has gradually started to become more inclusive. The type of people who watch birds has broadened from a base made up largely of men (of all ages and social classes), to include far more women—though even today the vast majority of what could be termed 'professional birders'—writers, artists, photographers, tour-leaders and so on—are still male.

Other social groups have found a voice, too. In Britain, the setting up of the Gay Birders Club in the mid-1990s and the Disabled Birders Association in 2000, indicated that there was a substantial minority of gay and lesbian, or disabled people who enjoyed watching birds. More importantly, it also indicated that some of them, at least, did not feel that their needs and interests were catered for by mainstream birding organisations.

But as Bo Beolens, founder of the Disabled Birders Association, points out, the main problem restricting participation for disabled birders (especially wheelchair users) is not attitudes but access. In his extensive experience of travelling abroad with groups of people with disabilities, the best facilities are at bird refuges and reserves in the US and Canada, though the fact that many African game reserves are only accessible by motor vehicle is, as he puts it, "a great leveller" **[6]**. Ironically, in the developing world, the more simple and basic the accommodation is, the better the access—especially for wheelchair users.

So things are improving for some minority groups at least. But in Britain and North America, one significant sector of society is either absent or very few and far between: Black and Asian people. Interestingly, this even applies to those whose families have been in their respective countries for several generations, and who therefore might describe themselves as 'African American', 'Black British' or 'British Asian'.

Several theories have been put forward to explain this, mostly focusing on two factors: a general lack of enthusiasm for 'outdoor leisure activities' amongst these ethnic groups, and a related feeling of 'standing out from the crowd' if they do attempt to engage in such activities and interests.

Given that birding is an intensely tribal pursuit, in which cliques and sub-groups tend to form, it is likely that the combination of an initial reluctance to take part (or simple lack of interest), combined with a heightened sense of being an 'outsider' if they do attempt to take up birding, is enough to keep participation amongst such groups so low. One of the very few black British birders, David Lindo, recalls being taunted by his black peers at school as 'Whitey' because of his interest in birds **[7]**.

The authors of the US Fish & Wildlife Service study suggest, probably correctly, that as birding becomes more prevalent amongst the general population, so the demographics will also change, becoming more inclusive:

> In the future, undoubtedly, we will see the demographic make-up of the American birder shift and become more diverse, just like the country's population is becoming more diverse. Women likely will assume a slightly larger share of the birding participant-base, Hispanic and Asian Americans are also likely to assume a higher profile, and more of the birding participant base is likely to be made up of persons under the age of 25. **[8]**

Whether this optimistic prediction will come true elsewhere is dependent on many complex social factors, beyond the scope of this essay. What can be said is that elsewhere in the developed world, such as Britain, there are factors increasing the participation of minority groups in birding; and other factors (such as difficulties of access, feelings of exclusion and changes in the way children are allowed to explore their surroundings) which may pull in the opposite direction.

In some parts of the developing world, day-to-day concerns such as the need to find food and shelter, avoid disease and simply survive may mean that the luxury of a 'leisure activity' such as birding is well-nigh impossible.

Birding, ornithology and conservation

As already discussed in Part 2, birding as a leisure activity not only derived from the science of ornithology, but has retained many links with it, not least through the participation of many amateur birders in large-scale scientific projects such as atlas surveys.

Likewise, birders are generally also keen conservationists: either active, by giving their time and effort to taking part in specific conservation projects; or more passive, as members of organisations such as the Audubon Society and the RSPB.

Of course, many professional scientists and conservationists are also active birders; indeed in many cases their interest in science and/or conservation began when, as a child or young adult, they became interested in watching birds.

Birders as 'Citizen Scientists'

Perhaps the most tangible contribution that many birders make to our ornithological understanding is through their participation in the simple, large-scale studies known collectively as 'Citizen Science'.

Because of their size, such projects typically use simple recording techniques to collect information about birds, their behaviour and where they live—providing basic ecological data which can then be used in a variety of ways, for example providing evidence of population changes of birds which can then inform government policy on environmental issues.

When well planned, Citizen Science studies can tackle quite complex ecological questions; for example, a study carried out by the BTO, in association with listeners to BBC Radio 4's Today Programme, revealed the complex patterns that influence the time at which birds begin foraging in winter. Foraging behaviour was found to differ according to habitat, with urban birds initiating foraging later in the morning because of the 'urban heat island' effect, which means that the climate in cities may be several degrees warmer than in the surrounding countryside **[9]**.

A number of ongoing, long-term monitoring schemes, for example the BTO's Garden BirdWatch, Cornell's Project FeederWatch and the Universities Federation for Animal Welfare's Garden Bird Health Initiative, rely on 'Citizen Scientists' to collect data on birds. Many of the participants in such studies would not consider themselves to be 'birders' but their regular weekly birdwatching generates information of sufficient quality to inform conservation policy and support ornithological research through a smaller network of paid professionals.

The power of such schemes can, for example, be seen from the way in which data from the BTO's Garden BirdWatch and the BTO/RSPB/Joint Nature Conservation Committee Breeding Bird Survey feed into UK government indicators charting the changing fortunes of bird populations **[10]**.

Similarly, it is only because of the backyard birders involved in Cornell's House Finch Disease Survey that researchers have been able to track the spread and impact of an emerging infectious disease, mycoplasmal conjunctivitis, in the North American House Finch (*Carpodacus mexicanus*) population **[11]**.

While science may seem to be becoming more and more esoteric and specialised, the day of the amateur making any useful contribution is far from over. Speaking at the 24th International Ornithological Conference (IOC), held in Hamburg in August 2006, Professor Jeremy Greenwood delivered a stirring account of the contribution of the amateur birder in Citizen Science projects **[12]**. Greenwood pointed out that, in Britain alone, birders spend 1·6 million hours a year contributing to bird surveys—work that has an estimated value of at least £20 million:

> Amateurs make a major contribution to ornithology and bird conservation science. They always have and there is no sign of their contribution diminishing. Though they may have no formal qualifications, they have considerable expertise, gained from many years of devotion to the subject.

For some birders this involvement in science goes much further, with individuals lacking formal qualifications going on to become recognised experts in their chosen area of study. UK birder Mark Constantine and his colleagues at the Sound Approach are a case in point, using their passionate interest in bird songs and calls to stimulate a reassessment of the taxonomic standing of recognised 'species' and a wider appreciation of bird calls and their function. They have become the leading experts in the field of avian sound recording, with acclaimed publications to their name and making a significant contribution to our wider scientific understanding **[13]**.

In fact, for many the division between time spent birding and that spent contributing to scientific study has become truly blurred. Records collected on birding trips and fed into BirdTrack (a partnership between BTO, RSPB and BirdWatch Ireland), not only feed through into county bird reports but are also being used to track changes in migration patterns **[14]**.

Additionally, and highlighting the conservation value of birding, the records collected through BirdTrack are also used to target valuable resources towards important bird sites. The Bird Conservation Targeting Project identifies these sites by mapping the distributions of birds of current conservation concern reported through BirdTrack and then uses this information to direct how millions of pounds in grant payments is distributed through agri-environment and woodland schemes within England.

Citizen Science projects are increasingly valued as weapons in the fight against environmental problems, not only because of the quality of their underlying scientific structure but also because they help to draw in a much wider section of society than seen in earlier surveys.

In Britain, the RSPB's Big Garden Birdwatch **[15]** (which annually attracts about half a million participants, including many families and, importantly, school children) reaches many people who would not consider themselves to be 'birders', thanks largely to widespread media coverage, especially on national radio and in the newspapers. The survey not only provides a snap-shot of birds in gardens but it also engages participants with science and the underlying conservation messages that the organisation puts across.

A similar scheme operating in North America, the Great Backyard Bird Count, annually records more than seven million individual birds of over 620 different species.

Whatever the level of involvement, from the backyard birder to someone who monitors a local patch or participates in nest recording or bird ringing, the role of the Citizen Scientist cannot be overestimated. As Professor Greenwood pointed out in his presentation to the IOC, sceptics have been predicting that the day of the amateur will soon be over for about 200 years! The role of the amateur has never been so strong as it is today and this bodes extremely well for the future.

Developments in science and their effects on birding

In 1990, two books published by Yale University Press caused a revolution in the worlds of ornithology and birding. Their titles—*Phylogeny and Classification of Birds* **[16]** and *Distribution and Taxonomy of Birds of the World* **[17]**—and their combined weight of several kilos, guaranteed that they would never reach the top of the best-seller lists. But their content, once it had been analysed and understood by the wider birding community, was the ornithological equivalent of a ticking time-bomb.

The authors were a trio of highly respected US biologists, Burt L. Monroe Jr., Charles G. Sibley and Jon E. Ahlquist. Their long study of bird taxonomy and classification, using new techniques to analyse DNA of individual species and related taxa, had reached some extraordinary conclusions. Not only did the authors propose an entirely new 'family tree' of the world's birds, with radical changes in relationships between families and groups; they also revealed that their studies had effectively created hundreds of 'new' species.

Distribution and Taxonomy of Birds of the World, written by Sibley and Monroe, produced a revised list of the world's living bird species—9672 in all—arranged according to the new classification, with explanatory notes on each, concentrating especially on taxonomy at the species level.

Phylogeny and Classification of Birds, by Sibley and Ahlquist, explained the complex scientific reasoning behind these changes. Its subtitle, 'A Study in Molecular Evolution', was a clue to the revolutionary nature of the approach. Until then, taxonomists had used a tried and trusted range of methods to classify the world's birds, including structural (also known as morphological) characters, such as shape, colour and anatomy; and behavioural characters such as courtship display and song.

The problem with these traditional methods was that they often relied on subjective comparisons between species, genera and families; comparisons that could sometimes produce wildly inaccurate results. This is due to two related but opposite factors: adaptive radiation and adaptive convergence.

Darwin's finches (Emberizidae), a group of 14 species found mainly in the Galapagos, are an excellent example of adaptive radiation: whereby species exhibiting very different appearance, traits and habits have been found to have evolved from a common ancestor. Adaptive convergence is shown by many families of Australian birds, such as the fairy-wrens (Maluridae), which despite their superficial resemblance to Eurasian bird families, are not closely related to them. Both adaptive radiation and

convergence can make it extremely difficult to work out the actual evolutionary lineage and relationship of a particular species or individual bird.

The new, molecular-based, approach promised—at least according to its most zealous proponents—to clear away all the doubt and confusion. Based on a process known as DNA–DNA hybridisation, it used biochemical techniques to compare the DNA of one species with another, and depending on the results, to work out the closeness of the relationship between them.

For the ordinary birder, the conclusions were exciting and baffling in equal measure. To give just one example amongst many, the existing order Ciconiiformes traditionally comprises several families of long-legged wading birds, including storks (Ciconiidae), ibises and spoonbills (Threskiornithidae), and herons, bitterns and egrets (Ardeidae)—about 120 species in all.

The new Ciconiiformes expanded this massively, also including such diverse groups as waders/shorebirds, gulls, terns and auks (Charadriiformes); cormorants, gannets and boobies (Pelecaniformes); day-flying birds of prey (Falconiformes); penguins (Sphenisciformes); grebes (Podicipediformes); divers/loons (Gaviiformes) and pelagic seabirds such as petrels, shearwaters and albatrosses (Procellariiformes)—a grand total of well over 1000 species from no fewer than eight existing orders. Incidentally, though many of the new findings have since been accepted by the scientific community, this particular hypothesis appears to have been comprehensively discredited.

At the species level, the new technique revealed even greater surprises, with many species being 'split' into two or even more new forms, each a species in its own right. So Bonelli's Warbler, from southern Europe and western Asia, was split into two new species, Eastern (*Phylloscopus orientalis*) and Western Bonelli's Warblers (*Phylloscopus bonelli*). To add to the confusion, DNA studies apparently revealed that another species, Wood Warbler (*Phylloscopus sibilatrix*), appears to be more closely related to both the new species than either was to the other.

The major problem with the new approach, from a birder's point of view, was that by overturning the established order it went to the heart of one of the main ways in which the ordinary birder deals with the birds they see—by listing them as different species.

So if, as was apparently the case, new scientific techniques were going to completely change not only the relationship between families and species, but also effectively 'create' a whole new range of species, the potential for confusion was obvious. Would bird books have to be updated every year or two to include new discoveries? Would some species, such as the Red Crossbill (*Loxia curvirostra*), be split into so many new species that the ordinary birder would be unable to tell them apart in the field? Might there in fact be as many as 20,000 different species out there, as opposed to fewer than 10,000, as previously assumed?

In fact, after the initial furore, the application of the new science took longer than expected, and had less of an apocalyptic effect than had been predicted. So, for example, the fifth edition of James F. Clements' *Birds of the World: a Checklist* **[18]** (published in 2000) included 9800 species. Moreover, these were arranged in the traditional order, beginning with the ratites (Ostrich and its relatives), and progressing through penguins, divers, grebes and procellariiform tubenoses.

In the Foreword to the fifth edition, William T. Everett defends Clements' conservatism by pointing out that any attempt to keep up with new findings would be rendered "at least partially obsolete" almost immediately after publication. And while acknowledging the enormous strides made by Monroe and his colleagues, Everett also warns that this might not be beneficial to everyone:

> This is how science progresses but it is not particularly good news, for example, to birders who want to keep track of their observations or curators who have to keep thousands of avian specimens properly cataloged, sorted and organized.

Other authors and publishers have been quicker to adopt at least some of the new findings. The most recent checklist, *Birds of the World: Recommended English Names* **[19]**, by Frank Gill and Minturn Wright (published in 2006) includes just over 10,000 species; and places tinamous at the front, followed by ratites, gamebirds and wildfowl (ducks, geese and swans), before returning to the more conventional order.

Almost two decades on, with the benefit of hindsight, we can look back on the new approach as a major evolutionary step rather than a giant revolutionary leap. As Christopher Leahy wrote in 2004:

> The Sibley-Ahlquist phylogeny should not be seen as the new Truth vanquishing a discredited earlier version. It is rather a hypothesis—a bold one—supported by some proofs. Both its experimental design and analysis of the data have been criticised by

> colleagues…There is no question, however, that increasingly sophisticated methods of DNA analysis have opened a new path of biological systematics that will provide immense opportunities for new research… for decades to come. **[20]**

Back in the field, one current benefit of the new approach is that it has encouraged birders to take a closer look at 'odd' birds—either a well-marked subspecies or perhaps simply something 'a bit different from the rest'—rather than dismissing them as mere curiosities. However, groups such as the *Motacilla flava* wagtail complex, or the larger gulls of the genus *Larus*, appear to blur the distinction between species and even subspecies, by presenting a bewildering range of minor differences between individuals and populations.

Dutch birder and ornithologist Arnoud van den Berg, whose field experience of the world's birds is more extensive than almost anyone alive, takes a view that mixes inquiry and flexibility in equal measure. He regards every taxon (a term which includes any distinctive group of birds whether or not they merit full specific status, including subspecies) as worthy of interest. In these uncertain times, this seems to be an eminently sensible approach **[21]**.

Birding and the media

For many years, birding was rarely covered in the mass media; and when it did appear, it was usually represented as something rather amusing, peculiar or sad: the widespread use of puns based on the word 'twitcher' indicating a rather patronising journalistic attitude towards the pastime.

Indeed, the 2001 tabloid story that US pop star Britney Spears might be a birdwatcher (based on the acquisition of pictures of birds for the walls of her Los Angeles home) was based on the fact that the juxtaposition between the coolest teen pop idol and birding was, quite simply, ridiculous.

Nevertheless, birding (and its sister science, ornithology) not only receives considerable coverage nowadays, but the tone of that coverage is subtly changing. When the *Guardian* commissioned a major feature on the BBC television event *Springwatch*, in June 2005, it chose the respected writer and novelist Blake Morrison to cover the story **[22]**. He, in turn, avoided the usual tongue-in-cheek journalistic style, and instead wrote a thoughtful analysis of why what he called a "real-life avian soap-opera" had become such a hit with the public.

Morrison observed that the series allowed viewers to satisfy (albeit vicariously) "a dream of living in close harmony with nature", and concluded that its success was another indication that the British public was "quietly falling in love with nature again".

BBC Radio 4, which tends to attract an older and more conservative audience than does television, covers birding stories less flippantly than its television and newspaper counterparts. The early morning *Today* programme, in particular, has a long tradition of featuring such events as the RSPB's Big Garden Birdwatch—something that has undoubtedly contributed to the massive increase in the numbers of people taking part in this annual survey.

More recently, even the advertisers have got in on the act. Fans of Bill Oddie's wildlife programmes may have been surprised to see footage of thousands of Common Starlings (*Sturnus vulgaris*) indulging in their pre-roost aerial displays appearing in an advert for a well-known brand of lager.

At one of the best-known Common Starling roosts, on the Somerset Levels, the arrival of dozens of visitors hoping to see the evening flight prompted a lively debate on the website of the Somerset Ornithological Society **[23]** as to the drawbacks and benefits of so many novice birders (and indeed non-birding members of the general public) wanting to see the spectacle for themselves.

The popularity of the Common Starling roost has revealed how quickly an avian spectacle known only to a select few can, with the aid of the media, rapidly become a public event. If more and more people who do not consider themselves to be birders nevertheless begin to visit sites to watch birds, the distinction between 'birders' and 'non-birders' will blur even more. Eventually, perhaps, birding may simply become something the majority of people do—a bit like gardening or cookery—rather than a relatively specialised pastime.

New technology

One of the main themes of my book on the social history of birdwatching, *A Bird in the Bush*, was how the development of new means of communication (especially,

though not exclusively, those that have allowed a more rapid spread of rare bird sightings) helped to promote changes in the way we watched birds.

The progression went something like: postcards (1950s), domestic telephones (1960s and 1970s), mobile phones and pagers (1980s and 1990s) and the Internet (early 21st century). Without such rapid (and largely unforeseen) developments in communications technology, it is hard to imagine that birding would have developed in quite the way it did.

Today, the keen birder has a plethora of communications aids, enabling them to get up-to-the-minute news of sightings, virtually wherever they are—mobile signals permitting. The widespread use of personal pagers, in particular, has had major changes on the way many people watch birds.

In the old days (actually not so old—perhaps two or three decades ago), people had little or no choice but to go out and find their own birds. Nowadays, it is sometimes said that it is better to sit in one, centrally located, place; wait for the pager to alert you to the news of a bird's arrival; then dash off to see it.

One British birder has scathingly dismissed those who indulged in this practice as "the prawn sandwich brigade" **[24]**—itself a reference to a comment made by Manchester United footballer Roy Keane about a new breed of football fans, who want all the benefits of supporting a major team without undergoing any of the discomforts. This fits in with a long tradition in British birding subculture—that you have to suffer the bad times to appreciate the good.

Once our new birder has located the site of a rare bird (using first a pager and then a satellite navigation system), they now have a range of gadgets with which to confirm its identity and create a record of the sighting. Field guides and notebooks are, most definitely, out; electronic guides held on a palmtop device (including pictures *and* sounds), 'pens' containing a selection of bird calls and songs that can be retrieved instantly in the field, video cameras, and 'digiscoping' (attaching a digital camera to a telescope in order to get a long lens shot of the bird) are in.

Digiscoping (a technique originally developed in Malaysia by Laurence Poh **[25]**) means that once the picture (or indeed video clip) is obtained, a birder can use mobile technology to send it instantaneously to other birders—especially important if the identity of the bird is in question.

One unforeseen result of this is that the type of thorough, complete notes required by national and state or county records committees, are hardly ever taken nowadays—after all, goes the reasoning, what is the point when you can take a picture of the actual bird? Indeed, in 2006 no fewer than three potential 'firsts for Britain'—an Olive-tree Warbler (*Hippolais olivetorum*), Black-eared Kite (*Milvus migrans lineatus*) and Long-billed Murrelet (*Brachyramphus perdix*)—were initially misidentified in the field, their true identity only coming to light after images of the birds were posted on the web.

Sceptics believe that a decline in note-taking, and a reliance on photographic evidence as opposed to close observation of the bird, will lead to a falling-off in field identification skills—and they may well be right. After all, some of the developing world's greatest field birders, such as Hadoram Shirihai in Israel, learnt their trade without any optical aids at all—not even binoculars.

Another use of new technology is to help human observers. Much in the same way as closed-circuit television (CCTV) cameras reduce the need for human security, so the installation of a huge robotic camera in the area where the Ivory-billed Woodpecker (*Campephilus principalis*) was supposedly sighted (in the southern US state of Arkansas) aims to capture sightings of this elusive (and possibly actually extinct) bird. In an article headlined 'Spy cameras on the bayou could spell end of twitchers', a spokesman from Cornell University was quoted as saying:

> Humans are expensive, and they're not always alert, and their presence disturbs the environment, even when they're camouflaged and sitting quietly. **[26]**

New technology is not solely used with regard to rare birds. The Internet allows new kinds of communication—either between birders in different parts of the country or around the world, or between birders and ornithological organisations—to work in ways we could not have envisaged even a decade ago. The BTO's BirdTrack programme allows participants to log on and check sightings of migratory birds, and indeed post sightings of their own. BirdTrack is a quick, efficient and highly effective way of mobilising thousands of ordinary birders in order to contribute to our scientific knowledge of birds **[27]**.

A global version of this, proposed at a meeting of conservationists in Edinburgh in autumn 2003, involves a worldwide 'air traffic control' network to monitor the movements and numbers of migrating birds across the globe **[28]**.

But whatever we think about it, and whatever the consequences for the future of birding, new technology is here to stay—and the next decade or so will undoubtedly see even greater technological advances to help birders.

The economic importance of birding

It has long been understood that birds themselves—or at least our exploitation of them for food, fuel and other products—contribute major benefits to regional, local and (at least in the case of the domestic chicken) global economies. There are far too many examples to list in full, but even a random selection gives some idea of how human civilisation might have taken a very different course had we not learned to exploit wild, and later domesticated, birds:

- The domestic chicken, whose ancestor is the Red Junglefowl (*Gallus gallus*) of southern Asia, is easily the commonest bird in the world. With estimates of between eight and 35 billion individuals, its population comfortably outranks the number of human beings on the planet (approximately 6·5 billion).
- The islanders of St Kilda, a remote island group off north-west Scotland, were known as 'the bird people' because they lived almost entirely on seabirds, which they used for food (meat and eggs), fuel (burning the oil from the fatty young) and even clothing (whole Northern Gannets (*Sula bassana*) were used as primitive slippers!).
- The droppings of the Guanay Cormorant (*Phalacrocorax bougainvillii*) of South America, which are rich in nitrates, have been harvested for centuries for use as fertiliser, bringing profit to the people of various South American countries where it occurs. During the late 19th century Chile, Bolivia and Peru even went to war over the guano supplies.
- The use of bird feathers and skins in women's fashion reached a peak during the late 19th and early 20th centuries. During a fifty-year period between 1870 and 1920, 20,000 tons of plumage, from millions of individual birds, were imported into the UK.
- Since 1934, the US government has raised revenue from hunters through the sale of 'duck stamps'—effectively permits allowing the right to shoot waterfowl. In the year 2000, over US$25 million of revenue was generated by the programme.
- Birds are frequently used for advertising and marketing purposes, as manufacturers, retailers and other businesses seek to increase their sales or improve their public image, by association with some of our favourite creatures. Perhaps the best-known of a myriad of examples are the famous 'Guinness toucan', created in 1935 to advertise the well-known brand of Irish beer; Swan Vestas matches; and the publishing imprints Penguin Group and Puffin Books.

There are countless other examples of our exploitation of birds for direct or indirect economic benefits. But what about the economic benefits of *watching* birds? Until recently, very little attention had been paid to the actual and potential spending by birders, but nowadays both the US Fish & Wildlife Service and the RSPB are beginning to produce detailed reports on this important aspect of birding.

Economic value of birding in the US

In the US, the figures are simply staggering. In 2001, according to the US Fish & Wildlife survey **[29]**, wildlife-watchers (of which birders represent the vast majority) spent a total of US$31·7 billion in pursuit of their hobby. To put this figure into perspective, it almost exactly matches the annual Gross Domestic Product (GDP) of Costa Rica, a popular travel destination for US birders.

Of this sum, the largest costs were travel-related, including the purchase or hire of vehicles, the services of expert guides, and food and lodging. Participants spent over US$1·9 billion on optical equipment, including binoculars, telescopes and cameras; over US$0·6 billion on nest boxes and bird feeders; and a staggering US$2·2 billion on bird food—equivalent to two Big Macs for every man, woman and child in the US.

Overall, the impact of wildlife-watching on US economic output is even greater: its total economic value has been estimated as US$85 billion a year, producing US$13 billion in state and federal tax revenues and creating over 860,000 jobs—a substantial contribution to the country's economy.

On a local level, the economic impact of birders is even greater, as the report's author points out:

> Towns such as Cape May, New Jersey, and Platte River, Nebraska, attract thousands of birding visitors each year generating millions of dollars—money that would likely otherwise be spent elsewhere.

The survey as a whole illustrates the immense scale of birding-related expenditure, something welcomed by Julian Hughes of the RSPB **[30]**. However, he has also pointed out that the methodological approach of the survey does raise some important questions, and also make like-for-like comparisons between the US and the UK more difficult.

The main problem is that the survey takes a very liberal view of the kinds of expenditure related to birding activities: for example it includes the sales value of cars, boats and other personal transport (totalling more than US$11 billion), despite the fact that not even the keenest birder owns a car purely in order to go birding. Other questionable figures include more than US$4 billion for 'land leasing and ownership', over US$500 million for camping equipment, and more than US$2·6 billion on food.

As a result, the figures for total birding-related expenditure have been, Hughes believes, greatly exaggerated, and the true figure is likely to be much lower—perhaps in the region of US$5–10 billion—nevertheless, still a staggering amount.

Economic value of birding in the UK

With a much lower population (60 million compared to over 300 million) and smaller economy (US$2·2 trillion compared to US$12·49 trillion—2005 figures **[31]**), the United Kingdom's statistics may appear rather insignificant compared to those of the United States.

Another reason the figures are lower is that UK economists do not measure the *total* spending made by birders on their hobby, but instead measure the *extra* spending people make because they watch birds.

On a regional and local level, there is no doubt that birders do make a significant contribution to the economy. In 2006, the RSPB produced a report, *Watched Like Never Before* **[32]**, on the local economic benefits of what it called 'spectacular bird species'—mainly raptors such as the Osprey (*Pandion haliaetus*), White-tailed Sea-Eagle (*Haliateeus albicilla)*, and Red Kite (*Milvus milvus)*, but including a variety of other species and groups.

As the report noted, the phenomenon of mass viewing of birds is not confined to traditional birding sites:

> Spectacular birds attract attention from the popular media, which in turn stimulates the public to visit sites and watch them in new ways… The resulting social and economic benefits can occur anywhere, from office-workers enjoying city-centre Peregrines (*Falco peregrinus*) in their lunch break, to tourists visiting seabird colonies on remote islands.

The report does not attempt to provide a total figure for the economic benefits of birding in Britain, but instead concentrates on specific sites, most of which are promoted by the RSPB in its *A date with nature* scheme **[33]**, which provides expert guides to show these spectacular birds to the general public.

Even so, the sums generated are economically significant, especially in remote parts of the UK such as the Scottish Highlands and Islands, which rely heavily on tourism for revenue.

For example, an estimated 290,000 people now visit sites with nesting Ospreys each year—mainly Loch Garten in Scotland, but also other locations in Scotland, England and Wales. In doing so, they bring an estimated additional expenditure of £3·5 million per year, making the Osprey, in the report's words, "probably the UK's top bird-tourism species".

Another spectacular bird-of-prey attracting visitors is the White-tailed Sea-Eagle (popularly known as the Sea Eagle). Following a successful reintroduction programme (the species became extinct as a British breeding bird during the First World War), a number of pairs of Sea Eagles now breed on the Isle of Mull. Visitors to the island spend about £38 million every year, of which approximately £1·4–1·6 million is generated by the presence of the eagles.

The RSPB has estimated the number of jobs created by this extra revenue, using a figure of one full-time post created by every £38,650 of expenditure. As a result, about 90 jobs have been created by the presence of Ospreys, and between 36 and 41 jobs from the Sea Eagles—a significant figure on an island with a population of fewer than 2000 people.

Together, the RSPB's 200 nature reserves in the UK attract over 1·5 million visitors each year. In 2006, these visitors spent almost £19 million on products and services in the local communities around these reserves, supporting almost 500 jobs. In addition, the management of these reserves has created a further 1000 or so jobs. While insignificant at a national level, many of these jobs are in rural areas where traditional employment opportunities have diminished.

But as in North America, by far the largest sums spent on birds and birding in the UK are those related to feeding and providing nesting places for garden birds. Bird gardening has a long history, going back to the 6th century, when St Serf of Fife first tamed a European Robin (*Erithacus rubecula*) by giving it food. Regular feeding of birds began in the late 19th century, while the first decade of the 20th century saw the arrival in Britain of the first nestboxes, imported from Westphalia in Germany and sold for sixpence each—about £1 in today's money.

However, until two or three decades ago, providing food and homes for garden birds was little more than a cottage industry, with supplies mainly provided by pet shops and other local retailers. Some retailers, such as Haith's (which started in 1937 in a pet shop in Cleethorpes, Lincolnshire, UK) had been retailing specialised food and feeders since before the Second World War. But it was not until the 1980s that the market began to become really competitive. The following decade saw an unprecedented expansion in the bird food industry, with several major companies setting up mail-order retail outlets.

The BTO has estimated the value of the industry today at approximately £200 million per annum **[34]**. The figures for the consumption of individual products are equally staggering: 16,000 tonnes of peanuts, 30,000 tonnes of sunflower seeds and 2000 tonnes of fat products. As a result, the number of species coming to feeders in the UK has grown to more than 100, and several species formerly rare or absent from gardens, such as European Goldfinch (*Carduelis carduelis*) and Eurasian Siskin (*Carduelis spinus*), are now regular visitors.

Until a reliable, detailed study is carried out, only a rough estimation of birders' total contribution to the UK economy as a whole can be made. But using a simple extrapolation from the US figures, the UK's 2·85 million birders probably spend £500 million—perhaps as much as £1 billion—on their hobby each year.

Economic value of birding in the developing world

In the developing world, birders also bring significant economic benefits, simply by visiting different countries, regions and sites to watch birds. Unfortunately no reliable studies have been made on actual revenues, so we can only guess how much this is actually worth in economic terms.

Given that hundreds of thousands—probably millions—of birders travel abroad every year to watch birds, the sums involved are likely to be colossal. Of course much of the profits generated by foreign bird tours go to international airlines, major hotel chains, and the bird tour companies themselves, rather than remaining within the local economies where the birding actually takes place.

However, the recent trend towards environmentally and socially responsible ecotourism does mean that many bird tour companies do try to spend as much as they can on local goods and services, while others pay a small percentage of their profits towards local conservation projects.

As foreign travel has become the norm rather than the exception, birders have broadened their horizons by visiting more long-haul destinations. Of these, perhaps the best-known are Costa Rica and Trinidad and Tobago, both of which attract large numbers of visitors from both North America and the UK. While Tobago has always been a popular holiday destination, Trinidad has not, so the annual influx of birders to locations such as the Asa Wright Nature Centre and the Pax Guest House makes an important contribution to the local economy.

In the Old World, long-haul holiday destinations such as The Gambia and Thailand have also proved popular, especially with British visitors. And during the 1980s and 1990s, the British tour company Sunbird pioneered a series of relatively low-cost (at least in bird tour terms) package holidays to places such as Eilat in Israel, the Indian resort of Goa, and even the Chinese seaside resort of Beidaihe.

In many of these destinations, such as Trinidad and Tobago and The Gambia, local birders can now make a good living from becoming tour guides, often accompanying a leader from the US or UK, and providing up-to-date local knowledge and expertise. Ironically, their extraordinary ability to identify the birds they see derives from the fact that most spent their formative birding years either using poor-quality binoculars, or in some cases without any optical aids at all.

An example of how birding contributes to a local economy, albeit on a small scale, is the 'Jardin de los Picaflores' in the small town of Misiones, near the Iguazu Falls in northern Argentina. This private garden attracts up to 16 different species of hummingbird (Trochilidae), coming to feed on nectar provided by the householders. By selling a colour brochure about the hummingbirds, and asking for a small finan-

cial contribution, at least one family enjoys a financial benefit from a steady stream of foreign birders. The birds are likely to benefit as well: if local people can make money from the bird-friendly exploitation of local species, they are more likely to ensure that birds and their habitats are protected against damage from other economic interests.

Elsewhere, similar projects are also helping both people and birds. In South Africa, the Zululand Birding Route **[35]** was established in 1997, and along with the Greater Limpopo Birding Route, is worth an estimated US$6·8 million per year to the region. On the tenth anniversary of the establishment of the route, in 2007, of BirdLife South Africa's Duncan Pritchard commented:

> To see the Zululand Birding Route reach 10 years is testament to how simple and effective the avitourism [birding ecotourism] concept has been in this case... There have been winners all round: local economies, jobs, education and, of course, the birds. **[36]**

South Africa has, of course, a long birding tradition. But even in places where birding is a relatively recent pastime, the link between conserving birds and tourism is now being made. In the central Asian republic of Azerbaijan, for example, government officials have included the country's 52 Important Bird Areas (IBAs) in their national tourism plan, and provided an infrastructure for birding tours, thus ensuring their continued protection **[37]**.

The dignified and low-key nature of these projects is in stark contrast to the frenzy of commercial exploitation that followed an apparent sighting of the potentially extinct Ivory-billed Woodpecker in the forested swamps of Arkansas, in early 2004. The reaction of one excited ornithologist set the tone: "It's kind of like finding Elvis!" **[38]**.

For the people of Brinkley, the nearest small town to where the woodpecker had been sighted, the arrival of thousands of birders, accompanied in its train by the news media bandwagon, was like a modern-day goldrush. Local businesses sought to exploit the woodpecker in any way they could: one motel changed its name to 'The Ivory-billed Inn', while 'ivory-billed salad' and 'ivory-billed burger' were on the menu at Gene's Restaurant and Barbeque. A local barbershop even offered an 'ivory-billed' haircut, a variation of the Mohawk style complete with a red tint.

The only problem was that despite reports to the contrary, the Ivory-billed Woodpecker may actually be extinct. Expert ornithologists have begun to question the authenticity of the initial observation, and despite dozens of alleged sightings elsewhere in the southern states of the US, the woodpecker may indeed live up to its reputation as the Elvis Presley of the bird world.

Part 4: Birding Future

> *With his television outfit set up in a Devon heronry or at a lek of a blackcock in Northumberland the bird-watcher of the fairly near future may check, without leaving his house, or perhaps without leaving London, detailed observations painfully secured by isolated pioneers cramped, wet through, at dawn under flimsy canvas hides. It may be shocking that the acuter discomforts of bird-watching should be abolished for those willing to command increasingly intricate apparatus, but that undoubtedly is the way we are going.* **[1]**
>
> Max Nicholson, 1931

Despite the uncanny accuracy of Max Nicholson's 1931 forecast, which prefigured the arrival of webcams by about 70 years, making predictions about the future development of global birding is not an easy task. Indeed anyone who does so is likely to be proved wrong very rapidly, such is the complexity of the various factors involved.

So rather than making firm forecasts about how birding is likely to grow and develop during the coming decades, I shall instead endeavour to identify key factors which, in my opinion, are most likely to affect that development.

Broadly, these break down into three main categories:

- **The current and future status of bird species**.
- **How technological changes are likely to impact on birding**.
- **Environmental issues and birding**.

Finally, I shall draw on the thoughts of previous and current writers on birding, in order to answer an apparently simple question once posed by the legendary American bird artist Roger Tory Peterson **[2]**:

- **What are birds for?**

The current and future status of bird species

In 2000, BirdLife International and Lynx Edicions published what may prove to be the most important book on birds ever to appear. *Threatened Birds of the World* **[3]** was a catalogue of no fewer than 1111 of the world's bird species, representing about one in eight of all the species currently in existence.

Each of these species had become enough of a cause for concern to be placed on The IUCN Red List of Threatened Species, which included all birds potentially at risk of extinction, in categories ranging from 'Extinct' or 'Extinct in the Wild', through 'Critically Endangered' and 'Endangered', to 'Vulnerable'.

Since then, the number of species on the Red List has risen to 1227, of which 192 are classified as Critically Endangered, 15 of which are possibly already extinct (2009 figures) **[4]**. With more than 800 further species categorised as 'Near Threatened', this means that well over 2000 species—more than one in five of all the bird species in the world—are considered urgent priorities for conservation action. Of these, it is predicted that more than 200 species will become extinct by the year 2100—more if the factors affecting their declines get worse. This compares with an estimated total of about 80 to 100 species having become extinct since the year 1600 **[5]**—an increase of a factor of between ten and twelve in the rate of extinction.

Other studies are even more pessimistic. A 2004 report from the Stanford Center for Conservation and Biology in California **[6]** suggested that in a worst-case scenario one in four of all bird species—2500 in all—could become extinct by the end of the 21st century. Even the best-case scenario predicted that 700 species would be lost, while the intermediate figure was 1200 species. As Dr Russell Mittermeier, President of Conservation International, has said:

> All the indications are that we are standing at the opening phase of a mass extinction event. **[7]**

The reasons for the unprecedented decline and imminent extinction of so many bird species are depressingly familiar: human over-population, leading to widespread destruction of habitat (which once gone may be either very difficult or impossible to recreate); hunting for food or sport; and pollution (especially of wetlands). Now we face the new and terrifying spectre of global climate change, which threatens to alter our weather patterns, habitats and ecosystems more catastrophically and rapidly than ever before **[8]**. As Dr Stuart Butchart of BirdLife International noted in the 2008 report:

> Species are being hit by the double whammy of habitat loss and climate change. **[9]**

The authors of *Threatened Birds of the World* put the situation into stark clarity: we are both the problem and, potentially, the solution. Birders—especially those travelling to poorly-known regions of the world—have long been a vital tool in collecting information about the birds of a particular area, and at times instrumental in saving them and their habitat from destruction. In the future, their role promises to be even more critical:

> The challenge… is to promote behaviour changes amongst the world's people. These changes should effectively conserve threatened birds, and the habitats, sites and ecosystems in which we all live. **[10]**

But despite the optimism of this statement, pessimists might take a very different view: in the future, will there be any birds left for people to see? Of course some species will continue to prosper, especially those which have adapted to live alongside man and exploit our wasteful misuse of resources, but these are not usually the birds most sought-after by birders travelling abroad.

And if birders are no longer willing to pay large sums of money to travel to watch birds, or decide not to travel so as to reduce their 'carbon footprint', what effects might this have on the local economies of such places that have grown to depend on an annual influx of visiting birders? A vicious circle could ensue, in which the reduction in numbers of people travelling to watch birds, and the consequent fall in income

related to ecotourism activities, leads to the inability to protect the birds and their habitats that people are no longer coming to see.

A different, but equally valid, point of view is that a reduction in global birding tourism could ultimately be for the benefit of the birds, as Dr Nigel Collar of BirdLife International suggested in his Foreword to Volume 5 of the *Handbook of the Birds of the World*, in 1999:

> Birdwatchers and biologists get to ever more remote places by virtue of new airports, new logging roads, new tourist facilities. They arrive as tiny components of the great machinery of economic development which, in a few short years, mutilates natural landscapes and human cultures beyond recognition and brings Coca-Cola, television, chainsaws, DDT and debt to every cultivable corner of the planet. By the year 2010 not only will we know more about birds than ever before… we will also have most of them *completely surrounded*. **[11]**

How technological changes are likely to impact on birding

Technology changes so rapidly, and so unpredictably, that any specific examples I might give may seem hopelessly wide of the mark in just a few years time. Nevertheless, we can be fairly sure that the breakneck pace at which computing power is able to increase, combined with the increased economic purchasing power of birders, means that the pace of change is likely to accelerate at an even faster rate.

Birders, like any other community of people, are quick to take advantage of new ways of communicating. So just as pagers and mobiles dominated the late 20th century, and e-mail and websites have so far dominated the early 21st, we can expect that recent changes in the Internet will soon be taken up by at least some birders.

Social networking services such as MySpace (more than 100 million users) and Facebook (more than 200 million users) allow rapid and informal communication; while similar use of shared spaces by 'closed' communities (such as schools and universities) are now being mimicked by online birding communities in the UK, US and Australia, and elsewhere **[12]**.

Given the global nature of birding nowadays, the Internet is the perfect way to communicate sightings, opinions and advice between individuals anywhere in the world, and can only help develop the cohesive nature of birding in the 21st century. The sense of isolation felt by many new or young birders as recently as two or three decades ago is surely gone forever. In tomorrow's world, the novice birder will need to learn to cope with too *much* information and too *many* ways to communicate with other birders, rather than too little and too few.

Another factor which might put a brake on progress—certainly for individuals in the developing world—is expense. Gadgets such as field guides on a PDA (Personal Digital Assistant—a small, hand-held computing device), or a microphone attached to binoculars which can digitally record the sound of a singing bird, may be assets, but they also cost money. Just as the wide difference in cost between cheap and expensive binoculars can create 'second-class' birders disadvantaged by their cheap optics, so the ever-increasing need to update hi-tech gadgets may do the same.

But however much technology may change, the fundamental needs of birders remain remarkably similar to those of a century ago: discovering good places for birds, getting there, and identifying the birds once you find them. And it is this latter, fundamental building-block of identification—for after all, you cannot really learn about a bird until you know to what species it belongs—which may see the most radical changes.

We already have the ability to take a sample of DNA from a captured bird, and analyse this to assign that particular individual to a known species. This has been compared to a kind of 'barcode'; so the logical next step is to wonder if a device could be invented that could 'read' this code in the field—making field identification skills redundant virtually overnight.

This scenario was envisaged by Irish birder Anthony McGeehan in *Birdwatch* magazine a few years ago **[13]**. It was only after reaching the conclusion of McGeehan's article, that most readers realised that it was, of course, an April Fool's Day spoof. Maybe it soon won't seem so far-fetched after all. Professor Paul Hebert of the University of Guelph in Canada has now set out to create unique barcodes—similar to those used to identify products in our supermarkets—for each individual species of plant and animal in the world. He claims that the system is accurate in 98% of cases, and that within five years every species on the planet (or at least all those known to us) will have its own barcode **[14]**.

Environmental issues and birding

The next uncomfortable question for today's birders is this: even if we want to travel to see birds around the world, will we be able to?

Three major factors are making it more and more difficult to watch birds in far-flung corners of the world. The first is political instability: nowadays, few birders visit Middle Eastern trouble spots such as Jordan, Syria and even Israel; nor are there many regular tours to Colombia. People are naturally put off by the perceived (and sometimes very real) dangers of travelling in such regions; and where they have a choice, will go elsewhere **[15]**.

Second, the recent 'credit crunch', in which the world's major economies (in both the developed and developing world) are entering what may be a prolonged period of economic recession, will no doubt have impacts on the numbers of people able to afford expensive birding holidays.

But the biggest change in our travelling habits is a consequence of our wastefulness and profligate use of the world's resources in the past. Now that global climate change is fast rising up the political agenda (even, finally, in the US, where successive governments have ignored the problem in the vain hope that it would go away), there are demands for 'something to be done'.

This is likely to take the shape of measures designed to reduce the carbon footprint of each individual: such as increased taxes on air travel and aircraft fuel; and ultimately individually based 'carbon allowances'—effectively a form of rationing. Given that currently each American emits 20 tonnes of carbon per year, and each Briton ten tonnes (compared to just three tonnes per person in China and one tonne per person in India), it is likely that long-distance air travel will eventually undergo a rapid decline in accessibility. This would effectively put paid to non-essential inter-continental travel, and the current era of global bird tours would enter a period of rapid and possibly terminal decline.

If the more extreme predictions about the effects of climate change on our ecosystems come true, then not only will we be unable to travel to see birds, but even if we did so, there would be very little to see. A depressing thought, but potentially a realistic one.

Looking on the brighter side, birding in one's local area—the regular watching of a 'local patch', or on a wider scale, county or state—is likely to become much more important. As Mark Obmascik notes in his account of obsessive birding in North America, *The Big Year* **[16]**, the era of trans-continental twitching was effectively brought to an end by the terrible events of 9/11. Obmascik points out that Sandy Komito, the record-holder for the most species seen in a single calendar year (achieved in 1998), was travelling "in a different, friendlier world":

> It would not be easy to log 270,000 last-minute miles through the increased security of today's borders and airports.

As birders turn towards the birds of their local area, some benefits may occur. The reduction in geographical horizons is likely to lead to a decline in the recent obsession with seeing rare birds and logging long lists of species, and a greater focus on the interests of an earlier age: such as the intricate details of bird behaviour, which so fascinated the pioneering birders of the early 20th century.

The literature of birding, too, has taken a very different turn. Books such as Scott Weidensaul's *Return to Wild America* **[17]**, Mark Cocker's *Crow Country* **[18]** and my own *A Sky Full of Starlings* **[19]** have resurrected and updated a fine tradition of personal writing about natural history—and what birds and the landscapes they live in mean to us.

Epilogue: What are birds for?

This brings me to my final question: what are birds for? This was originally posed in 1966, as the title of an essay written by Roger Tory Peterson in a book published by the US Department of the Interior entitled *Birds in Our Lives* **[1]**.

The question was put to Peterson at the end of a talk he had given in his hometown of Jamestown, New York. At first, the great man was lost for words:

> What does a clergyman say to somebody who asks him to explain the reasons for religion? What does a teacher tell a boy who wants to know what good is reading? Or a parent, should anyone ask him to list the values of a baby to parents, the human race, creation?

After his initial hesitation, Peterson begins by enumerating the various reasons for the existence of birds, divided into the two categories identified by another American ornithologist, Dean Amadon: "on the one hand, aesthetic, personal, impractical; on the other, utilitarian."

The latter category is, of course, easy to answer. Peterson points to the science of ornithology, and how it teaches us so much about the living world, and, indirectly, about our own lives. He notes the economic value of birds: the money spent on hunting and watching them; and the incalculable benefits to human civilisation of the domestication of birds. He mentions the widespread keeping of birds as pets, an area beginning to shade into the former category: "the aesthetic, personal, impractical" aspect of birds.

Then, finally, he takes the gloves off and makes a spirited defence of the 'use' of birds purely for the interest, pleasure and entertainment of birders. In this he follows in a long tradition of the defence of the pastime of birding as more than just a mere hobby. Peterson's friend and colleague, the great British ornithologist James Fisher, summed it up when he made a characteristically wry comment on the nature of birding at the start of his book *Watching Birds*:

> The observation of birds may be a superstition, a tradition, an art, a science, a pleasure, a hobby, or a bore; this depends entirely on the nature of the observer. **[2]**

In recent years, writers and observers have become more aware of the philosophical basis of birding; coinciding with a heightened interest in the benefits that an interest in nature as a whole can bring to people's mental health and emotional well-being **[3]**.

In Western societies in particular, increased affluence over the past few decades has paradoxically led to higher levels of stress, mental health problems and general unhappiness, summed up in the memorable title of a book by psychologist Oliver James: *Affluenza* **[4]**. James identifies this as a problem with people's 'emotional immune system', which can only be cured if they can reconnect with things that really matter.

Another, growing fear, is that generations of modern children may be suffering from what has been termed 'Nature-deficit Disorder'—a lack of unmediated, spontaneous contact with the natural world **[5]**. Things that older generations took for granted—fishing for tiddlers, picking wild flowers, collecting natural objects for a nature table at school—are being denied to many of today's children. As a result, we are raising children who appear to be suffering from a whole range of physical, mental and psychological problems.

Meanwhile, for adults in the Western world, where religion and spirituality are generally on the decline, a passion for the natural world appears to be helping to fill the void. A 2003 report from English Nature, *Nature and Psychological Well-being* **[6]**, analysed how connecting with the natural world not only brings benefits for people's physical health, but can greatly improve their emotional, mental and spiritual health too:

> The natural world offers the potential for significant positive affect on individual and community psychological well-being.

These include the reduction of negatives, such as stress and anxiety; as well as more positive aspects, such as increase in people's attention span and the strengthening of relationships and communities; and wider benefits such as improving local environments.

Although the report was mainly concerned with general 'outdoor activities' such as outdoor play, country walks and wildlife gardening, there is no doubt that a focused activity such as birding would bring the same, if not even greater, benefits to the individual and their community. As a similar study by the US Academy of Leisure Sciences, *The Benefits of Leisure* **[7]**, noted:

> Evidence is mounting that that systems of social support and companionship contribute to a longer, more disease-free, and higher quality life. Certainly many of these systems rely, or are highly dependent, on leisure opportunities… the "social good" of leisure is truly staggering.

This is something many birders have known about—subconsciously or consciously—for a long time. Few people can spend any length of time engaged in watching birds without at some point musing on why they do it; and most will have come to the same conclusion—that a life with birds is better, on the whole, than one without them. As Peterson's essay concludes:

> The truth of the matter is, the birds could very well live without us, but many—perhaps all—of us would find life incomplete, indeed almost intolerable, without the birds.

I—and I imagine every reader of this essay—would wholeheartedly agree.

Stephen Moss

Acknowledgements

I should like to thank the following people who have contributed to the research and writing of this essay: Mark Barrow, Bo Beolens, Arnoud van den Berg, Martin Collinson, Dominic Couzens, Ian Dawson, Jeremy Greenwood, Julian Hughes, Marco Lambertini, Adrian Long, Graham Madge, Jeremy Mynott, Richard Porter, Nigel Redman and Lim Kim Seng. Mike Toms and Andy Clements at the BTO helped draft the section on Birders as 'Citizen Scientists', in Part 3.

At Lynx Edicions, I should like to thank Josep del Hoyo and Amy Chernasky.

My wife Suzanne has, as always, been a huge support, and has read over various drafts and made many helpful suggestions.

Finally, I should like to dedicate the essay to the man who had more influence over the development of birding in the 20th century than any other, and whose foresight, wit and intelligence are evident from the quotations used here: Max Nicholson.

Introduction to Volume 14

The present volume contains an unusually high number of complicated issues of contentious nomenclature. This is not the place for an exhaustive examination of each case, and we apologize to readers if we only touch rather briefly on some of the main arguments affecting the cases that we consider to require special mention here.

Over the years, there has been little consensus as to the family placement of the White-winged Chough (*Corcorax melanoramphos*) and the Apostlebird (*Struthidea cinerea*), with the species being variously placed in Corvidae, Grallindae, each in its own monospecific family, or, as here, together in a family of two species. The name used for this two-species family has normally been Corcoracidae, but the name Struthideidae is actually slightly older. Given the taxonomic chopping and changing that has gone on, Corcoracidae can not be considered a particularly well-established concept in the literature, so it has been deemed more appropriate to follow strict priority and use the name Struthideidae.

In the case of the butcherbird family, the name Streperidae actually appeared one year before the name Cracticidae. However, Bock (1994) explains that through synonymy the latter takes priority from the earlier name Baritidae, with the result that Cracticidae is the name that should be used, as indeed it has been universally in recent times, for this taxon.

The type genus for the bird-of-paradise family has traditionally been given as *Paradisaea*. However, two different spellings appeared in the original description and David *et al.* (2009) have shown that Linnaeus himself acted as the First Reviser and selected the spelling *Paradisea*. Under the current (1999) International Code of Zoological Nomenclature, the concept of prevailing usage is not applicable in the case of two different original spellings. However, in view of the extensive use of the form *Paradisaea*, and the fact that the spelling of this name could have implications for the spelling of the family name, Paradisaeidae, Mary LeCroy and Richard Schodde (*in litt.*) have been working on an application to the Commission calling for formal protection of the spelling *Paradisaea*. As a result, for the purposes of HBW it was considered inappropriate to adopt a rarely used spelling that might (or might not) shortly be officially rejected.

Another genus name with disputed spelling is that of the Asian glossy starlings, traditionally listed as *Aplonis*. It has been shown that another spelling, *Aplornis*, is actually older, by a matter of about a fortnight. There are those who consider *Aplonis* to be a junior synonym of *Aplornis*, whereas others (including the HBW editors) consider *Aplonis* an incorrect subsequent spelling. However, at present this difference in opinion is immaterial because an application (case 3474) has been filed to the Commission to conserve the name/spelling *Aplonis*. Article 82.1 of the Code requires that prevailing usage must be maintained while a case is under consideration by the Commission. Since this issue first arose, in 1990, several Australian sources have adopted the spelling *Aplornis*, with the result that the case for the prevailing usage of the spelling *Aplonis*, although still overwhelming, is slightly less one-sided than it was in 1990. This highlights one of dangers of the concept of prevailing usage under the current Code: prevailing usage can change; an original spelling can not. There may be two or more spellings that qualify as "original", in which case First Reviser action may be required, but again this should always lead to a single, theoretically indisputable and permanent correct version.

A rather unusual case came up in the present volume affecting a disputed common name. When working on HBW13 we had already covered MacGregor's Honeyeater (*Macgregoria pulchra*). In our initial lists for that volume we had the vernacular name written using the form "Macgregor", but it was pointed out to us that Sir William MacGregor's name should correctly be written with a capital "G". At the time, we checked a number of different sources and came to the conclusion that this was correct. Now, in the present volume, we have MacGregor's Bowerbird (*Amblyornis macgregoriae*). Our lists had the version "MacGregor" when we received the comment

that this name ought correctly to be written with a lower-case "g"! We were determined to get this right, and carried out an extensive search but, although clearly favouring the version "MacGregor", the search did not prove totally conclusive. So emissaries went out to the parish of his birth, and even checked Sir William's gravestone: the name appears all in block capitals, so we were no further forward! Finally, we tracked down letters written by Sir William's widow, Lady Mary. She signed her name "MacGregor", and here, at last, we had what we considered sufficiently definite proof that this was the version that they used themselves, all the more pertinent as the bowerbird was specifically named in honour of Lady Mary. We are very grateful to Margaret Mack and also to June Ellner (University of Aberdeen) for their efforts and help in clarifying the issue.

Continuing our series of essays on assorted subjects related to birds, this volume's foreword is a most welcome piece by Stephen Moss dedicated to the past, present and future of birding, with all its manifold implications. This is unquestionably a subject that offers something for everybody, and we are sure that Stephen's fascinating account will help to settle many aspects in their various contexts.

Once again we include brief definitions of a couple of terms that occur repeatedly in the Status and Conservation sections. As defined by BirdLife International, a "restricted-range species" is one which throughout historical times is reckoned always to have had an overall breeding range of under 50,000 km^2. An Endemic Bird Area (EBA) is an area within which the overlapping breeding ranges of at least two restricted-range species are wholly encompassed. Following the last complete figures (1998), restricted-range species account for some 27% of the world's avifauna, or about 2600 species, and these are restricted to about 220 EBAs, which in turn support roughly 75% of all globally threatened bird species. They are thus areas of high priority for conservation, all the more so as they tend equally to be centres of endemism for other life forms.

Acknowledgements

We should like to thank the Natural History Museum at Tring (Robert Prys-Jones, Mark Adams, Katrina Cook, Alison Harding), the American Museum of Natural History in New York (Paul Sweet, Peg Hart, Mary LeCroy), the Smithsonian Institution, National Museum of Natural History in Washington (James Dean), the Peabody Museum at Yale University (Kristof Zyskowski), the Natuurhistorisch Museum at Leiden (Hein van Grouw), the Muséum National d'Histoire Naturelle in Paris (Eric Pasquet, Jean-François Voisin, Anne Préviato), the Transvaal Museum (Tamar Cassidy), the Australian Museum in Sydney (Walter Boles), the Field Museum in Chicago (David Willard, Mary Hennen), the Bernice P. Bishop Museum in Honolulu (Carla Kishinami), the Zoological Museum at the University of Copenhagen (Jon Fjeldså), the Museum für Naturkunde in Berlin (Jürgen Fiebig, Antje Dittmann) and the Forschungsinstitut und Naturmuseum Senckenberg in Frankfurt am Main (Gerald Mayr).

For help with the preparation of the bibliographies and scientific descriptions, as well as with matters of nomenclature, we are especially grateful to Alison Harding (Natural History Museum at Tring, England), Sharon Touzel and Paul Cooper (Natural History Museum, London), Hans-Ulrich Raake and Martina Rißberger (General & Zoology Library, Museum für Naturkunde, Berlin), Pascal Eckhoff (Ornithology, Museum für Naturkunde, Berlin), Bernd Nicolai (Museum Heineanum, Halberstadt, Germany), Till Töpfer (Museum für Tierkunde, Dresden), Christiane Quaisser (Natuurhistorisch Museum, Leiden), Ulf Johansson (Naturhistoriska Riksmuseet, Stockholm), Storrs Olson (Smithsonian Institution, Washington), Walter Boles (Ornithology Section, Australian Museum, Sydney), Darcy Ogada (Editorial Assistant, Scopus, National Museums of Kenya), Dieter Oschadleus (Bird-ringing Coordinator, SAFRING, Cape Town), Rolf Schlenker (Library, Max-Planck-Institute for Ornithology, Radolfzell), Rory Cooke (State Library of Victoria, Melbourne), Elizabeth Caplice (National Library of Australia, Sydney), Philippa Horton (South Australian Museum, Adelaide), Dietmar Schmidt (Editor, Gefiederte Welt, Backnang, Germany), Carlo Violani (Università di Pavia, Italy), Walter Bock (Columbia University, New York), Steven Emslie (University of North Carolina), Richard Schodde (Chair, Standing Committee on Ornithological Nomenclature), Edward Dickinson (Trust for Oriental Ornithology, Eastbourne, England), Robert Dowsett, Alan Peterson (Zoonomen, Wallawalla, USA), Norbert Bahr, Steven Gregory, Stephen Debus (University of New England, Armidale, Australia), Guy Dutson (Birds Australia), Phil Gregory, Theo Kleefisch and Katja Bräunlich.

We are most thankful for the assistance of many individuals who helped to improve the volume in a wide variety of ways, including by refereeing texts, providing access to

unpublished information and literature, and answering queries. We would like to voice our particular appreciation of the contributions made by Desmond Allen, John Anderton, Richard Banks, Bruce Beehler, David Bigas, Christian Boix, Nicole Bouglouan, Stuart Butchart, Pedro Cardia, Carla Cicero, Pierre-André Crochet, Bob Dowsett, Françoise Dowsett-Lemaire, Guy Dutson, Heidi Fiebig, Jürgen Fiebig, Dick Forsman, Clifford Frith, Dawn Frith, Nick Garbutt, Brian Gill, Jean-Louis Grangé, Robert Gray, Michael Griesser, Peg Hart, Frank Hawkins, Robert Hutchinson, Ian Jamieson, Leszek Jerzak, Gilbert Lachaume, Tim Laman, Mary LeCroy, Anna Motis, Killian Mullarney, Johannes Penner, Richard Porter, Dewi Prawiradilaga, Peter Ryan, Hans Schmocker, Richard Schodde, Edwin Scholes, Jessica Stapley, Paul Sweet, Van Wallach and David Wells. Special thanks go to Robert Ridgely for his revision of the individual maps affecting the Neotropics. We are very fortunate to count on the continued assistance of Normand David in checking all the genus- and species-level taxa for gender agreement, correct spelling and numerous other details. Also, we offer our sincere gratitude to both Normand and Edward Dickinson for having helped us once again with many important consultations on scientific names, their original descriptions, accurate dates, and a host of other important issues. We would like to thank Guy Tudor for entrusting us with his large collection of reference material; warm thanks as well to Michelle le Marchant.

The French, German and Spanish names come from the usual sources, for which we are indebted to Normand David, Einhard Bezzel, Renate van den Elzen, Christoph Hinkelmann, Peter Barthel, Frank Steinheimer and Eduardo de Juana, along with their respective associates.

The individual authors and artists of the volume would like to thank the following individuals and institutions: Tino Aguon, Alexandre Aleixo, Desmond Allen, Sandra Colli dos Anjos, Paul Banko, John Bates, E. Berg, K. David Bishop, W. Boarman, Walter E. Boles, Reed Bowman, David Breininger, the late Richard Brooke, Jerram L. Brown, Bill Busby, James Cadbury, Diego Calderón-Franco, P. Cale, Graeme S. Chapman, Terry Chesser, Darrell Clegg, Ludwig Coetzer, Mario Cohn-Haft, René Corado, Danielle D'Auria, Richard Dean, René Dekker, Scott Derrickson, Edward C. Dickinson, Guy Dutson, Kazuhiro Eguchi, Renate van den Elzen, Heidi Fiebig, Rob Fleischer, Dieter Glandt, Steve Goodman, Shannon J. Hackett, Jürgen Haffer, Martine Hausberger, José ten Have, Frank Hawkins, B. Heinrich, Nell Higgins, Masanao Honda, Pat Hulley, Rob Hutchinson, Mohammad Indrawan, H. James, Gayle Johnson, Jiro Kikkawa, M. Kochert, Teresa Lorenz, Michel Louette, John M. Marzluff, John McCormack, Gabriel B. McCrate, Killian Mullarney, Camilla Myers, Janette Norman, Kevin Omland, David Parkin, John Peter, Town Peterson, A. Piston, Fabíola Poletto, Jean Marc Pons, Kobie Raijmakers, Hajanirina Rakotomanana, Richard Ranft, Marcos Raposo, Van Remsen, Ann Robinson, Scott K. Robinson, Gérard Rocamora, Stan Roth, the late Ian Rowley, Peter Ryan, Roger Safford, Pedro Scherer Neto, Richard Schodde, Ed Scholes, Karl-L. Schuchmann, Frederick Sheldon, Luís Fábio Silveira, José Eduardo Simon, the late Jack Skead, Jill Smith, Soekarja Somadikarta, Walter Sontag, P. F. Stewart, Dan Strickland, Jaynia Tarnawski, Cheryl Tipp, Edson Varga Lopes, Carl Vernon, Jean-François Voisin, Thomas A. Waite, W. Webb, Thomas Webber, Kate Webster, André Weller, David Wells, David Willard and Iain Woxvold, as well as the Alaska Department of Fish and Game, the Australian Museum in Sydney, the British Library Sound Archive, the Celebes Bird Club, the Conselho Nacional de Desenvolvimento Científico e Tecnológico in Brazil, the Departamento de Zoologia da Universidade de São Paulo, the Direction de l'Agriculture et de la Forêt de Mayotte, the Field Museum in Chicago, the Florida Museum of Natural History, the German Academic Exchange Service (DAAD) in New York, the Louisiana State University Museum of Natural Science, the Museu de Biologia Prof. Mello Leitão, the Museu de História Natural do Capão da Imbuia, the Museu Nacional in Rio de Janeiro, the Muséum National d'Histoire Naturelle in Paris, the Seychelles Island Foundation, the Smithsonian Institution, Sunbird Tours, the US Forest Service, and the Zoologisches Forschungsinstitut und Museum Alexander Koenig in Bonn.

As always, we are grateful for the many forms of support and help received from Mª Josep de Andrés, Dolors Buxó, Cam Christie, Marc Duquet, Marta Fenollar, Billy Fordson, Fortunato Frías, Isabel Martínez, Rafael Martínez, Tere Pardo, Mary and Jim Ramsay, Olga Rius, Jamer Rivera, Iván Teba and Aurea Vilalta. Our sincere thanks yet again go to Toni Llobet for this fourteenth instalment of excellent back-cover illustrations.

We are deeply sorry to have to report that one of our authors of the present volume, Ian Rowley, sadly died earlier this year. Ian's place in Australian ornithology is assured, not least for his period as Editor of *Emu*, and for his many books and papers, always written in his hugely readable but authoritative style. Ian and his wife, Eleanor, have been among our most loyal and consistent contributors over many years, starting with the family Cacatuidae way back in HBW4, and including no less than three families in the present volume.It has been both a great pleasure and a privilege to work with them.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family MALACONOTIDAE (BUSH-SHRIKES)

- Small to medium-sized passerines with robust, usually hooked and toothed bill, and long, lax and erectile rump feathers; plumage black, black and white, or boldly patterned mainly in green, yellow or russet and scarlet; several polymorphic.
- 13–25 cm.

- Africa, one species also in southern Arabia.
- Woodland, scrub and forest, often in farmland and gardens; several species in shrubby grassland, thornveld and semi-desert.
- 8 genera, 48 species, 138 taxa.
- 5 species threatened; none extinct since 1600.

Systematics

Relationships among several Old World groups popularly called "shrikes" have always been problematic. Formerly, the bush-shrikes, African birds, were habitually classified within the family Laniidae, as supposedly fairly close relatives of the "true" shrikes (mainly *Lanius*) and of various other genera with a hook-tipped and "toothed" bill. The first rationale for regarding the bush-shrikes as composing a family of their own, distinct from laniids, was made by W. P. Pycraft in 1907, but avian systematists remained conservative in their outlook for many decades thereafter. In 1960, for example, A. L. Rand, in J. L. Peters's *Check-list of Birds of the World*, treated the bush-shrikes as a subfamily, Malaconotinae, within Laniidae, in which he also included, in addition to the true shrikes, two other subfamilies currently treated as full families, namely the helmet-shrikes (Prionopidae) and the peculiar Bristlehead (Pityriaseidae).

In 1971, the family Malaconotidae was formally erected by the authors of *The Birds of Zambia*, C. W. Benson and colleagues, for the genera *Malaconotus*/*Chlorophoneus*, *Tchagra*, *Laniarius*, *Dryoscopus*, *Nilaus* "and perhaps *Laniotur dus*", this group being characterized by its plumage colours and patterns, loud vocalizations, neat nests, small clutches, woodland habitats, gleaning habits and absence of prey-storing larders. Nevertheless, the bush-shrikes were for many years still retained in Laniidae, usually as a subfamily, by some systematists and by many authors of African regional textbooks. In a series of reports on molecular studies in the 1980s, C. G. Sibley and J. E. Ahlquist demonstrated the ancient phylogenetic link between true shrikes, bush-shrikes and several Australasian taxa, including shrike-tits (*Falcunculus*), shrike-thrushes (*Colluricincla*), cuckoo-shrikes (Campephagidae) and crows (Corvidae), arguing that Australia was the origin of shrike-like lineages that in the late Eocene invaded Asia and Africa. In their radical new classification of birds in 1990, these authors, and Sibley and B. L. Monroe, recognized the differences at a higher taxonomic level between true shrikes, bush-shrikes and helmet-shrikes, placing the first in Laniidae, and the second and third as the respective tribes Malaconotini and Vangini in a subfamily, Malaconotinae, along with six other subfamilies including crows, orioles (Oriolidae), drongos (Dicruridae) and monarch-flycatchers (Monarchidae) in a greatly enlarged family Corvidae. Further, Sibley and Monroe placed the peppershrikes (*Cyclarhis*) and the shrike-vireos (*Vireolanius*) with the vireos (*Vireo*) in the New World family Vireonidae, sequencing them between Laniidae and Corvidae, and they united African helmet-shrikes and Madagascan vangid shrikes with African batises (*Batis*) and wattle-eyes (*Platysteira*), as well as with the two south Asian wood-shrikes (*Tephrodornis*), in the tribe Vangini, next to the tribe Malaconotini.

Meanwhile, T. Harris and G. Arnott analysed 90 characters of plumage, morphology, parasites, behaviour and DNA, following which, in their 1988 work *Shrikes of Southern Africa*, they recognized a single family, Laniidae, comprising the three subfamilies Laniinae, Prionopinae and Malaconotinae, the last two more closely allied to each other than to Laniinae. In this arrangement, the Malaconotinae included two more African gen-

The family Malaconotidae is characterized by its plumage colours and patterns, loud vocalizations, neat nests, small clutches, woodland habitats, gleaning habits, and absence of prey-storing larders. With one exception, bush-shrikes are restricted to Africa. Relationships among the six bush-shrikes of the genus Malaconotus *are subject to disagreement. The Fiery-breasted* (M. cruentus), *Monteiro's* (M. monteiri), *Lagden's* (M. lagdeni) *and* ***Grey-headed Bush-shrikes*** *are very alike in appearance and biology. The Grey-headed, Monteiro's and Lagden's Bush-shrikes are parapatric or allopatric, and are best treated as a superspecies.*

[*Malaconotus blanchoti*, Modimolle, Limpopo, South Africa. Photo: Warwick Tarboton]

The tchagras are a fairly well-defined genus of semi-terrestrial, russet-winged bush-shrikes, smaller than Malaconotus *but with a similarly powerful bite. Most tchagras live in open, dry savanna, with coarse grass and thickets of thorn trees. Four species, including the* ***Three-streaked Tchagra****, are sexually monomorphic and somewhat uniform, but a fifth, the Marsh Tchagra* (Tchagra minutus)*, is sexually dimorphic. The Three-streaked Tchagra forms a superspecies with the Brown-crowned Tchagra* (T. australis)*, with which it has hybridized, and the Southern Tchagra* (T. tchagra)*. Two subspecies of Three-streaked Tchagra are recognized.*

[*Tchagra jamesi jamesi*, Negele, Ethiopia. Photo: Ketil Knudsen]

era, namely the diminutive flycatcher-like *Batis* and *Platysteira*. With improving knowledge, especially with regard to communication characteristics, bush-shrikes and true shrikes are currently seen as being sufficiently distinct to be regarded as separate families, with Malaconotidae more generalized than the specialist-foraging Laniidae.

Malaconotid limits, however, remain controversial. In Volume V of *The Birds of Africa*, edited by E. K. Urban and colleagues and published in 1997, the batises and wattle-eyes, together with the White-tailed Shrike (*Lanioturdus torquatus*) and the two shrike-flycatchers, namely the Black-and-white Shrike-flycatcher (*Bias musicus*) and the African Shrike-flycatcher (*Megabyas flammulatus*), were treated as constituting the family Platysteiridae, related only distantly to Malaconotidae. In Volume VI of *The Birds of Africa*, published in 2000, C. H. Fry and colleagues deemed that the latter family embraced the bush-shrikes of the genera *Malaconotus*, in which they included *Chlorophoneus*, and *Telophorus*, the tchagras, which they treated in two genera (*Antichromus* and *Tchagra*), the puffbacks (*Dryoscopus*), the boubous and gonoleks (*Laniarius*) and the Brubru (*Nilaus afer*); thus, it excluded not only the platysteirids, but also the helmet-shrikes (*Prionops*), which were retained in their own family, Prionopidae.

In the present arrangement, the Malaconotidae, the Platysteiridae and the Prionopidae are still treated as three separate families, since they are such distinctively different birds in

A rather small, large-headed, thickset tchagra with a comparatively short, graduated tail and a bill which is shorter and relatively wider than that of its congeners, the ***Marsh Tchagra*** *also differs in its sexual dimorphism and habitat preference. It is a wetland species, commonest in rank growth at the edges of papyrus swamps, marshes and coastal lagoons. But morphologically and biologically, the differences between the Marsh Tchagra and other tchagras are no greater than the differences among species within other malaconotid genera. The male is shown here; the female is similar, but has a striking, well-defined superciliary stripe from the base of the bill to above the ear-coverts.*

[*Tchagra minutus minutus*, Masindi, Uganda. Photo: Pete Morris]

Several bush-shrike species fluff out the rump feathers in territorial and courtship flight displays, a feature brought to extremes by the puffbacks (Dryoscopus). *There are six species. The* ***Black-backed Puffback*** *forms a southern-tropical superspecies with the Red-eyed Puffback* (D. senegalensis). *There is also a northern-tropical superspecies formed by the Northern Puffback* (D. gambensis) *and Pringle's Puffback* (D. pringlii). *And finally, there are two independent forms, Sabine's Puffback* (D. sabini) *and the Pink-footed Puffback* (D. angolensis).

[*Dryoscopus cubla hamatus*, Lebata Camp, Northern Province, South Africa. Photo: Johannes Ferdinand]

the field. The enigmatic White-tailed Shrike, included in Malaconotidae for administrative reasons, is, in fact, closer in its affinities to the batises, a conclusion given strong support by recent studies of molecular systematics by P. Beresford and colleagues. The definitive analyses of shrike characters presented in 2000 by Harris and K. Franklin in *Shrikes and Bush-shrikes* does, however, indicate that platysteirids and prionopids are more closely allied with bush-shrikes than is suggested by field appearances and behaviour. These authors recognize solely the two families Laniidae and Malaconotidae, the second consisting of 18 African and Asiatic genera dealt with in the sequence *Malaconotus*, *Chlorophoneus*, *Telophorus*, *Rhodophoneus*, *Laniarius*, *Dryoscopus*, *Antichromus*, *Tchagra*, *Tephrodornis*, *Megabyas*, *Bias*, *Philentoma*, *Nilaus*, *Lanioturdus*, *Batis*, *Platysteira*, *Dyaphorophyia* and *Prionops*.

The family Malaconotidae, as currently delimited, is restricted almost entirely to Africa. Only the Black-crowned Tchagra (*Tchagra senegalus*), which has a wider range within sub-Saharan Africa than any other bush-shrike, extends into Arabia, where it occurs in Yemen and in the Dhofar province of Oman; it is also the only bush-shrike that ranges north of the Sahara.

If there has been little consensus about family limits, there was formerly even less agreement about generic limits. Several bush-shrike species have, since their initial discovery, been shunted to and fro among four or five of the genera listed above. Currently, however, there appears to be no disagreement over the boundaries of *Laniarius* and *Dryoscopus*, nor about the validity of the monotypic *Nilaus* and *Lanioturdus*. *Laniarius* is discussed in detail below. *Dryoscopus* has six species, all sexually dimorphic, with pied males and brown females, and rather uniform in character. The genus consists of a northern-tropical superspecies composed of the Northern Puffback (*Dryoscopus gambensis*) and Pringle's Puffback (*Dryoscopus pringlii*), a southern-tropical superspecies formed by the Red-eyed Puffback (*Dryoscopus senegalensis*) and the Black-backed Puffback (*Dryoscopus cubla*), and two independent forms, Sabine's Puffback (*Dryoscopus sabini*) of West Africa and the equatorial Pink-footed Puffback (*Dryoscopus angolensis*). The Brubru, in the monotypic genus *Nilaus*, is genetically basal in malaconotid phylogeny. It is arboreal and widespread, with seven little-differentiated subspecies north and south of two distinctive ones; the nest, the white back and the fluffy white rump of the Brubru are features also of the Platysteiridae, and the species may link the two families. Similarly, the enigmatic, monotypic, terrestrial White-tailed Shrike, the sole member of the genus *Lanioturdus* of semi-arid south-west Africa, also links the families, and is often treated in the Platysteiridae, rather than in the Malaconotidae.

The odd Rosy-patched Shrike (*Telophorus cruentus*) of arid north-eastern Africa, Linnaeus's *Lanius cruentus*, was placed in *Tchagra* in E. Mayr and J. C. Greenway's *Check-list of Birds of the World*, in 1960, and for many years thereafter it landed in its own genus, *Rhodophoneus*. It is now thought to be closest to the southern African Bokmakierie (*Telophorus zeylonus*), and is currently treated as congeneric with it. The congeners of these two species, the Gorgeous Bush-shrike (*Telophorus viridis*) and Doherty's Bush-shrike (*Telophorus dohertyi*), are smaller birds

The puffbacks are all sexually dimorphic, with pied males and less contrastingly coloured females. Differing from the glossy bluish-black forehead, hindneck and mantle of the male, the upperparts of the nominate female of the ***Northern Puffback*** *are medium grey or greyish-brown. Where the male's underside is a creamy greyish-white, the female is predominantly rufous. The five races of the Northern Puffback differ mainly in the plumage of females. That of the female of race* erythreae *is notable in that it resembles the plumage of the male, but the upperparts are dark chocolate-brown as opposed to the male's bluish-black.*

[*Dryoscopus gambensis gambensis*, Bauchi, NE Nigeria. Photo: A. P. Leventis]

Laniarius, *containing the boubous and gonoleks, is the most species-rich malaconotid genus, with 19 species. Morphologically, they are strikingly similar, but they vary in plumage colour and pattern. Nine, including the* ***Swamp Boubou****, are white or buff below and black above, and four are entirely black. Six, including the* ***Crimson-breasted Shrike****, are black above and bright scarlet or yellow below. Some are dimorphic in plumage. Biologically the genus is rather uniform, but the species differ in habitat preferences. The Swamp Boubou lives in woody swamps, mangrove and papyrus, the Crimson-breasted Shrike in acacia woodland or thornveld. In 2008, genetic analyses of* Laniarius *species threw conventional wisdom about the systematics and phylogeny of the genus into some disarray, indicating how misleading opinions based on features such as plumage colour and pattern can be, even when they seem to be corroborated by geographical distribution, and by such characters as voice, and even by morphology. Four black-and-scarlet species have been regarded as so closely related as to constitute a superspecies. However, the DNA analysis provided evidence that the Crimson-breasted Shrike represents a much deeper branch than the others, and hence is only distantly related to them; it may be closer to the all-black Sooty Boubou* (L. leucorhynchus) *than to any other congener. The Swamp Boubou has been treated as a race of the Southern Boubou* (L. ferrugineus). *The DNA analyses indicate that this species is indeed closest to* L. ferrugineus, *and to the East Coast Boubou* (L. sublacteus), *the three composing a sister lineage to two more black-and-white (or buff) species, the Tropical Boubou* (L. aethiopicus) *and Turati's Boubou* (L. turatii).

[Above: *Laniarius bicolor sticturus*, Okavango Delta, Botswana.

Below: *Laniarius atrococcineus*, Nylstroom, South Africa. Photos: Warwick Tarboton]

Nearly all taxonomists have believed the four all-black Laniarius *bush-shrikes to be very closely allied, forming a distinctive lineage within the genus. Recent DNA analysis, however, indicates that they represent three branches arising on the* Laniarius *tree trunk at different times, and separated by branches giving rise to other congeners. The* ***Slate-coloured Boubou*** *constitutes the latest branch. The Sooty Boubou* (L. leucorhynchus) *forms a deep branch in the phylogeny; the Mountain Boubou* (L. poensis) *and Fülleborn's Boubou* (L. fuelleborni) *form a later branch, and are not even close enough to each other to compose a superspecies, as was previously thought.*

[*Laniarius funebris funebris*, Tarangire National Park, Tanzania. Photo: Dave Richards]

of montane and lowland forest, and are close enough to form a superspecies. The former is often regarded as consisting of two species, the green-bellied nominate race in western parts of Africa being treated as distinct from the three eastern subspecies, which have the belly yellow. *Tchagra* itself is a fairly well-defined genus of middle-sized, semi-terrestrial, russet-winged, open-country bush-shrikes. Four of the tchagras are sexually monomorphic and somewhat uniform, but a fifth, the Marsh Tchagra (*Tchagra minutus*), is sexually dimorphic and, mainly for that reason, has sometimes been awarded its own genus, *Antichromus* or *Bocagia*.

In Peters's *Check-list of Birds of the World*, the genus *Telophorus* comprised ten species, six of which have frequently been separated into *Chlorophoneus*. One of the six, the Endangered and little-known Mount Kupe Bush-shrike (*Chlorophoneus kupeensis*), is atypical, intermediate in character between *Chlorophoneus* and *Malaconotus*, and perhaps should be removed into a genus of its own. In fact, *Chlorophoneus* has been united with *Malaconotus* in several systematic works, including C. M. N. White's *A Revised Check List of African Shrikes, Orioles, Drongos, Starlings, Crows, Waxwings, Cuckoo-shrikes, Bulbuls, Accentors, Thrushes and Babblers*, published in 1962, *An Atlas of Speciation in African Passerine Birds* by B. P. Hall and R. E. Moreau, in 1980, *A Contribution to the Distribution and Taxonomy of Afrotropical and Malagasy Bird Species* by R. J. Dowsett and F. Dowsett-Lemaire, in 1993, and the sixth volume of the handbook *The Birds of Africa*, published in 2000.

Differences between *Chlorophoneus* and *Malaconotus* are outweighed by their similarities. The former, without *Chlorophoneus kupeensis*, are small-bodied and slender-billed birds, whereas the latter are large, being two to three times as heavy, and robust-billed; juveniles of *Chlorophoneus* are barred, while those of *Malaconotus* are plain; and the vocalizations of the two genera differ somewhat, although they resemble each other more than either resembles the voices of other bush-shrikes. Both groups, however, are colourful, several species being polymorphic in plumage, the colours varying geographically in an intriguingly congruous manner. It is hardly surprising that they have all been regarded as congeneric, yet an analysis of mitochondrial DNA by J. Fuchs and co-workers in 2005 suggests that the main malaconotid genera fall into two deeply divided clades, with *Malaconotus sensu stricto* in one clade and *Chlorophoneus* in the other. The first clade contains *Malaconotus*, *Tchagra*/*Antichromus* and *Dryoscopus*, and the second *Telophorus*, *Chlorophoneus* and *Laniarius*. The same study also figures a maximum-likelihood tree for nuclear myoglobin, which gives similar results except that *Dryoscopus* falls into the second clade, close to *Laniarius*. A more recent cladistic analysis of both nuclear-DNA and mitochondrial-DNA sequences of the main genera except *Malaconotus*, undertaken by B. Nguembock and colleagues in 2008, indicates much the same, the resulting clades being *Tchagra* and *Dryoscopus* on the one hand and, on the other,

In 1988, a strange bush-shrike was found at Bulo Burti, in Somalia. In 1991, it was described as a new species, Laniarius liberatus, *the "Bulo Burti Boubou". Controversy about its taxonomic status continued; was it an aberrant Tropical Boubou* (L. aethiopicus), *or perhaps a hybrid between the* ***Somali Boubou*** *and the Red-naped* (L. ruficeps) *Bush-shrike? In 2008, DNA analysis of the bird's moulted feathers settled the question. It was practically identical to, and conspecific with, the Somali Boubou, constituting just a well-marked morph. The Somali Boubou is a recently recognized species, previously treated as a subspecies of the Tropical Boubou.*

[*Laniarius erlangeri*, Bulo Burti, Somalia. Photo: Ed Smith]

The Chlorophoneus *bush-shrikes are mostly small-bodied and slender-billed. The Many-coloured* (C. multicolor) *and Black-fronted Bush-shrikes* (C. nigrifrons) *are highly polymorphic, and form a superspecies. The* ***Olive Bush-shrike*** *and Bocage's Bush-shrike* (C. bocagei) *seem to be closely allied. Five subspecies of Olive Bush-shrike are recognized. The nominate race occurs in two colour morphs, which may be two formerly allopatric races beginning to intergrade. The olive morph differs from the buff morph, shown here, in having the whole of the upperside bright olive-green, lores and supercilium greenish-yellow, the belly and undertail-coverts greenish-yellow, and the flanks bright green.*

[*Chlorophoneus olivaceus olivaceus*, Plettenberg Bay, South Africa. Photo: Geoff McIlleron]

Telophorus, *Chlorophoneus* and *Laniarius*. It would appear, therefore, that *Malaconotus* and *Chlorophoneus* are not synonymous with each other after all, nor even are they closely related.

There is little agreement about relationships among the six *Malaconotus* bush-shrikes. They have been regarded variously as a single polymorphic species, as a single superspecies, and as various combinations of superspecies and independent species. With the exception of the savanna-woodland Grey-headed Bush-shrike (*Malaconotus blanchoti*), all of them inhabit forest. The Grey-headed, Fiery-breasted (*Malaconotus cruentus*), Monteiro's (*Malaconotus monteiri*) and Lagden's Bush-shrikes (*Malaconotus lagdeni*) are very alike in appearance and biology; the restricted-range Green-breasted (*Malaconotus gladiator*) and Uluguru Bush-shrikes (*Malaconotus alius*) are more distinctive, at least in coloration. Of the four lookalikes, the Grey-headed, Monteiro's and Lagden's Bush-shrikes are parapatric or allopatric, and are therefore best treated as constituting a superspecies; the Fiery-breasted Bush-shrike, being sympatric with Lagden's Bush-shrike, should be regarded as an independent species, even though the two are alike vocally. The little-known Monteiro's Bush-shrike has populations in north-western Angola and western Cameroon, although the latter may prove to be a colour variant of a congener, the Fiery-breasted, Grey-headed and Green-breasted Bush-shrikes having been proposed as candidates. Most or all Fiery-breasted Bush-shrike populations vary in the degree of orange, red or scarlet infusion in the yellow underparts, and the species may yet be found to be polymorphic, rather than polytypic.

Without the atypical Mount Kupe Bush-shrike, the genus *Chlorophoneus* consists of four forest-dwelling species and one savanna-woodland species. Bocage's Bush-shrike (*Chlorophoneus bocagei*) and the Olive Bush-shrike (*Chlorophoneus olivaceus*) seem to be closely allied, and the highly polymorphic Many-coloured (*Chlorophoneus multicolor*) and Black-fronted Bush-shrikes (*Chlorophoneus nigrifrons*) form a superspecies and are often regarded as conspecific. The savanna-inhabiting Orange-breasted Bush-shrike (*Chlorophoneus sulfureopectus*) is probably quite closely related to the Many-coloured and Black-fronted Bush-shrikes, although its plumage bears a greater resemblance to that of the much larger Grey-headed Bush-shrike, fully sympatric with it throughout Africa's savanna woodlands.

There is an extraordinary regional parallelism in colouring between the large, mainly monomorphic *Malaconotus* species on the one hand and the small, polymorphic *Chlorophoneus* bush-shrikes on the other. One species in each genus inhabits savanna woodlands; these are the large Grey-headed Bush-shrike and the small Orange-breasted Bush-shrike, and their plumages are strikingly similar. In lowland forests, the underparts of the large Fiery-breasted Bush-shrike, in *Malaconotus*, vary in any one population, and they vary also regionally. Some individuals of this species in Sierra Leone and many in Cameroon have the chin orange-yellow, the throat and breast bright orange-red, the upper belly orange, and the lower belly, flanks, thighs and undertail-coverts bright yellow; the population on Mount Nimba, in Liberia, is rather uniform, with an orange suffusion in the underparts paler and less extensive. In south-western Cameroon the breast is sometimes yellow, and half of the Fiery-breasted Bush-shrike population around Kumba has the breast yellow-orange and the other half has it red-orange; most of those in Gabon and DRCongo have a bright orange chin and throat, a red-orange or scarlet breast, and a yellow belly and undertail-coverts. The small, highly polymorphic Many-coloured Bush-shrike, representing the genus *Chlorophoneus*, has much the same geographical distribution as that of the Fiery-breasted Bush-shrike and looks much like the latter, except that it possesses a black mask and dark eyes. It has five main colour morphs and six intermediate types occurring in varying proportions throughout its range, with a tendency for the colour of the underparts of the predominant morph in a particular locality to match that of Fiery-breasted Bush-shrikes there. Moreover, Many-coloured Bush-shrikes in north-west Angola seem to be largely yellow-breasted, matching the *Malaconotus* species, Monteiro's Bush-shrike, in the area. It is, in fact, quite possible that Monteiro's Bush-shrike is itself a colour variant of the Fiery-breasted Bush-shrike, rather than an allospecies of the Grey-headed Bush-shrike.

Black-fronted Bush-shrikes, in *Chlorophoneus*, are mostly red-breasted in Kenya and northern Mozambique and mostly orange-breasted in Zambia. There are no *Malaconotus* species in these countries but, in eastern Tanzania, Uluguru Bush-shrikes occur in the mountains of that name. They have greenish-yellow underparts, and nearly all of the Black-fronted Bush-shrikes in Tanzanian lowlands are of either the yellow or the buff morph.

The relatively small-billed ***Doherty's Bush-shrike*** *forms a superspecies with the Gorgeous Bush-shrike* (Telophorus viridis). *Both have conventionally been grouped in* Chlorophoneus, *but studies of nuclear and mitochondrial DNA support their placement in* Telophorus, *albeit closer to* Chlorophoneus *and* Laniarius *than the clade formed by* Malaconotus, Dryoscopus *and* Tchagra. *Doherty's Bush-shrike occurs in two colour morphs, the crimson, shown here, and the rarer yellow, in which the crimson face is replaced with bright yellow. The remaining two* Telophorus *species are larger and heavier. The Rosy-patched Shrike* (T. cruentus) *once had its own genus but is now thought to be closest to the Bokmakierie* (T. zeylonus).

[*Telophorus dohertyi*, Mount Elgon National Park, Kenya.
Photo: Günter Ziesler]

Olive Bush-shrikes and Doherty's Bush-shrikes, in the respective genera *Chlorophoneus* and *Telophorus*, are both dimorphic in plumage; no *Malaconotus* species occurs in either of their separate ranges, and they are not implicated in colour convergences. Hall and colleagues analysed the situation in 1966; they concluded that parallelisms are due to the fact that *Malaconotus* and *Chlorophoneus* are very closely allied and share genomes that have expressed themselves similarly in phenotypes under similar selection pressures in similar environments, and that the essentially monomorphic *Malaconotus* species may have derived directly from ancestral stock that was polymorphic. It should be pointed out here that *Malaconotus* would contain one dimorphic species if Monteiro's Bush-shrike proved to be a colour morph of the Fiery-breasted Bush-shrike, as Hall and colleagues proposed. As for the genetic mechanisms involved, these scientists found polymorphism in *Chlorophoneus* to be accounted for by three genes, each with two alleles. They discussed the possibility that colour patterns of *Malaconotus* species might have a selective value in warning potential predators that these robust bush-shrikes with a strong, predatory bill are well able to defend themselves, and that *Chlorophoneus* species have gained protection from the same field of predators by evolving mimicry of their large, better-protected sympatric relatives. This is the well-understood principle of aposematic coloration, whereby vulnerable mimics converge evolutionarily upon warningly patterned models. Unfortunately, the principle demands that mimics be much rarer than models, which is not the case in this instance; the convergence could prove to be an example of some other form of mimicry, such as that of *Accipiter* sparrowhawks by *Cuculus* cuckoos discussed by N. B. Davies and J. A. Welbergen in their 2008 paper. There remain other difficulties, too, not least that, as now appears to be the case, the two genera are not at all closely related within the family. Knowledge of the biology of *Malaconotus* and *Chlorophoneus* species has not improved greatly since the 1966 review, and an understanding of their convergences is unlikely to be advanced until field research reveals far more about intraspecific and, particularly, interspecific ecological, social and communication attributes.

Laniarius is by far the largest malaconotid genus, with 19 species. Morphologically, these are strikingly similar, but they vary in plumage colour and pattern. Four are entirely black, six are black above and bright yellow or scarlet below, with or without a coloured crown and a white wingstripe, and the remainder are white or buffy below and black above, with or without a white wingstripe. Some are dimorphic in plumage. Biologically, too, the genus is rather uniform, but the species differ in habitat preferences, living in forest, mesic woodland or thornbush canopy or lower levels, with some almost terrestrial, and in woody swamps, mangrove and papyrus (*Cyperus papyrus*). Most authorities have grouped the majority of these species into a number of superspecies, the limits of nearly all of them being a matter of opinion. In 2008, genetic analyses of *Laniarius* species by Nguembock and co-workers threw conventional wisdom about the systematics and phylogeny of the genus into disarray. Studying two mitochondrial genes and a nuclear-DNA intron sequence in 16 species and 34 subspecies, the researchers drew up three broadly similar phylogenetic trees, using five other malaconotid genera as outgroups. The results include the following unexpected revelations, which indicate uncomfortably how misleading appraisals of features such as plumage colour and pattern can be, even when they seem to be corroborated by geographical distribution and by such characters as voice and morphology.

Nearly all taxonomists have believed the four all-black *Laniarius* bush-shrikes to be very closely allied, forming a distinctive lineage within the genus, but it now seems that they represent three branches arising on the *Laniarius* tree trunk at different times and separated by branches giving rise to other congeners. The Sooty Boubou (*Laniarius leucorhynchus*) forms a deep branch in the phylogeny; the Mountain Boubou (*Laniarius poensis*) and Fülleborn's Boubou (*Laniarius fuelleborni*) form a later branch and are not even close enough to each other to compose a superspecies, although hitherto generally thought to do so; and the Slate-coloured Boubou (*Laniarius funebris*) constitutes a still later branch. A branch arising from the trunk between the older *poensis–fuelleborni* lineage and the more recent *funebris* carries two Horn of Africa endemics, the Red-naped Bush-shrike (*Laniarius ruficeps*) and the newly recognized Somali Boubou (*Laniarius erlangeri*).

Four black-and-scarlet species have been widely regarded as being so closely related as to constitute a superspecies, to which the Yellow-breasted Boubou (*Laniarius atroflavus*) has often been added. Nguembock and colleagues, however, have provided

*The **Brubru** is placed in the monotypic genus* Nilaus. *Its nest and some plumage features are very like those of the batises* (Batis), *but many aspects of its behaviour are typical of Malaconotidae, and the Brubru may link the two groups. Along with Pringle's Puffback* (Dryoscopus pringlii), *at 12·5–15 cm and 13–27 g it is among the smallest of the malaconotids. The Brubru occurs in a wide range of habitats, from the canopy of broadleaf woodland to flat-topped acacia woods, and scrub in arid environments. In Botswana, it occurs in 11 out of 17 woodland types. It is widespread, with seven little-differentiated subspecies north and south of two distinctive ones. Brubrus have thick rump feathers, speckled black and white, but do not fluff them out.*

[*Nilaus afer massaicus*, Chyulu Hills, Kenya. Photo: Morten Strange]

strong evidence that the Crimson-breasted Shrike (*Laniarius atrococcineus*) represents a much deeper branch than the others and hence is only distantly related to them; in fact, it may be closer to the Sooty Boubou than to any other congener. Genetically, the Yellow-breasted Boubou is quite closely allied to the Papyrus Gonolek (*Laniarius mufumbiri*), the two being sisters to the superspecies consisting of the Yellow-crowned (*Laniarius barbarus*) and Black-headed Gonoleks (*Laniarius erythrogaster*). In each pair, one species is yellow-crowned and the other is black-crowned, invalidating the taxonomic significance of that particular character. Similarly, the presence or absence of a white stripe in the black upperwing in this lineage in the Tropical Boubou (*Laniarius aethiopicus*) cluster, as well as in the genus *Dryoscopus*, is of little or no taxonomic value.

Among a group of boubous with black upperparts and white or buff underparts, all except one, Turati's Boubou (*Laniarius turatii*), have a long white stripe in the black wing. They are the wide-ranging Tropical Boubou, extending in several races from Senegal east to Eritrea and north-western Somalia, and south to central Angola and northernmost South Africa; the Southern Boubou (*Laniarius ferrugineus*), with six races in southern Africa, the Tropical and Southern Boubous being parapatric and intergrading where they meet in the Limpopo valley; Turati's Boubou in Guinea-Bissau, Guinea and Sierra Leone, parapatric with the Tropical Boubou; and the Swamp Boubou (*Laniarius bicolor*), with three subspecies along the mangrove coasts from Cameroon south to Angola, and inland through the valleys of the River Cunene and River Cubango into Zambia, Namibia and Botswana. These four are closely related, forming one lineage or clade, and often thought of as composing a single superspecies; the clade is sister to a not very closely allied clade consisting of Lühder's Bush-shrike (*Laniarius luehderi*) and its two circumscribed allospecies, Braun's (*Laniarius brauni*) and the Gabela Bush-shrikes (*Laniarius amboimensis*). A surprising find is that the species named as the East Coast Boubou (*Laniarius sublacteus*), embedded in the range of the Tropical Boubou and hitherto held to be a race of it, is in fact more closely related to the Southern Boubou, although not so closely as to be conspecific with it. The East Coast Boubou has a wholly black morph, but the Tropical and Southern Boubous do not. Remarkably, a single specimen from the Arabuko-Sokoke Forest, well within the range of the East Coast Boubou, appears to be genetically very closely related to Turati's Boubou, found on the other side of the continent.

A further revelation is that a poorly known population in south-east Somalia which has been widely regarded as a race of Tropical Boubou is, in fact, only distantly related to the younger "Tropical Boubou complex", to the Lühder's Bush-shrike superspecies, and to the four species making up the "Yellow-crowned Gonolek group". Named the Somali Boubou and el-

*The **White-tailed Shrike**, the sole member of the genus* Lanioturdus, *has a plumage pattern and nest strongly reminiscent of batises* (Batis); *it also shares some structural characters, like jaw musculature, with both batises and wattle-eyes* (Platysteira), *and may belong with them in the family Platysteiridae, rather than in Malaconotidae. A largely terrestrial forager, the White-tailed Shrike has long legs, where those of the other malaconotids are of medium length. Small for a bush-shrike, at 14–15 cm and 23·5–45 g, it has a large head which can appear crested, and a short tail. The sexes are alike, the male perhaps fractionally larger. Its rump feathers and uppertail-coverts are long and fluffy*

[*Lanioturdus torquatus*, Etosha National Park, Namibia. Photo: Peter Craig-Cooper/ VIREO]

Bush-shrikes are retiring birds which skulk in undergrowth, on shady ground beneath it, and within canopy foliage. They are rarely observed in the open for any length of time, and little appears to have been recorded of aspects such as comfort behaviour, preening, scratching, water-bathing and dust-bathing. The ***Southern Boubou*** *normally keeps low down in dense, woody vegetation, but this one has come into the open to sunbathe. Some boubous break their generally secretive habits around human dwellings, hopping around the edges of sunny lawns in leafy suburbs.*

[*Laniarius ferrugineus ferrugineus*, Nature's Valley, Western Cape, South Africa. Photo: Peter J. Ginn]

evated to species rank as *Laniarius erlangeri*, its closest relative is evidently another rather poorly known Horn of Africa species, the Red-naped Bush-shrike. The pair compose a deep branch or clade between the older black boubous *L. poensis* and *L. fuelleborni* and the younger black *L. funebris*; interestingly, the Somali Boubou has an all-black morph.

In 1988, a strange bush-shrike was found at Bulo Burti (Buulobarde), in Somalia. It was caught, taken to Europe, and returned to Somalia, where it was released into Balcad Nature Reserve, near Mogadishu; it was not seen again. In 1991, it was described as a new species, *Laniarius liberatus*, the "Bulo Burti Bush-shrike" or "Bulo Burti Boubou". This promoted lengthy debate on the propriety of naming a taxon without the existence of a museum type specimen, as well as controversy about its taxonomic status. Was this bird an aberrant Tropical Boubou, or perhaps a hybrid between the Somali Boubou and the Red-naped Bush-shrike? Several works, including *The Birds of Africa* volume VI and *Shrikes and Bush-shrikes*, continued to treat it as a valid species, but the molecular-genetic analyses by Nguembock and colleagues in 2008 indicate otherwise. These researchers, having analysed DNA extracted from the bird's moulted feathers, show emphatically that the Bulo Burti Bush-shrike was not a hybrid but was, perhaps surprisingly, almost identical to and conspecific with the Somali Boubou.

Morphological Aspects

In the majority of structural respects, malaconotid shrikes are somewhat unexceptional passerines. They vary in size from Pringle's Puffback and the Brubru, at only about 15 cm in length and 15–30 g in weight, up to the members of the genus *Malaconotus*, the largest of which is the Green-breasted Bush-shrike, measuring up to 28 cm in length and to 100 g in weight. Most species weigh about 40 g.

In the field the smaller bush-shrikes do not look particularly strong, although some are rather bull-headed, and in the hand they do not feel especially robust or full of fight. They have the build of a large *Sylvia* warbler and, like the latter, they creep about in vegetation. So, too, do the larger species, which are, however, decidedly bull-headed, with a heavy, black, hooked-tipped bill much like that of *Lanius* shrikes in shape, with a notch in the cutting edge of the upper mandible just behind its tip. Tchagras and, particularly, *Malaconotus* bush-shrikes have a powerful bite, but the bite of *Dryoscopus* and *Chlorophoneus* species is weaker, as befits birds with bills and eating habits more similar to those of a *Turdus* thrush than those of a shrike. In *Malaconotus*, the bill, measured from its tip to the corner of the mouth, is about the same in length as the rest of the head. All of these species have a row of rictal bristles, generally four, on each side of the gape, longest and strongest in *Malaconotus*, which also have small nasal bristles. Observations on the function of rictal bristles were made by M. Dyer, who fed large grasshop-

This ***Tropical Boubou*** *has just emerged from bathing. Usually keeping to the cover of dense thickets, elephant grass, tangled creepers or the unkempt hedges of farms and gardens, Tropical Boubous are inquisitive and can become quite confiding, coming into the open in large gardens and around game lodges. They also emerge after the rain to forage in roadside drains or wet silt along paths. Bush-shrikes live in pairs throughout the year, in territories which they defend by singing and displays. They fly reluctantly, travelling short distances low over the ground, with fast wing-flapping until the bird is about to alight, or fluttering briefly into the air in pursuit of an insect.*

[*Laniarius aethiopicus major*, Karatu, Tanzania. Photo: Anabel Harries]

pers of the genus *Acanthacris* to a captive Black-crowned Tchagra. These grasshoppers have formidable-looking tibial spines on the hind legs and, when the shrike seized an insect, the legs invariably struck out at the bird's face but were deflected away from its eyes by the stiff rictal bristles.

The neck of the Malaconotidae is short. Lühder's Bush-shrike and probably several of its relatives have the neck skin thickened and distensible, which is likely to be an adaptation for inflation of the neck when the bird calls. The wings are rounded and the primaries curved, with projections of only 10–20 mm beyond the tips of the folded secondaries, while the tail is mainly of medium length, narrow, and rounded or graduated. The tail of the White-tailed Shrike is very short, but this species, as mentioned above (see Systematics), may not be a malaconotid at all but, rather, a terrestrial platysteirid.

The legs of the White-tailed Shrike are long. Those of the remainder of the family are of medium length, not so strong as might be expected of these semi-predatory birds, many of which are quite terrestrial. The feet are scutellate, with the tarsi booted or sparsely scutellate; in the case of the Brubru, another taxonomically enigmatic bird, the pattern of scutellation is akin to that found in helmet-shrikes. The members of the genera *Chlorophoneus* and *Telophorus* have the toes somewhat fused at their bases. Relatively little variation is apparent in the colour of the bare parts of malaconotids. The legs are brownish grey-black in all except one species, the Pink-footed Puffback, which, for some odd reason, has pink or violet legs and feet. So far as is known, the palate is black in all malaconotid species except for the Mount Kupe Bush-shrike, in which it is orange or yellow. The iris of most bush-shrikes is blackish or dark reddish-brown, but it is yellow or pale bluish-grey in all except one of the *Malaconotus* species, red in four out of the six species of puffback, white in the Black-headed Gonolek, and pale yellow in the Papyrus Gonolek and the White-tailed Shrike. The single exception in *Malaconotus* is the Uluguru Bush-shrike, which has dark reddish-brown eyes, rather than pale blue-grey or yellow ones. In the Pink-footed Puffback, the edge of the sclerotic membrane is bright blue and the rim of the eyelids is dusky, tinged with red. Crimson-breasted Shrikes have greyish-brown eyes with a narrow ring of pale violet, whereas Brown-crowned (*Tchagra australis*), Three-streaked (*Tchagra jamesi*) and Black-crowned Tchagras have purplish-brown eyes with a ring of tiny silvery dots surrounding the pupil.

Malaconotid plumage is a little soft to the touch, but lies close against the body. The word *Malaconotus* can be translated as "soft-backed". Aside from the extravagant colours and sharply defined patterns of many of the species, the most notable feature of the family is the feathers of the lower back and rump, which are, in most genera, full, long, soft and fluffy and can be erected or, at least, fluffed out. Several species fluff out the rump feathers in territorial and courtship flight displays, a feature brought to extremes by the puffbacks. Black-backed Puffbacks, for instance, have a striking, bouncy display-flight during which the rump feathers are puffed out into a dense white hemisphere, about the size of a golfball, above the back; alighting in vegetation, males expand the puff ever further, to the extent that it almost envelops the wings. Brubrus have thick rump feathers which are speckled black and white, but they do not fluff them out.

Habitat

In brief, bush-shrikes are birds of woody and leafy vegetation. Being a large family with a good number of moderately diversified genera almost entirely restricted to Africa, the Malaconotidae could be expected to occupy most of the many distinct woody habitats that the continent provides, and that is, in fact, pretty much what they do. Some species live in lowland tropical rainforest, where they skulk in the gloomy understorey and among foliage in undergrowth along the forest's borders or in secondary growth springing up along paths and the edges of windfall gaps, foraging near the ground or, often, on it. They utilize middle and high forest strata, too, and a few species regularly occur in the canopy, where they seldom venture out of the leafiest parts and can be difficult to observe. Malaconotids thrive equally well in wet and mesic montane vegetation, including stands of bamboo and dense woods and scrub with *Hagenia*, *Podocarpus*, juniper (*Juniperus*), olive (*Olea*) and *Philippia* heaths, up to altitudes of 3385 m in Cameroon, 3000 m in East Africa and 2000 m in southern Africa.

Most members of the family are found outside the rainforest zone proper, being inhabitants of the gallery forests that flourish along watercourses and perennial seepages in savannas and in

Both sexes of puffbacks can erect the long, soft, fluffy feathers of the rump to look something like a ball. This is a female ***Black-backed Puffback****, separated from the male by the less intensely black upperparts, creamy rather than snowy white underparts, and greyish rump with shorter feathers than the male's. In the striking, bouncy display-flight, used in defence of territory as well as in courtship, the rump feathers are puffed out into a dense white hemisphere, about the size of a golfball. On alighting, the males expand the puff even further, to the extent that it almost envelops the wings, while the female clicks her bill and occasionally puffs her feathers.*

Several kinds of bush-shrike sing in duet, either almost synchronously or antiphonally. One member of a pair answers its mate, perhaps some distance away in the forest. Duetting is best developed in the boubous and gonoleks in the genus Laniarius, *with the responses given after an extremely short time lapse. The male* ***Black-headed Gonolek*** *gives a loud, resonant, bell-like, disyllabic whistle, "hweeu", which the female answers after 0·125–0·160 seconds with a hiss or short, rasping "zeeer", the combined "hweeuzeeer" sounding like the song of a single bird. A pair may often have a number of different duet songs. In Yellow-crowned Gonoleks* (L. barbarus), *it appears that either sex can whistle "hweeu" or rattle "kkkkk" at will, and either can initiate the duet.*

[*Laniarius erythrogaster*, Queen Elizabeth National Park, Uganda. Photo: Ketil Knudsen]

drier savanna woodlands. There they skulk in thick growth, foraging often only a metre or two above the soil; they can still be difficult to see, even though territorial individuals give away their presence by repeatedly calling. Many species are common in open, broadleaf woodlands as typified the southern-tropical miombo (*Brachystegia*), mopane (*Colophospermum*) and gusu (*Baikiaea*) formations, where the birds are often in leafy or thick woody growth such as the thickets growing around termite (Isoptera) mounds. Most tchagras live in even more open situations, in dry wooded savannas with underlying coarse grass and stands or thickets of acacia (*Acacia*) and other thorn bushes. In south-western Africa, the largely terrestrial White-tailed Shrike inhabits leadwood (*Combretum imberbe*), mopane and miombo woods, but also semi-arid savanna scrub on rocky hillsides. Rosy-patched Shrikes are the most desert-adapted of all, living in arid thornbush and hot, sandy coastal plains in north-eastern Africa, where they keep to the densest cover available, such as acacia and aloe (*Aloe*) scrub in lava-fields and dry wadis. Similarly, Red-naped Bush-shrikes in the Horn of Africa inhabit semi-desert thorn-scrub.

At the other extreme, three bush-shrikes are thoroughly water-dependent. The Papyrus Gonolek is confined to the interior of swampy papyrus beds, either in pure stands or in areas of mixed grass–papyrus and a few woody shrubs. The Swamp Boubou is a bird of river floodplains and choked streams, living in dense growth of reeds, papyrus and water figs (*Ficus*), as well as in riverside bushes and gardens; in Cameroon, it inhabits mangrove thickets growing on muddy, tidal shallows. Third, the Marsh Tchagra is commonest in rank growth at the edges of papyrus swamps, marshes and coastal lagoons, although it also occurs in watered sugar-cane (*Saccharum*) and maize (*Zea mays*) fields, tree plantations and abandoned cultivation.

In many regions, two or more congeneric bush-shrike species live sympatrically. In such instances, they generally differ somewhat in the environments which they occupy, although their habitats may also overlap. For example, both the Brown-crowned and Black-crowned Tchagras, regular species throughout Zimbabwe, occur widely there in undifferentiated drier savannas with light thicket cover, obtaining much of their food on the ground. The Black-crowned Tchagra, however, is perceptibly more arboreal and tends to replace its congener in miombo woodland; the Brown-crowned Tchagra predominates in drier situations.

On the whole, bush-shrikes seem to be moderately adaptable, taking to farmland, rural and town gardens, and exotic wattle (*Acacia*), gum (*Eucalyptus*) and coffee plantations wherever there is suitably dense ground cover. It is a tolerance of diverse environments that has enabled the Black-crowned Tchagra to live in a rich variety of natural woodlands and climates, as well as in anthropogenic situations, throughout its huge range in north-western and sub-Saharan Africa and southern Arabia.

General Habits

Bush-shrikes are retiring birds that skulk in undergrowth, on shady ground beneath it and in canopy foliage, and they do not readily show their gorgeous colours, at least to human observers. Tchagras live more in the open and sometimes perch on bushtops or forage on bare soil, where they can be watched for a few minutes, and in leafy suburbs some boubous hop around at the edges of sunny lawns. Except for White-tailed Shrikes, which form small flocks in winter, the members of this family are not gregarious. They live throughout the year in pairs, in territories in forest, woodland, thornveld and large gardens, and they defend the territory from incursion by neighbouring pairs by means of loud singing accompanied by branch-top posturing, which is still largely hidden from human view. Up to 15 Black-backed Puffbacks, mostly juveniles, have been seen together in the treetops, noisily displaying and chasing, but such observations are exceptional.

All malaconotids nest as solitary pairs, the offspring of which disperse away from the parental territory within a few months of fledging. So far as is known, co-operative breeding, with multiple adults tending the nest, is not practised by any member of the family, nor are any bush-shrikes migrants which form visible aggregations when on the move. They are, on the contrary, reluctant fliers. The flights are generally short and low over the ground, and a little heavy, the wings flapping fast until the bird is about to alight, or they consist of flapping followed by a rapid glide.

The territorial song of the ***Rosy-patched Shrike*** *is a whistled duet between two males, or a male and a female. It is initiated with the male's high-pitched "tzee" or "twee-u" or "tzwee-wee" notes, immediately answered by the female with slightly lower "ter-ee" or "tzee-ur" notes, the two then alternating indefinitely. Calling birds duet monotonously for long periods from the top of a bush, perching out in the open, or with only the head visible. Two pairs may duet together, the males only a few centimetres apart. Several functions of duetting have been proposed. The main ones are maintaining long-range contact between mates out of sight of each other in dense undergrowth; promoting mutual mate-guarding; and joint advertising and defence of the lifelong territory of the pair. A study of 18 pairs of Tropical Boubous* (Laniarius aethiopicus) *suggested additional functions. Using playbacks to simulate intrusions into the pairs' territories, the study's authors deduced that duetting serves also as a post-conflict display to advertise social-dominance "victories", in disputes with neighbouring boubous at the territorial interface. Sixteen of the18 pairs stood their ground when confronted with sound recordings of strangers' duets, eleven of them breaking into victory duets as soon as the recordings were switched off. Victory songs are longer and louder than other types of duet, and can be heard across two territories, or throughout an area of the extent of about 25 football pitches. Females responded to recordings of a solo male by beginning to duet, but the male of the pair started to sing in near-synchrony, which the researchers interpreted as trying to jam the signal from an intruding competitor.*

[*Telophorus cruentus hilgerti*, Djibouti. Photos: Roland Seitre]

*The male song of the **White-tailed Shrike** is a mix of a high-pitched, crescendo whistle, and an abrupt liquid "tewp". The female song consists of low-pitched, discordant sounds given at irregular intervals, synchronously with the male's. One 25-second male song consisted of three, one and six whistles alternating with one to ten "tewp" notes, separated by variable-length pauses; the female uttered five "tchzrr" notes, interpolated only with the "tewp" calls. Most or all bush-shrikes also loudly snap or click the bill, or perhaps the tongue, when excited or alarmed; and snap or "frip" the wings in flight, with a noise like a person snapping the middle finger against the thumb, several times in a second.*

[*Lanioturdus torquatus*, Namibia.
Photo: Michael Gore]

Fifty years ago, V. G. L. van Someren, in his book *Days with Birds*, gave descriptive accounts of several Kenyan malaconotid species, and these serve well to give a rounded impression of the general deportment of the family. Writing of the "Pied Bush Shrike", now known as the Tropical Boubou, he stated that "These birds hunt for food by creeping and hopping about among heavy tangled bush, often searching the ground for insects that lurk in leaf debris and moss. When on the ground they stand with legs at full length, tail slightly raised above the wing tips, and body feathers drawn close. They may turn a leaf or a bit of bark if they have seen an insect disappear under it. They just hop, disturbing the insects as they move [and] may sometimes come out of the bush and hunt in the side drains of a road or the silt along a path after heavy rain. They are secretive and skulking; if one does see them momentarily in the open, they immediately take cover."

Perhaps it is not surprising that so little appears to have been observed of such habits as comfort behaviour, preening, scratching, water-bathing and dust-bathing, pellet regurgitation and roosting. A few species have been seen to drink. Most of their diet of insects and small vertebrates is obtained by searching, creeping through undergrowth or hopping over the ground and snatching any suitable animal encountered. Bush-shrikes

Tchagras are middle-sized bush-shrikes, only one-third to half the weight of Malaconotus *species, but with a fairly heavy bill, and they take much the same range of prey as the larger birds. The **Black-crowned Tchagra**, because it is an open-country bird with a vast range, is one of the best-known bush-shrikes. It captures most of its prey on the ground, or in low bushes, where it creeps about while gleaning stems and lower branches for insects. Hops about under dense growth around the bases of trees and bushes, flicking aside debris, pulling apart dung, scratching at soil, and making small jumps to snatch insects from overhead leaves. Prey is mostly insects, but also spiders, snails and reptiles.*

[*Tchagra senegalus kalahari*,
Okavango Delta,
Botswana.
Photo: Nick Garbutt]

Bush-shrikes in the genus Laniarius *are mostly larger than tchagras, and take quite large prey, including beetles, caterpillars, large numbers of grasshoppers and locusts, and occasionally small birds and nestlings.* ***Yellow-crowned Gonoleks*** *forage singly and in pairs, low down in woody growth. If undisturbed, they spend much of their time on the ground, assuming a rather upright posture. They hop or creep among branches and on the ground, flicking aside dry leaves and woody litter, and making short runs after insects. They fly reluctantly. They also forage in the canopy up to 5 m high. Partners usually forage within a few metres of each other, and call frequently, whether in sight of each other or not.*

[*Laniarius barbarus barbarus*, Western Division, Gambia. Photo: Dick Forsman]

will also make short fluttering flights through foliage or the air in pursuit of an insect, and they have been seen, infrequently, to chase a small bird, seldom catching it, but they are never sit-and-wait or full-chase predators in the manner in which laniid shrikes are. To their own kind they can be aggressive: the chasing of rivals out of the territory or the chasing away of a third party during courtship is frequent, and to some extent other bird species are chased out of the territory also. Contrarily, bush-shrikes often join mixed-species foraging flocks of mainly insectivorous birds, although it is not yet clear whether the ones concerned are territory-holders or, likely enough, unestablished juveniles; nor is there any information on the ways in which they interact with their fellow travellers.

Voice

The various genera of Malaconotidae all have loud and distinctive songs and a varied vocabulary of calls. The same songs seem always to function both in courtship and in territorial proclamation and defence; countersinging across territory boundaries is common. In addition to producing vocalizations, most or all spe-

The ***White-tailed Shrike*** *is both terrestrial and arboreal, foraging in low, dense vegetation and on the ground beneath, and also commonly in trees at all levels up to the canopy. On the ground it moves restlessly in long hops, seizing prey from the soil surface, or jumping up to take insects from the tips of grass stems. In trees, it gleans insects from trunks, branches and foliage, sometimes hanging momentarily upside-down, occasionally darting out to catch insects in flight. Prey includes beetles, moths and butterflies, caterpillars, mantids and grasshoppers. Mostly seen singly and in pairs, in winter it is also found in flocks of up to twelve birds, and joins mixed-species foraging flocks.*

[*Lanioturdus torquatus*, Erongo Mountains, Namibia. Photo: Dick Forsman]

*The **Southern Tchagra** forages low down in dense scrub, or on the ground, where it runs and hops, flicking over debris in the manner of a* Turdus *thrush. Prey includes beetles, corn crickets, larvae, small molluscs, and berries. There are reports of the similarly-sized Black-crowned Tchagra* (Tchagra senegalus) *holding down grasshoppers with its foot and dismembering them, wedging a snake between roots and tearing it apart, and disembowelling a mouse, pulping it and feeding it to nestlings.*

[*Tchagra tchagra caffrariae*, Addo, South Africa. Photo: Geoff McIlleron]

cies loudly snap or click the bill—or is it, in fact, tongue-clicking?—often when excited or alarmed; they also snap or, as it is usually called, "frip" the wings in flight, each wingbeat making a noise rather like that made by a person snapping the middle finger against the thumb, several times in less than a second.

Several kinds of bush-shrike sing in duet, either almost synchronously or antiphonally, one member of a pair answering its mate, perhaps some distance away in forest, after what is often an extraordinarily short time lapse. This has stimulated practical experimentation and a good deal of playback analysis, both in the aviary and in the field, as well as a considerable body of theoretical speculation on the communicative functions involved. Bush-shrike duets are undoubtedly among the most remarkable of African bird vocalizations; the various voices of each species have been described in great detail, and summarized genus by genus at much greater length than can be repeated here, by Harris and Franklin in their comprehensive work *Shrikes and Bush-shrikes*.

Members of the genus *Malaconotus* do not duet, but they deliver, from the depths of thick forest or woods, loud and far-carrying whistles, generally in a series of 4–10 notes, "hoh" or "whooooooo" by different species, the series repeated after a pause of a few seconds. The whistles have a strange quality, described variously as haunting, spooky, hollow, resonant, mournful, quavering, short or drawn out, although mostly of 0·5–0·7 seconds' duration, penetrating, and sometimes falsetto at the end. Uluguru Bush-shrikes have a low-pitched but strident and far-carrying two-syllable "huw-teew", the second note a little higher than the first; the song is quite recognizable generically.

Male tchagras have a cheery, jaunty song of 5–10 whistles in the case of some species, 10–30 in that of others, the whistles usually progressively longer and descending the scale, and commonly preceded by wing-fripping. The whole lasts for up to six seconds, and sometimes more. Female Southern Tchagras (*Tchagra tchagra*) have the same song as the males, and it is sung nearly in unison with the partner's song. Male Black-crowned Tchagras deliver a series of mellow, lilting, warbling whistles, sweet and deliberate, and descending the scale; the female sings, often in duet with the male, with a hard, rattling, descending trill. Marsh Tchagras have a shorter, cheery song, those of the male and the female quite alike and given often in duet; there is considerable regional variation, which is partly the basis on which some southern African taxonomists split this into two distinct species.

Differing from those of the preceding genera, and varying much among species, the songs of the puffbacks often incorporate a tearing "zzztz" component. They are given commonly in flight and with much wing-fripping and bill-clicking. The territorial song of the Red-eyed Puffback is a rolling snore of two seconds' duration, "tzzzzrrrreeeeawrrrrr". Sabine's Puffback has a descending series of 5–15 or, often, many more notes and lasting for up to two minutes; it starts with thin, squeaky and high-pitched notes like the sound made by a bicycle pump, and develops into longer, louder, ringing notes, the male and the female singing almost synchronously. In contrast, male Black-backed Puffbacks utter a percussive click followed by a loud, clear whistle repeated about ten times in ten seconds, the female often responding instantly with a tearing scold; alternatively, the female can initiate the sequence and the male respond in duet.

The six *Chlorophoneus* species have generically similar songs, commonly given in almost synchronous duet. The males deliver repeated ringing whistles, the females emitting harsh dry snarls like those of female puffbacks. In *Telophorus*, Gorgeous Bush-shrike males sing repeated short-phrase whistles, and females of one subspecies, but perhaps not those of the other, respond in duet with harsh rasps. Bokmakieries give very varied songs, consisting of loud whistles by both sexes in near-synchronous duet. This species' English vernacular name is onomatopoeic; it is derived from the "bok-mak…" vocalization made by one sex followed immediately by a trilling "rie-rie-rie…" by the other. The songs of the other two *Telophorus* species are not well known.

Turning to the two monotypic genera, the male Brubru makes a far-carrying, regionally variable trill, resembling the sound of a pea-whistle or a telephone, and the female has a variety of soft notes and squeaks, sometimes given in synchronous or antiphonal duet; the English name of this species, too, is onomatopoeic, reflecting the male's trilled call. White-tailed Shrikes have a diversified and ill-researched vocabulary of whistles, churrs, explosive and ratchet-like notes and songs, the sexes often vocalizing in antiphonal duet.

Duetting is developed best in the boubous and gonoleks in the genus *Laniarius*. The vocalizations of this genus of bush-shrikes are consequently the ones which have been the most thoroughly studied of all malaconotid vocalizations. As Harris and Franklin describe it, the basic structure of the song consists of repeated low-pitched ringing, monosyllabic or disyllabic whistles, along with harsh, croaking, tearing, ratchet-like clicking and

Bush-shrike foraging methods are quite different to those of the "true" shrikes (Laniidae). None of them are sit-and-wait predators, scanning the ground from a perch. Although they have been seen chasing small birds in flight, they rarely catch them, and certainly do not hunt them down in the relentless manner of the laniid shrikes. Among the foliage, the smaller bush-shrikes creep and glean like the Sylvia *warblers that some of them resemble. On the ground, the foraging methods of several genera of bush-shrike are similar to those of* Turdus *thrushes. But rather than tossing leaf litter aside in a thrush-like manner, in the hope of revealing prey, the boubous and gonoleks turn over particular leaves or bits of bark, as if they have seen prey moving or disappearing underneath. Although like most bush-shrikes,* ***Southern Boubous*** *are usually secretive and keep mainly to the shelter of dense vegetation, they will also emerge to feed in gardens. They will even visit bird tables, where they are known to eat grain and porridge. Their usual diet is of insects such as beetles and grasshoppers, snails, small birds, nestlings and eggs, and house mice. They have been seen pulling bark off dead trees, in search or pursuit of geckos. They can deal with prey that other species might find unpalatable or too dangerous to eat. Hairy caterpillars are rubbed vigorously against branches or in sand before being swallowed. The stings of bees are similarly rubbed off against a perch. To eat a snail, the Southern Boubou breaks open the shell by repeatedly beating it against a branch, or wedges it into a crevice, and tugs the flesh out with its bill. This bird is eating the seeds of the South African endemic* Strelitzia.

[*Laniarius ferrugineus ferrugineus*, Cape Town, South Africa. Photos: Peter Ryan]

*A large bush-shrike with a robust, strongly hooked bill, the **Grey-headed Bush-shrike** can tackle bigger prey, including large insects, rodents, bats, frogs, geckos and other lizards, and snakes up to 60–70 cm long. Prey such as geckos may be beaten to death against a branch, before being wedged between twigs, torn apart and eaten piecemeal. A bird may return frequently to a favoured place for killing, wedging and dismembering prey. It often raids birds' nests, and may attempt to catch a small bird by pursuing it through vegetation. It forages at all levels, working its way up a tree to the canopy, appearing to pay more attention to branches than leaves.*

nasal twanging sounds, delivered by the male and the female in well-developed duets, a pair of individuals often having a number of different duet songs. In the case of, in particular, the Crimson-breasted Shrike and the three crimson-bellied gonoleks, the time between the start of one individual's song and its mate's response is incredibly short, so that the combined song has something of a whiplash quality, and, especially when male and female are close to each other, it sounds exactly like one single quick-fire song. A pair of Yellow-crowned Gonoleks, for instance, has a precisely synchronized duet in which the motif of the initiating partner, a loud, pure liquid whistle 0·2–0·3 seconds long, is answered by its mate after one-tenth of a second, or fractionally less, with a rasping trill also 0·2–0·3 seconds long, so that the whole duet is delivered in 0·3–0·4 seconds. It appears that either sex can whistle "hweeu" or rattle "kkkkk" at will, and also that either one of them can initiate the duet, which can therefore sound like "hweeu/kkkkk" or "kkkkk/hweeu" or even a tripartite "hweeu/kkkkk/hweeu", in each case the "hweeu" and "kkkkk" being largely synchronous.

The biological functions of these extraordinary duets have been investigated by W. H. Thorpe, W. Wickler, U. Seibt, E. Sonnenschein, H. U. Reyer and others, focusing on Slate-

*The laniid shrikes store their prey by impaling it on thorns or barbed wire. One of the distinguishing characteristics of bush-shrike behaviour is that they do not normally do this. Yet there are a few records, particularly of captive **Southern Boubous** and Tropical Boubous* (Laniarius aethiopicus), *apparently storing surplus food in "larders" in this way. Although one captive Southern Boubou was described as regularly impaling prey, it is possible that the food had become wedged on a spiny protuberance as the bird secured it in order to tear it apart. This kind of accident could be the evolutionary origin of deliberately impaling and storing food for later.*

coloured Boubous. This species sings in antiphonal, rather than synchronous, duet, the males usually with gong-like notes and the females with fluty whistles. A gong-and-whistle duet, lasting only 0·7 seconds, is generally initiated by the male, but an individual of either sex can sing its mate's phrases, and a female can initiate a duet with its own or its mate's notes. The boubous learn "male" and "female" components from a same-sex tutor in their first few months; once learnt, individual repertoires do not change, and a mated pair combines its notes into a set of pair-specific duets which remain constant for life. The pair uses several standardized call–answer sequences, and switches between them; the two partners can deliver a thousand duets in a day, the total duetting time amounting to 1–1·5 hours daily. Pair duets and repertoires vary regionally, local dialects being passed from one generation to the next by social learning. Besides reacting vocally to its mate, a Slate-coloured Boubou reacts to same-sex rivals that it sees or hears by countersinging with them, and it will occasionally duet with other species, including Tropical Boubous and Black-headed Gonoleks. Several functions of duetting have been proposed. The main ones are that of maintaining long-range contact between mates out of sight of each other in dense undergrowth, that of promoting mutual mate-guarding, and that of joint advertising and defence of the lifelong territory of the pair. The strengthening of the pair-bond and the ensuring of breeding synchrony also have been suggested as possible functions.

Earlier studies of the duetting behaviour of the Southern Boubou and Tropical Boubou species pair led to much the same conclusions about functions as have been reached with regard to Slate-coloured Boubous. They have recently been supplemented by the investigations of Tropical Boubous undertaken by T. U. Grafe, J. H. Bitz and colleagues, who have proposed fascinating additional functions. These authors' novel deduction, arising from voice-playback study of simulated intrusions into 18 Tropical Boubou pair territories in Comoé National Park, in Ivory Coast, is that duetting serves also as a post-conflict display to advertise social-dominance "victories" in disputes with neighbouring boubous encountered near the territorial interface. Sixteen of the 18 pairs stood their ground when confronted with sound recordings of strangers' duets, eleven of them breaking into victory duets as soon as the recordings were switched off. Victory songs are longer and louder than other types of duet and can be heard across two territories, or throughout an area of the extent of some twenty-five football pitches. In nature, victory duets are sung probably to deter strangers or neighbours from entering a pair's territory. Grafe and Bitz also played tape-recorded male solo voices to territorial pairs. Females responded, creating duets, and with three of the six pairs studied the male started to sing in near-synchrony with the "foreign" male recordings, an action which the researchers interpreted as the jamming by males of the signal from an intruding male competitor.

These studies are providing new insights into the complexities of vocal communication by tropical birds living in dense habitats. Among bush-shrikes, interspecific differences in duet structure and duetting behaviour are likely to have been shaped adaptively by the conflicting sociosexual demands of competition and co-operation. It is an exciting and fast-developing field of research, and there is every reason to believe that in the case of *Laniarius* and other bush-shrike genera, as well as the many other duetting genera such as *Thryothorus* wrens and *Hypocnemis* antbirds, researchers to date have been merely scratching the surface.

Food and Feeding

The secretive nature of bush-shrikes, skulking in thick cover often high up in trees, makes them difficult birds to study, and as a result there have been no systematic field investigations into their feeding behaviour. Indeed, there are only a few protracted series of observations at the nest of food items brought to chicks. Much of what is known is the result of opportunistic, transient observations.

Among the six species of *Malaconotus*, almost nothing is known about the Green-breasted, Monteiro's and Uluguru Bush-shrikes, the problem of learning about the feeding habits of these species being compounded by their rarity and apparent canopy-foraging habits. So far as is known, they all search for food by moving rather cautiously, hopping along or between mainly small branches and tangles of creepers in forest undergrowth, middle strata and high canopy; sometimes they come to the ground. Fiery-breasted Bush-shrikes often remain motionless for several minutes, and it is tempting to suppose that they are then waiting patiently for a cryptic prey animal to reveal itself by movement. In all events, these large shrikes are predatory, taking quite large insects such as beetles (Coleoptera), tree locusts (*Anacridium*), cicadas (Cicadidae), butterflies and caterpillars (Lepidoptera), and small vertebrates such as tree-frogs (Rhacophoridae). The bush-shrike holds down its prey under one foot and uses its bill to tear

All malaconotids are thought to be monogamous breeders, in single pairs with lifelong bonds, maintaining the same large, all-purpose territories throughout their lives. A pair of ***Bokmakieries*** *will defend and advertise the territory throughout the year. They perch on a low eminence with body inclined, and neck upstretched so that the yellow throat is displayed, and sing solos or duets. Bush-shrike courtship displays are much the same as territorial threat displays and the singing can change into a more threatening or sexually charged display, with bowing, jerky side-to-side movements, wing-flicking and tail-fanning.*

[*Telophorus zeylonus zeylonus*, Bontebok National Park, South Africa. Photo: Rolf Kunz]

it apart, consuming the food piecemeal. Lagden's Bush-shrike preys on lizards of the genus *Agama* and on small birds, as well as on insects, and it beats a large item vigorously against the perch in order to immobilize it. Rather more is known about the Grey-headed Bush-shrike, as this is a bird of savanna woodland, living in more open, less lofty trees than its forest congeners. It also forages among dense foliage and twiggy growth at all levels up to the canopy, seeming to glean items from wood, rather than from leaves, and clambering or creeping along slowly, twisting the head and peering about, even beneath branches, as if making a thorough search for animal prey. It often glides down to the base of a tree and takes its time in working its way up to the canopy, repeating the process in an adjacent tree. On finding prey, the shrike makes a lunge at it, grabbing it with the bill; it holds down a small item under the foot or wedges a large one into a fork, and then dismembers the prey. Occasionally, the Grey-headed Bush-shrike makes a short flight to capture a flying insect, with an audible snap of the bill as it seizes its victim. On the ground it pursues a fleeing animal in long leaps. This species is known to take a wide variety of prey, ranging from mason wasps (Vespidae) and other Hymenoptera, grasshoppers (Acrididae), scorpions (Scorpiones) and centipedes (Chilopoda) to small birds and their eggs and nestlings, small rodents, frogs, chameleons (Chamaeleonidae), skinks (Scincidae), snakes and even bats (Chiroptera).

Tchagras are middle-sized bush-shrikes, only one-third to one-half of the weight of *Malaconotus* species, but they have a fairly heavy bill and they take the same range of prey as the larger birds and catch it in much the same manner, except that the tchagras are more terrestrial. The Black-crowned Tchagra, because it is an open-country bird with a vast range in the Maghreb, sub-Saharan Africa and southern Arabia, is one of the best-known bush-shrikes. Reviewing the literature, B. Hillcoat reported on its diet in the Maghreb, and Harris and Franklin on that in the rest of the continent. This bush-shrike eats mainly grasshoppers up to 6 cm in length, beetles of many kinds, larvae and small lizards; in addition, it takes crickets (Tettigoniidae), cockroaches (Blattodea), mantises (Mantidae) and mantis egg cases, nymphs, cicadas and other bugs (Heteroptera), termites, wasps, moths and caterpillars, spiders (Araneae) and occasionally tadpoles, tree-frogs and small snakes, with single records of an earthworm (Oligochaeta), a mouse (Muridae) and small fruits. It captures most of its prey on the ground or in low bushes. When on the ground, Black-crowned Tchagras hop about under dense, shady growth around the bases of trees and bushes, flicking aside debris rather in the manner of a Eurasian Blackbird (*Turdus merula*), pulling apart dung, scratching at the soil, and making small upward jumps to snatch an insect from an overhead leaf. They can run quite swiftly, perhaps more to cross an open space than to chase prey. They clamber up into bushes, where they creep about while gleaning stems and lower branches for insects. Occasionally they fly out in brief aerial pursuit of a flushed insect, and sometimes they join mixed-species flocks foraging in trees. They have been known to attack small birds, but not to kill any. There are reports of Black-crowned Tchagras holding down and dismembering grasshoppers, wedging a snake between roots and tearing it apart, and disembowelling a mouse, pulping it and feeding it to nestlings. Van Someren reported that nestlings of this species in Kenya are fed with moth larvae, acridid nymphs, beetles and spiders, and that, if there happens to be a temporary water pool where frogs are breeding, tadpoles also are taken. It would be interesting to know exactly how the last-mentioned are caught. The little that is known about other tchagra species suggests that their diets and foraging behaviour are much the same as those of the Black-crowned Tchagra, although Marsh Tchagras regularly search the stems of reeds and grasses, as well as gleaning in bushes; their prey spectrum includes dragonflies (Odonata). Van Someren observed several pairs of Brown-crowned Tchagras closely at their nests; one individual was seen to hold a grasshopper nymph under one foot and use its bill to pull off the victim's legs, and then to pulp the insect's body by passing it to and fro across the bill, before feeding it to a chick.

Gonoleks, boubous and bush-shrikes in the genus *Laniarius* are mostly somewhat larger and heavier than tchagras, but still only half the weight of *Malaconotus* species; commensurate with their size, they take quite large prey. Their diets and their ways of

All bush-shrike nests are bowl-shaped or cup-shaped structures, rather loosely built, and placed in bushes or trees. In some species the female does all the work, although the male may escort her. ***Crimson-breasted Shrike*** *nests are built by both sexes, usually around 3 m up in a fork of an acacia tree. They are made largely of shreds of fibrous bark from acacia trees, which are added to the nest by each bird in turn. The base of the nest is secured with spiders' web. Work takes around five days, and the result is a rather untidy and bulky, poorly bound open cup, lined with rootlets, dry weed stalks and strips of maize leaf. In one study, around half the nests were "inexplicably" destroyed by their makers, before or after eggs were laid. Other species are thought to destroy and recycle the materials of failed nests.*

[*Laniarius atrococcineus*, Mahango Game Reserve, Namibia.
Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

*The nest of the **Orange-breasted Bush-shrike** is built by both sexes, usually near the site of the previous season's nest. It is placed between 4 m and 10 m up, in a multiple fork (or as here, wedged between numerous twigs), in the lateral branches of a thorn tree, or among thick foliage or creeper tangles. Made from grass, petioles and fine twigs, it is so flimsy and openly constructed that, despite the lining of fine rootlets and creeper tendrils, the eggs are visible from below. Most bush-shrikes are single-brooded and appear to be so throughout their ranges. Bush-shrike breeding seasons are long, and eggs and young have been found in nearly all months, with peaks at times of greatest prey availability.*

[*Chlorophoneus sulfureopectus similis*, Modimolle, Limpopo, South Africa. Photo: Warwick Tarboton]

searching for and catching prey are again similar to those of *Malaconotus*. They hop about on the ground under dense vegetation and creep through twiggy growth, thickets and tangles of lianas, moving rather slowly, searching methodically, and seizing prey as they encounter it. Several species have been observed to join mixed foraging parties of insectivorous birds as these work their way through trees in the bush-shrike's territory; in such circumstances, the malaconotids concerned glean food from trunks, branches and foliage, peer under flakes of bark, and occasionally hawk an insect on the wing. On the ground, rather than flicking debris aside in thrush-like manner, they turn over a leaf or a bit of bark as if they have just seen an insect disappear under it. Ground prey taken by *Laniarius* species include a variety of arthropods and other small animals, among them isopod crustaceans, ticks (Ixodoidea), spiders, millipedes (Diplopoda), small snails (Gastropoda) and worms. In studies of forest birds that attend swarms of carnivorous ants for flushed prey, E. O. Willis noted that Fülleborn's Boubous in Tanzania regularly follow carnivorous *Dorylus* ants in the West Usambara Mountains, hopping as low as 30 cm above the soil through weeds and tangles and making short sallies to the ground, and moving up into vine tangles to peck at stems; he found that Mountain Boubous did the same in Nyungwe Forest, in Rwanda. Tropical Boubous eat swarming *Dorylus* ants, and they and several others sometimes take small berries and nuts. Vertebrate prey include tree-frogs, geckos (Gekkonidae), skinks, eggs of reptiles and birds, nestlings of small birds, and mice; Tropical Boubous, and probably other species as well, are persistent plunderers of bird nests. Vertebrates, snails and larger arthropods are generally held down under one foot, or wedged into a tree fork, torn apart and eaten piece by piece. Van Someren observed that two-day-old nestlings were fed with grasshoppers, mantids and moth larvae, and that, at seven days, the chicks were given mantids, long-horned grasshoppers, saturnid moths, noctuid caterpillars, several tree-frogs and skinks, nestling Common Waxbills (*Estrilda astrild*) and a 30-cm tree-snake. One end of the snake was put into the mouth of one nestling and the other end was placed in the mouth of another chick, a situation which, had it not been for the ultimate intervention of the observer, might have killed the nestlings.

As noted by S. J. Tyler and L. Tyler in Botswana, Crimson-breasted Shrikes frequently associate with parties of Southern Pied Babblers (*Turdoides bicolor*) and those of the less common Arrow-marked Babbler (*Turdoides jardineii*), hopping around after them on the ground and snatching any insects that they disturb. Others constantly attended a Common Scimitarbill (*Rhinopomastus cyanomelas*) as it probed bark for food, and one once attended upon a Hoopoe (*Upupa epops*), following it as it foraged on an earth bank and repeatedly darting forward to try to catch dislodged insects. Crimson-breasted Shrikes are also on record as breaking up and eating, piecemeal, birdtable peanuts.

Puffbacks, because they forage largely in the canopy, are less well known than are boubous. Sabine's Puffback seldom comes below 8 m above the ground, and for much of the time it remains above 20 m and up to the tops of 45-m-tall trees, where it searches twigs, vine tangles, outer branches and clusters of foliage, picking prey off both the upperside and the undersurface of leaves. Puffbacks often join mixed flocks of insectivorous birds, sometimes hawk insects in the air in flycatcher fashion, and rarely come to the ground except to retrieve a dropped morsel. They thrive mainly on the same range of insects as is taken by other bush-shrikes, and they are known occasionally to eat spiders, small frogs, lizards, birds and bird eggs. Buds have been found in the diets of two puffback species.

Chlorophoneus bush-shrikes feed in a manner similar to that of the puffbacks, by creeping and hopping along mossy branches in the canopy while in a crouched posture, searching twigs, leaves and trunks. They may be incipient Hymenoptera specialists, since bees, wasps and ants have been found in the diets of three of the six species. The Mount Kupe Bush-shrike differs from its *Chlorophoneus* congeners in several ways, and has been seen to hang sideways on a vertical stem, springing up vertically to snatch an insect and falling back to the perch in a twisting way; its prey includes beetles, grasshoppers and caterpillars, large items being beaten against the branch before being consumed.

*The nests of the **Brubru** can be highly cryptic, being profusely covered with foliaceous lichen so that they blend with the lichen-encrusted branches they are built on. The nests are slight, and built from delicate materials. Two were found to consist of only three materials: spiders' web, around 95 pieces of lichen, and up to 550 fine, pliant leaf petioles. Brubrus have a strong tendency to abandon early nests without laying in them; one pair built and destroyed three nests in four weeks, eventually laying in a fourth nest which they began towards the end of that time. Brubru clutches are of two to four eggs, generally two; bush-shrike clutches in general are typically of two or three eggs. Complete clutches of one or four are rare.*

[*Nilaus afer solivagus*, Marondera, Zimbabwe. Photo: Peter J. Ginn]

The Gorgeous and Doherty's Bush-shrikes, small birds of dense undergrowth, glean insects from stems, branches and leaves. They often forage on the ground, by turning over leaves and debris. The two large *Telophorus* shrikes feed far more on the ground than in the foliage of bushes. The Rosy-patched Shrike runs about hurriedly on bare soil or through grass close to cover, and so, too, does the much better-known Bokmakierie, moving often in zigzags. The latter species, on catching a small insect, eats it immediately, but larger items such as hairy caterpillars it first wipes or beats against the ground and then carries in the bill to a concealed place, where it swallows the food. Bokmakieries search shady bases of clumps of grass, bush stems and tree trunks, jump up to take an insect just out of reach, and in bushes gradually work their way upwards, gleaning branches and foliage, perhaps flying out to hawk a passing moth, and gliding down to the base of another clump of bushes.

The two monotypic genera differ from each other in several respects. The White-tailed Shrike is a shy but inquisitive species which forages actively in low, dense vegetation and on the ground beneath it, as well as feeding commonly at all heights in trees. It gleans insects from trunks, branches and foliage, sometimes hanging momentarily upside-down, and occasionally flying out to seize an insect in flight. When on the ground, it moves restlessly, in long bounds, with the short tail held pointing straight downwards, and snatches prey from the soil surface or jumps upwards to take insects from the tips of grass stems. The White-tailed Shrike joins mixed-species foraging parties; in the non-breeding season flocks in Angola have been seen to forage on the ground often with White-headed Black-chats (*Pentholaea arnotti*), Sharp-tailed Starlings (*Lamprotornis acuticaudus*) and White-winged Babbling Starlings (*Neocichla gutturalis*). Lastly, the Brubru differs from other members of the family in being strictly arboreal and never coming to the ground. It is an active bird, constantly on the move, searching for small insects and spiders in foliage and for terminal fruits in the middle and upper strata of large woodland trees. It will sometimes hang upside-down to probe a pod, and it will occasionally hawk a flying insect. It holds larger morsels under one foot and tears them apart.

One of the characters that distinguishes malaconotid bush-shrikes from the "true" shrikes of the genus *Lanius* is that the former hardly ever impale prey on a thorn or wire barb for later consumption. Grey-headed Bush-shrikes have been said to cache food items, and a Yellow-crowned Gonolek in Nigeria was claimed once to have killed a Red-cheeked Cordon-bleu (*Uraeginthus bengalus*) and impaled it upon a thorn, but the account was second-hand and it remains in need of substantiation. Nevertheless, in captivity, Southern Boubous and Tropical Boubous have been known to impale prey, although it is not certain whether this was for storage, to be eaten later, or merely an accidental result of wedging the item in a spiny cleft as a means of securing it in order to tear it apart. Sonnenschein and Reyer reported that a captive Tropical Boubou also stuck pieces of ox heart on to branches in its aviary. The behaviour will doubtless be much easier to observe if practised by captive birds than it would be if carried out by wild individuals. In any event, cleft-wedging and the accidental impaling of prey on a splinter for the purposes of immediate dismembering may well be the evolutionary origin of deliberate impaling and caching for later consumption, a habit of considerable interest.

Breeding

At least as secretive in nesting as in all other aspects of their lives, bush-shrikes are for the most part ill known in that regard. Basic information about the breeding biology of several species was obtained decades ago by a handful of dedicated amateurs such as W. Serle, in West Africa, van Someren, in East Africa, and A. W. Vincent, in south-eastern Africa, all of whom patiently made observations from sweltering hides with little more at their disposal in terms of resources than binoculars and a notebook. In more recent times, benchmark studies have been made by W. R. Tarboton, who watched breeding Crimson-breasted Shrikes and Brubrus in South Africa, and by Sonnenschein and Reyer, who observed Slate-coloured Boubous in Kenya, but much remains to be learnt even about those species. Nothing at all is known about the breeding biology of Lagden's, Green-breasted, Monteiro's and Doherty's Bush-shrikes, Mountain and Somali Boubous and Papyrus Gonoleks, except the little that can be inferred about seasons, and the nesting habits of some 26 further species of bush-shrike are still poorly known. That said, it is thought that all members of the family are monogamous, breeding

For some bush-shrikes, incubation begins with the first egg laid, but most start to incubate only when the clutch is complete. Incubation in the ***Gorgeous Bush-shrike*** *is carried out mainly by the female. Similarly, in the puffbacks* (Dryoscopus)*, the Grey-headed Bush-shrike* (Malaconotus blanchoti)*, the Black-crowned Tchagra* (Tchagra senegalus) *and the White-tailed Shrike* (Lanioturdus torquatus)*, incubation is undertaken solely or mainly by the female. With all other bush-shrikes, so far as is known, the male and the female take practically equal shares in the tasks of incubating the eggs, brooding the young and feeding the nestlings and fledglings. The Gorgeous Bush-shrike's nest is a rather thin untidy platform or saucer of twigs, roots, stalks and grasses, lined with dry leaf petioles and tendrils, built relatively low down in the undergrowth. There is no information on the duration of incubation in this species or in most other bush-shrikes. Brubrus* (Nilaus afer) *incubate for around 19 days, with stints of 17–178 minutes, averaging 42 minutes. When the female Brubru is sitting, the male initiates the change-over by calling as he approaches, and she responds in duet. When the male is sitting, he initiates the change-over by calling from the nest, and the female takes over immediately. The female sits more than the male during the day, and does so exclusively at night. In the White-tailed Shrike, incubation is by the female alone. She is fed on and off the nest by the male. He utters a trilling call as he arrives on a nearby tree, and she immediately leaves the nest and joins him. Sometimes soliciting with quivering wings, she takes the offered food, hops about with him for a few minutes, then returns to the nest tree cautiously and indirectly, and resumes sitting.*

[*Telophorus viridis quadricolor*, KwaZulu-Natal, South Africa.

Upper photo: Guy Upfold. Lower photo: Hugh Chittenden]

This picture shows an apparently immature ***Gorgeous Bush-shrike*** *incubating. The photographer explains: "The mate was an adult in striking plumage—we presumed that the immature was the female, and the adult was the male, as the former did all the incubating. Periodically the 'male' would call from about five metres away, and the sitting bird would slip off the nest to fetch food." The adult did not come to the nest in the two days the photographer was present. Although the eggs hatched, the young probably did not fledge, since the birds were gone twelve days later, and the nestling period in the Gorgeous Bush-shrike is 19–21 days. When sub-adults breed, it may be because of a shortage of adults in the population.*

in single pairs with lifelong bonds, resident for most of their lives in quite large all-purpose territories which they defend vigorously by singing. There is no incontrovertible evidence of co-operative breeding by any of the species. This is, however, so widespread a phenomenon among the generality of birds in hot climates and relatively aseasonal habitats that it would not be unexpected, even though bush-shrikes are so rarely seen in groups of three or more individuals, whereas year-round flocking is commonplace among co-operatively breeding species. Additional, third individuals have been seen at the nests of pairs of Crimson-breasted Shrikes, but they have not been observed to help in any way with the rearing of the young.

Most species are single-brooded and appear to be so throughout their ranges, but in southern Africa good numbers of Tropical Boubous, Southern Tchagras, Bokmakieries and Orange-breasted Bush-shrikes are double-brooded. In any event, breeding seasons are protracted. In West Africa, most of the better-known malaconotids breed from about December to June, a period covering the dry season and the first few weeks of the following rainy season, but eggs or nestlings have been found in nearly all months. In southern Africa, breeding seasons are nearly all from about September to April, with egg-laying peaks in the vernal months of September to December. In East Africa, parts of which have "long rains" in March to June and a second "short rains" season in about August to November, bush-shrike populations breed in one or both of the wettest periods; in Uganda, Black-headed Gonolek clutches have been found in nearly all months, but mainly in April–June. It is much the same with Tropical Boubous in Kenya, where Black-headed Tchagras nest in both rains, mainly in April and November–December. Whether the same pairs of birds breed twice each year, once in each rainy season, is open to question. Presumably, breeding is timed so that the rearing of the young coincides with periods of greatest availability of food, especially insects.

Territories of malaconotids are large, and pairs are widely spaced. Density varies according to vegetation type, a solitary pair occupying seldom less than 3 hectares, often about 10–20 ha, and in the case of large and not very common birds, such as Grey-headed Bush-shrikes, up to 200 ha. Within their territory the male and the female often appear to forage some distance apart, so that in dense woody and leafy growth they may be unable to see each other; they do, however, keep in contact vocally, it seems, with frequent calling and near-synchronous duetting. Duetting increases in frequency during the breeding season, and it functions in rebuffing neighbouring pairs' attempts to transgress territorial boundaries, in advertising the territory-owners' victories in such encounters, and even in jamming the voice of an intruding rival. In this family, territorial advertisement and courtship behaviour are sometimes inseparable.

There is a broad measure of agreement that a principal purpose of duetting is that of maintaining the pair-bond, and it is only to be expected that duetting frequency increases as breeding gets underway. Two Bokmakieries, presumed male territorial rivals or the male and female of a pair, will perch conspicuously on top of a rock, bush or small tree and countersing or duet with loud, ringing calls. They adopt an upright, inclined stance, with the neck stretched and the bill pointing upwards, making the yellow throat and black pectoral band especially obvious as they call, and at the same time the yellow-tipped black tail is fanned; this can change into a threatening or sexually charged display with bowing, tense and jerky side-to-side movements of the body, wing-flicking and repeated tail-fanning, which can be followed by short flights with snapping, or fripping (see Voice), wing noises. Elements of this behaviour are exaggerated in the displays of other bush-shrikes. Van Someren observed territorial and breeding behaviour probably as closely as anyone else has. A somewhat abbreviated statement of what he had to say of the Slate-coloured Boubou as an example of the genus *Laniarius* is as follows: "Toward the beginning of the breeding season the male calls holding himself upright on extended legs; as each note is uttered he depresses the head and body and may swing from side to side. Then he bends forward, depresses his wings and raises the long, fluffy feathers of his rump into a puff above his back. These rump feathers, though blackish at the ends, have white bases, and these are exposed so that the puff has a mottled appearance. The tail is raised and fanned. After a while he takes a short flight from one cover to another, but the wings are quivered rapidly and the puff is expanded."

Puffbacks, in the genus *Dryoscopus*, have similar displays with involved calling, bowing, wing-drooping, tail-fanning and side-to-side swaying, but their rump-puff postures at perches and during short flights are more exaggerated, the long, soft rump

Not all bush-shrike nests are flimsy and untidy. The ***Black-backed Puffback*** *builds a small, neat, deep and well-knit cup, firmly attached to an upright fork in a tree 2–15 m above the ground. The nest is built by the female alone, although the male may provide some material. She undertakes this work mainly in the early morning, making up to 20 visits per day, for the ten days the work takes. She brings spider silk concealed inside her mouth, and slowly brings it out at the nest-site. She first places the silk on the selected site, then puts down a strip of bark, and then works the silk across, fastening it to the substrate. As she builds up the nest, she binds more spiders' web around the supporting fork, and weaves it around the nest. She lines the nest with fine, wiry dry grass, and sits in it and moves around, in order to mould it to the shape of her breast. While the building goes on, the male escorts her to and from the nest, calling and wing-fripping; at this stage he is extremely aggressive towards other birds. The female also undertakes most of the incubation of the clutch of two to four eggs, being fed on the nest by the male, who relieves her for short periods. Both partners initiate "nest-relief", by calling. Incubation takes 13 days. Black-backed Puffback nests are sometimes decorated on the outside with pieces of lichen, dry leaves and bark. Bokmakieries* (Telophorus zeylonus) *sometimes decorate their nests externally with asparagus fern, and Marsh* (Tchagra minutus) *and Black-crowned Tchagras* (T. senegalus) *with fragments of snakeskin.*

[*Dryoscopus cubla hamatus*, KwaZulu-Natal, South Africa. Photo: Hugh Chittenden]

On hatching, bush-shrike chicks are naked and blind, and they are brooded continuously for at least the first five or six days. ***Bokmakierie*** *eggs hatch after between 14 and 19 days, usually 16 days. Both parents incubate the eggs, and both brood the chicks, and take turns in feeding and guarding them. They will often bring more than one item of food in the bill at a time. Both parents also remove the faecal sacs, dropping them a fair distance away. The nestling period lasts from 14 to 21 days, with an average of 18 days. Limited information is available on the development of bush-shrike chicks. One Slate-coloured Boubou* (Laniarius funebris) *nestling weighed 3 g when it hatched, had doubled its weight to 6 g by the third day, and gained weight almost linearly to reach 33 g at day 15. The feather tracts of the boubou's nestlings become apparent on the fifth day and the eyes open on the eighth day. The first feathers to emerge are those of the rump, on or about day nine, and the chick is fully feathered three days later, although the wings and tail are still short. Bokmakieries sometimes build several nests—again, working together—before settling on one. The nest, a bulky, shallow bowl, is placed on the ground, or an average of 60 cm above it on the fork of a branch, in the dense foliage of a bush, hedge or tree. Bokmakieries may be double-brooded in southern Africa, where clutches have been found in every month except April; in fact, a female with oviduct eggs was found in April in Namibia.*

[*Telophorus zeylonus zeylonus*,
Western Cape,
South Africa.
Photo: Will Nichol]

Adult bush-shrikes have four rictal bristles on either side of the gape, which are believed to protect them from damage by the spines on the legs of large grasshoppers. The chicks lack these bristles. ***Brown-crowned Tchagras*** *have been observed to hold grasshoppers in one foot and pull off the legs with the beak, then to pulp the insect's body by passing it to and fro across the bill, before feeding it to a chick. The young bush-shrikes' diet of insects and their larvae and pupae may sometimes be varied by larger items. On one occasion, a Brown-crowned Tchagra was observed to kill, disembowel and pulp a hairless* Leggada *mouse, which it fed to its nestlings; there is an almost identical report for a Black-crowned Tchagra* (Tchagra senegalus). *Other food reported to be given to Black-crowned Tchagra nestlings includes moth caterpillars, grasshopper nymphs, beetles and spiders, and if frogs are breeding nearby, tadpoles are also said to be taken, although it is not known how the tchagra may catch them.*

[*Tchagra australis minor*, Malawi. Photo: Michael Gore]

feathers being all white and puffed out above the back into a half-sphere. In the display-flights they use much bill-clicking and wing-fripping, which are often the immediate prelude to copulation. After copulating, a pair of Black-backed Puffbacks flew a short distance, noisily fripping their wings and calling loudly; perching well above the female in a high tree, the male fluttered down, with quivering wings and puffed-out rump feathers, calling the while, and the two went off to forage in the canopy, the male sometimes feeding his mate with a caterpillar.

Even more spectacular than puffback display-flights are those of tchagras, which are, in addition, more visible since all tchagras prefer open, low-bush habitat types. Brown-crowned Tchagras advertise and defend the territory by means of repeated flight displays. An individual zigzags its way up a large bush, takes off from the top and ascends to some 15 m in a steep jerky flight, noisily fripping its wings. At the apex of its flight it raises its head and its crown feathers, starts to sing, and glides conspicuously down, a little jerkily, the foxy wings outspread and, near the end of the glide, the white-tipped black tail widely fanned. The song of this species is a rapid stuttering trill, which soon changes into a series of up to 30 loud, liquid double whistles that fall in pitch and decelerate towards the end of the glide. The courtship of this species involves repeated aerial displays, the same as the above-described territorial display except that the rump feathers are fluffed up and the tail fanned for longer. At perch, a male postures in front of a female, bowing, stretching his body and pointing the bill upwards, fanning the tail and giving complex calls.

In an appendix in their monograph *Shrikes and Bush-shrikes*, Harris and Franklin presented an exhaustive compilation of the distribution of 140 different characters, a monumental task given that so little is known about many of the species. With regard to the courtship behaviour of bush-shrikes, tandem bouncing through vegetation is performed only by *Dryoscopus*, *Laniarius* and *Chlorophoneus*; all genera except *Chlorophoneus* and *Telophorus* have display-flights, and all or most genera use rump-fluffing to varying degrees, although there is some doubt about *Malaconotus* and *Chlorophoneus* in this respect. Only the Marsh Tchagra flicks its tail up and down, and all tchagras and puffbacks hold the head up in courtship flight. Puffbacks are the only ones in which the male has a special high-pitched nest-building call and escorts the female during nest-building. Courtship feeding has been noted for *Malaconotus*, and occurs regularly in *Dryoscopus*, the males of which regularly give their females an insect, often a caterpillar; courtship feeding may also be practised by Mount Kupe Bush-shrikes and Brubrus.

All known bush-shrike nests are bowl-shaped or cup-shaped structures, rather loosely built, and placed in bushes or trees, generally on the fork of a stout or slender branch. The base and walls are untidily and rather roughly made, those constructed by the large *Malaconotus* species consisting of thin licheny branched twigs, whereas those built by others are of various thinner and more pliable plant materials; the lining is neater, a profusion of even more slender plant material such as dry rootlets, not woven in but, instead, curved around to give a fairly strong and durable structure. No soft inner padding of feathers, animal hairs or plant down is ever added.

Most *Tchagra* nests and some *Laniarius* and *Chlorophoneus* nests are flimsy and shallow, quite like dove (Columbidae) nests. *Dryoscopus* species and Marsh Tchagras use spider web to bind their nests, and *Tchagra*, *Dryoscopus* and *Laniarius* species often incorporate pieces of bark. Marsh Tchagras are unusual also

*Although the **Grey-headed Bush-shrike** may lay as many as four eggs, no more than three ever seem to hatch. By the time three young reach the age of 14 days, or two get to 20 days, they can be far too big for the nest, and one or two may fall from it and die. Several bush-shrikes also have their eggs or young ejected by brood parasites such as Black Cuckoos* (Cuculus clamosus) *or Jacobin Cuckoos* (Clamator jacobinus). *Commonly building their own nests, Grey-headed Bush-shrikes may alternatively occupy the old nests of doves (Columbidae), sparrowhawks* (Accipiter) *or Grey Go-away-birds* (Corythaixoides concolor). *One was seen to destroy the nest of an African Thrush* (Turdus pelios), *taking away the material.*

[*Malaconotus blanchoti hypopyrrhus*, Marondera, Zimbabwe. Photo: Peter J. Ginn]

in that they often decorate their nests with one or two pieces of discarded snakeskin, or a few snakeskin scales. As described by Vincent, the nest of the Black-backed Puffback "is firmly attached to the fork by cobweb and plant-fibre... a neat and compact little cup, thickly built at base, of thin wood-shavings and dry fibrous grass-blades, round which is bound cobweb, snowy-white cocoon-webbing and some woolly plant-down, and with a lining of small strips of coarse dry grass or fine wiry dry grass". The nest of the Black-backed Puffback is built by the female alone, although her mate sometimes brings material to her. She undertakes this work mainly in the early morning, making up to 20 visits per day, and using material carried in her bill; she brings spider silk concealed inside her mouth, and at the nest she slowly brings this out and weaves it around. The work takes her about ten days, the male escorting her to and from the nest, while calling and wing-fripping; at this stage he is extremely aggressive towards other birds. The female first places spider web on the selected site, puts down a strip of bark, and then works the web across, fastening it to the substrate; as she builds up the nest, she binds spider web around the supporting fork. She sits in the nest and moves around, moulding it to the shape of her breast. The completed nest is firmly knit, and bound with spider web on the outside; bits of bark and lichen are worked in and held by cobweb, sometimes with cocoons still attached.

Brubru nests are small, slight structures, built mainly from leaf petioles bound and moulded on to the supporting branch by spider web, and marvellously camouflaged with bits of lichen copiously applied all around, often joining up with lichen growths on the branch itself. White-tailed Shrikes make a small, thick-walled nest generally of dry grass, smoothed on the outside with finely shredded, cotton-like bark fibres, usually matching the colour and texture of the branch to which the nest is moulded. The sexes of the Brubru take equal parts in the task of building, the two collecting material and visiting the site independently; if both arrive at the same time, one waits until the other has finished adding material, which takes 30–60 seconds. The individual bringing material first sits on the nest and then places material on the rim, using its bill repeatedly to tamp down the material and rotating its body through some 30° in order to compact the wall. It then drops down on to its breast and uses its feet to compact the inner side by means of a treading motion and body rotation. One individual which was collecting petioles of *Peltophorum africanum* flew with a beakful to a nearby spider web, where it gathered web on to the petioles before taking them to the nest.

With the exception of the puffbacks, the males of all bush-shrikes help their mates in the task of nest-building. Failed nests are sometimes pulled apart by their owners, perhaps for use in rebuilding.

Most malaconotid species have clutches of two or three eggs, laid at 24-hour intervals. Complete clutches containing a single egg or four eggs are rare, but Grey-headed Bush-shrikes lay clutches of three or four and, sometimes, two or five eggs. The eggs of this family have a creamy, pale grey, pinkish or pale greenish-blue background, generally finely speckled at the small end but the rufous-brown markings becoming more blotchy or scrawled at the large end, where, in the case of puffback eggs, they may form a distinct ring. Interestingly, the Black-crowned Tchagra lays eggs of two types in Nigeria. Most of its eggs are white, scrawled or irregularly streaked or smudged with claret, red-brown markings forming a ring around the large end; the less common type has the same colours but the red-brown forms blotches or spots, chiefly at the large end.

For some malaconotids incubation begins with the first egg laid, but most of the species start to incubate only when the clutch is completed. In the case of the puffbacks, the Grey-headed Bush-shrike, the Black-crowned Tchagra and the White-tailed Shrike, incubation is undertaken solely or mainly by the female. With all other bush-shrikes, so far as is known, the male and the female take practically equal shares in the tasks of incubating the eggs, brooding the young and feeding the nestlings and fledglings.

On hatching, malaconotid chicks are naked and blind, and they are brooded continuously for the first five or six days or more, but little is known about their development. Data are available for the Slate-coloured Boubou, whose hatchlings have black naked skin and conspicuously yellow gape flanges. One nestling of this species weighed 3 g when it hatched, had doubled its weight to 6 g by the third day, and gained weight almost linearly to reach 33 g at day 15. The feather tracts of this boubou's nestlings become apparent on the fifth day and the eyes open on the eighth day; the first feathers to emerge are those of the rump, on or about day nine, and the chick is fully feathered three days thereafter, although the wings and tail are still short. The chick exer-

*The **Southern Boubou** clutch of two to three eggs is incubated by both parents, with incubation starting as soon as the first egg is laid. The eggs hatch after 16–17 days, and the eggshells are eaten or, more usually, carried away in the adult's bill immediately afterwards. The chicks are fed by both parents. At one nest, one or the other parent constantly brooded the chicks for eleven days, and both fed the young thereafter. The faecal sacs are either carried away by the adult, or swallowed immediately. The nestling period is 16 or 17 days. At one nest, two young birds, of 16 and 17 days old, left the nest on the same morning, within two hours of each other. The nest of this species can be particularly flimsy, no more than a loosely knit bowl of slender twigs, roots and grasses, sometimes bound with spiders' web and lined with finer grass and rootlets; sometimes no twigs are used, and the nest is so thin that the eggs are visible from below. The nest is, however, usually well concealed, placed around 2 m above the ground in a fork in a dense bush or a mass of creepers. The pair will destroy the nest if too much disturbed, and may use the material to build another. Pair members will defend their territory throughout the year, with repeated loud ringing whistles, given mainly by the male while in an upright stance, bobbing his head slightly and with half-open tail, semi-exposed on an elevated perch. They become very aggressive towards others of their species during breeding, chasing them and plundering their nests. As with other species of bush-shrike, courtship seems to be indistinguishable from displays against rival birds. The male and female sway, and move close together, hopping, creeping and winding through the bush, fripping wings and duet-singing. In the display-flight, the male descends with slow, exaggerated wingbeats, head held up and rump feathers fluffed.*

[*Laniarius ferrugineus*, KwaZulu-Natal, South Africa. Photo: Hugh Chittenden]

Initially the female ***Black-backed Puffback*** *broods the chicks, feeding them with food brought by the male. Later in the nestling period, both parents feed the young, and both remove the faecal sacs. Food items given to nestlings include butterflies and moths, noctuid and saturnid moth caterpillars, long-horned grasshoppers and crickets, dragonflies, beetles, larvae, worms and small lizards, and once a stick-insect 115 mm long, from which the legs had been removed. The nestling period lasts around 18 days. Nestlings are sometimes killed by ants. Black-backed Puffbacks' nests are occasionally parasitized by Klaas's Cuckoo* (Chrysococcyx klaas)*, and possibly by African Emerald Cuckoos* (Chrysococcyx cupreus) *and Black Cuckoos* (Cuculus clamosus)*. In other species, breeding success can be variable, and is often poor. In the Crimson-breasted Shrike* (Laniarius atrococcineus)*, for example, which is heavily parasitized by the Black Cuckoo, two out of a brood of three will often die in the nest, in one instance because of infection by mites* (Ornithonyssus bursa)*. In one study of the Crimson-breasted Shrike, only seven broods fledged from 66 clutches, and in Nylsvlei, Limpopo Province, South Africa, only one young fledged from 13 clutches. A similar study of the Brubru* (Nilaus afer) *found that out of ten nests, only three were successful. Of 17 nests of the Slate-coloured Boubou* (Laniarius funebris) *at Lake Baringo, in Kenya, none was successful. Twelve clutches and five broods disappeared, with most nests remaining untouched. Predation by Nile monitors* (Varanus niloticus) *was believed to be responsible. However, another nest of this boubou was so poorly bound that it collapsed under the weight of the growing young.*

[*Dryoscopus cubla hamatus*, Marondera, Zimbabwe. Photo: Peter J. Ginn]

*This well-grown **Brown-crowned Tchagra** chick is seen with a parent bird in the act of removing a faecal sac. The nestling period is around 15 to 16 days. There are no data on fledging in this species, but in the Slate-coloured Boubou* (Laniarius funebris), *the chick is fully feathered at around twelve days, although the wings and tail are still short. The chick exercises by preening and stretching its legs and wings. It is able to fly a few days later. Young Brown-crowned Tchagras remain with the parents in a family party for at least five months. In Malawi, they probably become independent at six to seven months.*

[*Tchagra australis australis*, Modimolle, Limpopo, South Africa. Photo: Warwick Tarboton]

cises by preening, stretching its legs and wings, and standing, when it sometimes overbalances. It begs with plaintive "seee" calls. It is fully capable of flight a few days after leaving the nest, even though its tail is still very short.

In southern Africa, 2–2·5% of the nests of Tropical Boubous, Southern Boubous and Crimson-breasted Shrikes suffer brood parasitism by Black Cuckoos (*Cuculus clamosus*). The eggs of this cuckoo are similar to the bush-shrike eggs, although a little larger.

Movements

No species in this family is migratory in the conventional sense of the term. Most appear to be sedentary throughout their ranges, and paired individuals that occupy a territory throughout the year are strictly so, perhaps moving no more than a kilometre from the centre of the territory during the course of their lifetimes. This will apply particularly to populations living in rainforest and mesic woodlands that are not subject to marked seasonal micro-climatic or vegetational fluctuation. Some peripheral populations of the same essentially sedentary species, however, may well move a few kilometres seasonally in response to drying conditions, fire, rain or flooding. Bush-shrike species regarded as "resident", in the sense that some individuals are nearly always to be found in a particular region even if those present in the dry season are exclusively different from wet-season ones, are likely to exhibit post-fledging dispersal of several kilometres, as well as having non-breeders roaming over somewhat greater distances.

Long-term ringing studies undertaken in hot and humid *Acacia–Combretum* woodland near the Zambezi River in Malawi and Mozambique have produced strong circumstantial evidence for short-distance migration by parts of populations that are otherwise more or less sedentary. It seems that young Tropical Boubous and Black-backed Puffbacks disperse from their natal areas 5–6 months after fledging, most Tropical Boubous moving away after a year or two, resulting in a constant turnover of individuals in the area; some adult Southern Puffbacks stayed in their breeding territories for five years, but others passed through the trapping area in October and November and were not seen again. In southern Africa, a male Southern Boubou remained in the same territory for 11 years, and recoveries of 17 ringed bush-shrikes, of four species, were all within 15 km of the ringing station and mainly within 2 km of it.

Also in southern Africa, detailed analysis of field counts has suggested that Crimson-breasted Shrikes may move into riverine woodland during prolonged droughts, but no evidence was found that might corroborate earlier suggestions of seasonal movements by Gorgeous, Olive or Grey-headed Bush-shrikes. The last-named species, however, is a partial migrant in West Africa: moving north with the rains, it arrives in the Bamako region of Mali in March, probably breeds then, and departs in October, although farther south, in northern Guinea and northern Ivory Coast, it seems to be resident. Its most northerly records in Nigeria are during the rains, while coastal records of this species in Ghana are in the dry season. Field observations strongly suggest that Orange-breasted Bush-shrikes migrate likewise, at least in Ghana, Nigeria and Sudan. In Malawi, Black-fronted Bush-shrikes wander a few kilometres to small patches of forest where they do not breed, and some may move 60–100 km, while in Tanzania they are generally thought to be altitudinal migrants through 1000–2000 m in the Uluguru and East Usambara Mountains. In Tanzania Olive Bush-shrikes behave similarly, and so, probably, do Fülleborn's Boubous, too.

Relationship with Man

Members of the family Malaconotidae are of no commercial interest and of very little cultural interest to humanity. The great majority of bush-shrike species are unobtrusive, shy or even secretive birds of dense and gloomy forest undergrowth, thickets and leafy trees. They are not gregarious, nor are they conspicuously migratory, and on the whole they seldom impinge upon the lives of people in any way. Beautiful as many species are, and interestingly vocal as well, no malaconotid species has ever been systematically trapped for the cagebird trade. Perhaps a major reason for the lack of interest by aviculturalists is that bush-shrikes are primarily insectivorous, making them difficult to keep in captivity, especially outside the tropics. On the edges of various African cities and towns, one species or another, particularly the boubous of the genus *Laniarius*, will enter gardens and sometimes even make brief appearances into bright sunlight in order to forage near bushes around the edges of lawns. Even boubous, however,

Once young ***Black-backed Puffbacks*** *leave the nest, they continue to beg from their parents and be fed by them for at least three weeks. Juveniles appear to be tolerated in the parental territory until the next nesting season. Up to 15 individuals of this species, all or most of them juveniles, sometimes congregate noisily in trees, displaying their rump feathers, calling, wing-fripping and chasing each other. These aggregations are, however, exceptional. Although generally aggressive to conspecifics, bush-shrikes seem to tolerate the presence of the young within their territories for a few months, or at least until breeding begins again. Young Tropical Boubous* (Laniarius aethiopicus) *and Black-backed Puffbacks seem to disperse from their natal areas five to six months after fledging. Red-eyed Puffbacks* (Dryoscopus senegalensis) *remain with their parents almost until the next nesting attempt. There is little information on dispersal, but the birds do not appear to go far: recoveries of 17 ringed bush-shrikes, of four species, were all within 15 km of the ringing station, and mainly within 2 km of it. The bush-shrikes sometimes seen foraging in mixed flocks may well be unestablished juveniles rather than territory holders, but this has not been investigated. There is no incontrovertible evidence of co-operative breeding by any species of bush-shrike. This is so widespread a phenomenon among birds in hot climates and relatively aseasonal habitats that it would not be unexpected, even though bush-shrikes are rarely seen in groups of three or more individuals. Third individuals have been seen at the nests of pairs of Crimson-breasted Shrikes* (L. atrococcineus), *but they have not been observed to help in any way with the rearing of the young.*

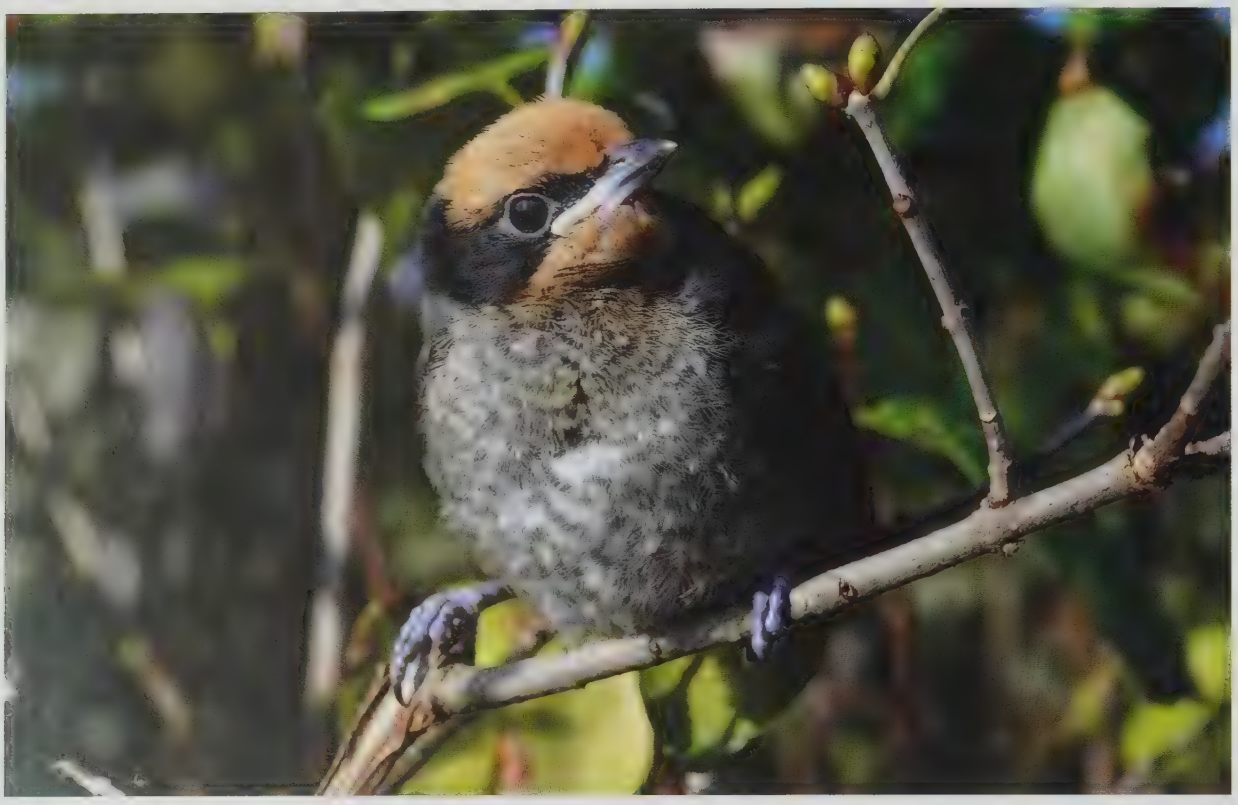
[*Dryoscopus cubla hamatus*, Marondera, Zimbabwe. Photo: Peter J. Ginn]

Two-day-old ***Tropical Boubou*** *nestlings are fed with grasshoppers, mantids and moth larvae. At seven days old, their diet begins to include items such as tree-frogs and skinks, and nestling Common Waxbills* (Estrilda astrild). *One parent brought a 30-cm tree-snake, putting one end in the mouth of one nestling, and the other in the mouth of another, which, but for the intervention of the observer, might have killed both. The young leave the nest at around 15 days, and can feed themselves after a further seven weeks, but they remain with the parents for five months, by which time they have acquired most of the adult vocabulary.*

[*Laniarius aethiopicus ambiguus*, Arusha National Park, Tanzania. Photo: Anabel Harries]

very seldom venture close to human habitation to take morsels from birdtables. Members of this family do not nest on or otherwise utilize man-made structures. While several species can be found in and around traditional farms, none has ever been regarded as a pest. Indeed, the insectivory of malaconotids would probably make them welcome, if anything, in the eyes of fruit-farmers and market gardeners.

Bush-shrike species are not known to make good eating, and they are not hunted or trapped in any numbers. Admittedly, some species often feature in traditional African magico-medicine markets, but probably not disproportionately when compared with the myriad other animals the remains of which are offered for sale there. Dried Black-headed Bush-shrike corpses occur quite commonly in market fetish stalls throughout the southern halves of Togo, Benin, Nigeria and Cameroon. In Benin, during a survey made in the large Dantokpa market, in Cotonou, where over 7000 birds were examined, there were no fewer than 19 Many-coloured Bush-shrikes, 22 Northern Puffbacks and 60 Black-crowned Tchagras. Besides corpses, live birds are offered for sale in these West African markets, but since the handling of them is generally brutal, and little or no care is taken with captives, any bush-shrikes caught alive would not last for long. Most passerine birds are, in any case, not trapped live, but are shot or are killed by catapult.



The very word "shrike" has entered literary English having derived perhaps from the Anglo-Saxon *scric*, for a bird that screeches, by way of "shrite", used in seventeenth-century to nineteenth-century England first for the Mistle Thrush (*Turdus viscivorus*), later for the Red-backed Shrike (*Lanius collurio*), and currently for a host of passerine families the members of which possess a hook-and-tooth-tipped bill. Bush-shrikes, with their strikingly loud, varied and always attention-demanding voices, have compounded vernacular nomenclature in interesting ways. Until quite recently, the name of "Bell-shrike" was widely used in anglophone Africa for several boubous. As recounted by D. A. Bannerman in *The Birds of Tropical West Africa*, the voice of "Turati's Bell-shrike", now known as Turati's Boubou, was described in 1914 as beginning "with a kind of harsh creaking note something like the grating of a rusty hinge... followed by a clear musical note almost exactly like the sound produced by rubbing a wet finger round the edge of a glass finger-bowl", and at first the experienced naturalist G. L. Bates supposed the double-chime call of the "West African Bell-shrike", today's Tropical Boubou, "to be the bell of a mission-school in some village out of sight".

A good number of bush-shrike species were discovered by F. Levaillant, the extraordinary traveller-naturalist who explored the South African region then known as "Cape Colony" in 1781–1784. To several malaconotids he gave onomatopoeic names in his native French — *Le Boubou*, *Le Brubru*, *Le Tschagra* and *Le Bacbakiri* — which quickly entered English usage and remained the definitive vernacular names, the last two, of course, as "tchagra" and "Bokmakierie". The name "gonolek", too, is almost certainly onomatopoeic, and it is surely the case that names in many African languages similarly have a sound-imitative origin, examples being *Bubu* and *Katcha* in the Mandingo tongue in Mali.

Several colloquial names in Afrikaans are colourfully descriptive. For instance, *Spookvoël* refers to the Grey-headed Bush-shrike, alluding to its haunting ghostly calls, *Sneeubal* to the Black-backed Puffback, the snowy rump feathers of which are often fluffed up into a half-snowball, and *Waterfiskaal* to the Southern Boubou, this being a reference to "its rapacity, which no revenue-officer could exceed". The name "fiscal" is applied to some *Lanius* shrikes, as well.

In the world of art, perhaps such beautiful birds as the Fiery-breasted, Many-coloured and Gorgeous Bush-shrikes, the Rosy-patched and Crimson-breasted Shrikes and the Bokmakierie have not made so much of a mark as might be imagined, although G. Arnott's lovely portraiture in his and Harris's *Shrikes of Southern Africa* is certainly well deserving of special mention.

By far the most important place of this family in human affairs lies in its popularity among ornithologists and biologists. Because many bush-shrikes are extravagantly coloured and patterned, they are sought out by birdwatchers and always admired when seen. It is, however, the synchronous or antiphonal male–female duets with astonishingly short auditory reaction times of many species that have excited much research attention in the field, investigators having used increasingly sophisticated methods in interpreting the adaptive functions of duetting and thereby building upon ever more detailed ideas about evolutionary sociobiology. Bush-shrikes are set to become some of the most important of birds worldwide as subjects for further comparative researches into the role of behavioural communication in avian social systems.

*Little is known about the breeding of the **Yellow-crowned Gonolek**, other than that it breeds primarily in the wet season, builds a cup-shaped nest of loosely intertwined coarse grass stems several metres up in a thicket, and lays at least two eggs. This fledgling will soon acquire a mustard-yellow crown, and ochre-yellow underparts, which in turn will acquire a scattering of red feathers, starting mainly on the throat and lower belly. No information is available on survival in this species, but in other bush-shrike species, at least six years seems typical.*

[*Laniarius barbarus barbarus*, Senegal. Photo: Roland Seitre]

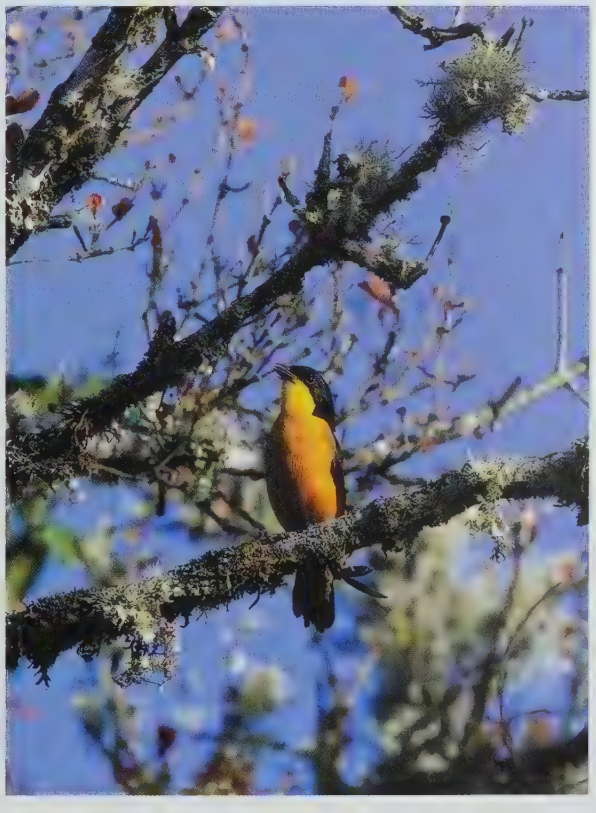
Status and Conservation

To read the accounts of ornithologists in the early or middle twentieth century studying birds all over sub-Saharan Africa, one might suppose that a great many species, including the bush-shrikes, were a good deal commoner then than they seem to be in many countries now. In the absence of earlier population-density estimates, it is perhaps questionable whether there really have been regional decreases in abundance, as perceived decreases in the numbers of some species may have something to do with the nature of field studies and the manner in which they are published. Nevertheless, it is likely enough that widespread declines have taken place, considering how widespread has been the destruction or modification of forest and woodland by man across the continent. Furthermore, this process of habitat change continues to accelerate with the demands of human population growth, agricultural, industrial and urban development and, it must be said, the desperate poverty that forces millions of people to cut trees for fuel and to exploit the natural environment in ways that not only are quite unsustainable but also are, in all practical regards, irreversible. Fortunately, most bush-shrike species, in common with other African woodland birds, have large or vast ranges and remain not uncommon, so that they are not of any immediate conservation concern. Moreover, several of them readily extend from natural woodland into secondary vegetation in farmland, plantations and wooded gardens and suburbs, where they thrive.

Of the 48 species of Malaconotidae currently recognized, five are listed as globally threatened. One of these is Critically Endangered, three are Endangered, and one is Vulnerable. A further two species are considered to be Near-threatened. Several others, obligate inhabitants of lowland rainforest which, at least in Africa west of Cameroon, has already become dangerously fragmented, are of regional conservation concern in the long term. Sabine's Puffback, for instance, inhabits lowland primary and secondary forest from Sierra Leone east to the eastern and south-western borders of DRCongo; in some countries it is still quite common, but in large parts of this great range it appears to be rare. Sabine's Puffback is known from 35 localities throughout Liberia, and from ten forests in Ivory Coast, where it is still quite frequent in Taï Forest and Banco National Parks, Yapo and Bossematié, while in Ghana, where in the 1870s it was said to be locally very common, it had by 2005 been reduced to being common in six selectively logged reserved forests, frequent in two and uncommon in seven others; it is very rare in Togo and Benin, uncommon in Nigeria's remaining coastal forests, uncommon or locally quite frequent in Cameroon, Gabon and PRCongo, and uncommon to rare, or, perhaps, widely overlooked, in DRCongo. Estimated densities of 2–5 pairs of Sabine's Puffbacks per 100 ha in Liberia and 8–10 pairs per 100 ha in Gabon sound healthy enough, but the long-term future of this and all other tall-forest endemics can be secured only by effective preservation and management of as many forests as is practicable. The same applies to other species confined to lowland or montane forest, particularly those with a lesser range than that of Sabine's Puffback or with a patchier distribution, such as the Fiery-breasted and Doherty's Bush-shrikes, the Mountain and Fülleborn's Boubous and the Black-shouldered and Pink-footed Puffbacks.

Most of the species of immediate conservation concern also inhabit forest, mainly in small montane isolates. Only the Papyrus Gonolek, which is listed as Near-threatened, has a markedly different habitat, being restricted to the interior of papyrus swamps. Recently, it was locally common in central and south-west Uganda from the shores of Lake Victoria up to about 1600 m in altitude, and perhaps it still is, but many papyrus marshes on the shores of this great lake are suffering from intensification of fishing and agriculture, incursions by cattle and goats, papyrus-harvesting, burning, pollution and, perhaps worst of all, falling water levels; in the last decade or so, the surface of Lake Victoria has fallen by a metre. Papyrus Gonoleks are widespread and locally abundant in eastern Rwanda and eastern Burundi and occur also in extreme north-west Tanzania and extreme western Kenya, where there may still be 6–10 individuals per hectare in unaffected papyrus swamps. In Uganda, a density of 13 birds per hectare was found in the centre of undisturbed swamps but less than one bird per hectare in degraded swamps. Populations may not be at immediate risk, but the species is in urgent need of monitoring, with a view to the establishing of conservation action for it and its habitat.

Lagden's Bush-shrike, with one subspecies ranging in lowland rainforest from Sierra Leone to Ghana and another, moderately distinct, from eastern DRCongo to Uganda and Rwanda, has also been classified as Near-threatened. It is widespread but uncommon in Liberia, with an estimated 6000 pairs, uncommon



in Ivory Coast, where it is known only in Taï, Mopri and Yapo Forests, possibly extinct in Ghana, and known in Togo from a single sight record in 1990. More montane in East Africa, it is uncommon in south-western Uganda and along the eastern borders of DRCongo at about 1400–2700 m and is known to occur in Rwanda at only five localities. Being so retiring and elusive, Lagden's Bush-shrike may be commoner than the sparse observations of it suggest, but forest destruction is bound to affect it adversely. Even though it may be capable of extending into secondary, degraded forest habitats, this splendid large bush-shrike should be added to those others in the genus *Malaconotus* the survival of which should be helped along by means of effective protection of evergreen forest.

At least two, and almost certainly three, other *Malaconotus* species are very much at risk. These are Monteiro's, Green-breasted and Uluguru Bush-shrikes. So, too, is the Mount Kupe Bush-shrike, formerly regarded as a *Malaconotus* but now placed tentatively in *Chlorophoneus* (see Systematics). Monteiro's Bush-shrike is something of a special case, since it is sometimes thought to be not a distinct species in its own right but, rather, a forest subspecies of the savanna-woodland Grey-headed Bush-shrike or even a colour variant of the Green-breasted Bush-shrike. It is a rare and elusive bird of the scarp forests of Angola, with an even smaller population in Cameroon. A Kenya specimen, now lost, and one from Kivu, in east DRCongo, have also been linked with Monteiro's Bush-shrike. This species is listed as Data-deficient, but is thought probably to be Endangered and of global conservation concern, being biome-restricted and of restricted range. The nominate subspecies was known from six old specimens and a handful of sight records up to 1957, but it was rediscovered in 2001–2003 and found to be surprisingly common locally in primary forest and secondary scrub in Kumbira Forest, on Mount Njelo, in Cuanza Sul. Widespread destruction of forest in Angola has doubtless compromised the survival prospects of this bush-shrike, which seems always to have been thinly distributed. In south-west Cameroon, after the type of the mysterious *perspicillatus* was collected on Mount Cameroon, there were no further records for a century, but then one was seen in 1992 on Mount Kupé, another in 1997, and one or two more in the Bakossi Mountains, also in 1997. In Angola, Monteiro's Bush-shrike may occur in Reserva do Ambriz, north of Luanda, but no relevant information is available from there. In Cameroon, surveys are required in order to confirm its occurrence on Mount Kupé and its continued existence on Mount Cameroon.

The Green-breasted Bush-shrike, listed as Vulnerable, is a hill-forest species, rare in much of its restricted range in western Cameroon, where it is found from Mount Cameroon and the Rumpi Hills north to the Bamenda-Banso Highlands, and in south-east Nigeria, where it is confined to the Obudu Plateau. In Cameroon, it is moderately common at 1100–1400 m in the Bakossi Mountains, where at least six territorial individuals or pairs were found in 1998 in less than 100 hectares of forest–grassland mosaic near Kodmin; it is also not uncommon around Lake Edib, and on nearby Mount Kupé at 1100–1950 m and Mount Nlonako at 1400–1600 m. In the Bakossis, there appear to be good numbers of this bush-shrike around Bali-Ngemba, but the species is rare in the Kilum-Ijim forests at 2250 m, while on the summit of Mount Oku, where conservation projects have been carried out for the past 20 years, Green-breasted Bush-shrikes have been seen only in 1984 and 1998. Middle-altitude forests in this part of Cameroon have been degraded by logging and shifting agriculture; this species is among those of greatest conservation concern, for which BirdLife International's Kilum-Ijim Forest Projects and, in 1991, the Mount Kupé Forest Project were initiated. In Nigeria, forest loss on the Obudu Plateau, already extensive, is continuing at an alarming rate; although a small forest patch has been established as a reserve, the security of this bush-shrike there depends on the protection of further forest areas on the plateau.

Distinctively different from its congeners, the Uluguru Bush-shrike is a Critically Endangered species, restricted to the forested peaks of the Uluguru Mountains, in east Tanzania, where it is elusive and rare. The Ulugurus are in two main massifs, one northern and the other southern. The species had only once been reported on South Uluguru until 2007, when two or three pairs were found. In 1948 one had been found 3 km away at Bunduki, at 1500 m on the saddle between the South and the North Ulugurus, now a tiny and badly damaged forest reserve. North Uluguru is a narrow ridge 25 km long, the highest peak at 2360 m, with Mount Lupanga at the north end rising to 2138 m and only 2 km from the large and populous town of Morogoro. By the 1980s, the luxuriant evergreen forest at 800–1500 m had been largely cleared for cultivation; between 1500 m and 1800 m there remains submontane forest, which gives way to wet moss forest up to the highest peaks. In North Uluguru, this striking bush-shrike was encountered in 1981 and 1982 at 1300 m, with several at about 1800 m near Bagilo, only 9 km south of Morogoro. In 1993, three or four territorial pairs were found during two months of fieldwork on the eastern slopes, and the total population was estimated to number 1000 pairs. Forest cover in the Ulugurus had been reduced by felling for agriculture to about 220 km² by the year 2000, and is now nominally protected in two reserves, namely Uluguru North and Uluguru South Forest Reserves, formerly adjoining but presently separated by 2 km of farmland. In 1999–2000, a detailed survey, using tape playback, failed to encounter any Uluguru Bush-shrikes in Uluguru South, but several were found in the Uluguru North Forest Reserve, an area of 83·6 km², which was estimated to hold about 1200 pairs, mainly at 1200–1700 m. Submontane forest was still being destroyed at an alarming rate in the closing years of the twentieth century, and in 1999 a three-year conservation action plan was initiated by the Royal Society for the Protection of Birds and by the European Union in collaboration with local organizations and communities. While lower forests continue to be modified by underplanting with banana and other cash crops, the resilience of other *Malaconotus* species to forest-habitat modification suggests that this grossly threatened bush-shrike may yet be able to sustain itself. Surveys in 2006 and 2007 indicated that the global population was much the same as that found in the 1999–2000 survey.

Another seriously Endangered species is the enigmatic Mount Kupe Bush-shrike. It was discovered on Mount Kupé, in south-western Cameroon, in 1951. Extensive searches by the ICBP Cameroon Montane Forest Survey in 1984, however, failed to rediscover it, but the species came to light again in 1989, and in the ensuing five years there were some 40 sightings on Mount Kupé at 1220–1310 m; in March–May 1997, there were believed

Most bush-shrike species have large ranges, and are not of any immediate conservation concern. A few have more restricted ranges. The ***Yellow-breasted Boubou*** *is confined to the Cameroon Mountains Endemic Bird Area, where it varies from not uncommon to abundant: at 2000–2900 m on Mount Oku. It is so abundant in nearby Big Babanki that it can be seen or heard constantly. Three other restricted-range bush-shrikes are found in the same EBA: the Endangered Mount Kupe Bush-shrike* (Chlorophoneus kupeensis)*, the Vulnerable Green-breasted Bush-shrike* (Malaconotus gladiator)*; and the Data-deficient Monteiro's Bush-shrike* (M. monteiri).

Most of the species of immediate conservation concern, like the Mount Kupe (Chlorophoneus kupeensis), *Green-breasted* (Malaconotus gladiator) *and Uluguru* (M. alius) *Bush-shrikes, inhabit small, isolated montane forests, which are subject to increasing pressure from logging, clearance for agriculture, and in the long term, climate change. The* ***Papyrus Gonolek****, which is listed as Near-threatened, has a markedly different habitat, being restricted to the interior of papyrus* (Cyperus papyrus) *swamps and beds, beside meandering rivers and along lake shores. Its abundance is directly related to the height and density of papyrus, with numbers larger in taller and denser stands. In 2008, the population estimate was of 2,000,000 adults. It was—and may still be—locally common in central and southwest Uganda, from the shores of Lake Victoria up to about 1600 m in altitude. But many papyrus marshes on the shores of this great lake are suffering from the adverse effects of increasing human population, including intensification of fishing and agriculture, incursions by cattle and goats, papyrus-harvesting and burning, pollution and, perhaps worst of all, falling water levels. In the ten years from 1998, the level of Lake Victoria fell by about one metre. Papyrus Gonoleks are widespread and locally abundant in eastern Rwanda and eastern Burundi, and occur also in extreme north-west Tanzania and extreme western Kenya. In Uganda, a density of 13 birds per hectare was found in the centre of undisturbed swamps, but less than one bird per hectare in degraded swamps. Populations may not be at immediate risk, but the species is in urgent need of monitoring, with a view to implementing conservation action for both the bird and its habitat.*

*The Vulnerable **Green-breasted Bush-shrike** was intended to benefit from BirdLife's Kilum-Ijim Forest Project in Cameroon, but has only been seen there twice in 25 years. It occurs at low densities at a few rapidly degrading montane forest sites in western Cameroon and eastern Nigeria. This species must be on the verge of extinction on Cameroon's Mount Oku, as there is almost no forest remaining within its altitudinal range. It may benefit from a small forest reserve on Nigeria's Obudu Plateau, where it is hoped more forest can be protected.*

[*Malaconotus gladiator*, Bakossi Mountains, Cameroon. Photo: Ron Hoff]

to be up to seven pairs along two mountain trails, the combined length of which is about 8 km. In 1992, Mount Kupe Bush-shrikes were discovered on Mount Bakossi, with several seen at 1150–1200 m near Kodmin, Lake Edib and Messaka; the population there may be only about 50 pairs. Some were found in Banyang Mbo Wildlife Sanctuary, a forested extension from the Bakossi hills, in 1999. Using tape playback, ornithologists searched for the species but did not find it, either on the lower slopes of Mount Nlonako in 1999 or on Mount Manenguba in 2000. Concern for its survival in the face of continuing forest destruction led to the inauguration of the Mount Kupé Forest Project by BirdLife International in 1991; the project involves local communities in education, forest conservation and the development of ecotourism, administered from a World Wildlife Fund office located high on Mount Kupé. Nevertheless, some forest was lost at 1250 m there in 1998. Like most other bush-shrikes, this species is elusive and may yet prove to be commoner than is supposed. It is encouraging that, in 2004–2005, this iconic bird was reported from a new locality, the Cross River National Park, in extreme south-east Nigeria.

The final two malaconotid species of conservation concern are in the genus *Laniarius*. Braun's and Gabela Bush-shrikes are, respectively, red-breasted and white-breasted versions of the brown-breasted Lühder's Bush-shrike of western and eastern Congo Basin rainforests; formerly treated as subspecies of the latter, they are now usually accorded full species status on account of their distinctive appearance. Each inhabits undergrowth in separate tiny areas of evergreen escarpment forest in north-west Angola, Braun's Bush-shrike 300–350 km south of the range of Lühder's, which does not occur south of the River Congo, and the Gabela Bush-shrike about 270 km south of Braun's. Both are Endangered.

Braun's Bush-shrike is known from very few historical specimens and sightings at six localities at elevations of 600–1265 m close to Camabatela, an Important Bird Area (IBA) in northern Cuanza Norte. In January 2005, three pairs were found when duetting in a small patch of degraded forest at one of the six localities, 30 km south of Uíge. Almost nothing is known about the present status of the Camabatela Forests IBA; the forests have been heavily logged, and by the early 1970s much escarpment forest had been replaced by coffee plantations. During the lengthy civil war in Angola, coffee *fazendas* were neglected and coffee production declined; the forest bird fauna, which had become fragmented and reduced, may well have benefited somewhat.

The Gabela Bush-shrike was discovered near Gabela, in western Cuanza Sul Province, in 1930 and was rediscovered there in 1960. In three days in 1992, two pairs were found nearby at Londa and Assango; during short visits in 2001, 2002 and 2003, the species was found to be fairly common in Kumbira forest at 800–1000 m on the west flank of Mount Njelo, 7 km south of Conda, and also in degraded farmbush below 800 m with subsistence agriculture. Gabela, Londa, Assango and Kumbira bound an area of only 700 km². In 2005, this bush-shrike was recorded north of Gabela at 735 m and at Gungo at 1030 m. Scarp forests had been selectively logged before civil war broke out, in 1974. In that year a proposal was made to protect an area of 50 km² around Gabela, but it was not implemented; valley bottoms have now been cleared of undergrowth and 20–70% of canopy trees felled for banana, sweet potato, cassava and maize agriculture. Little more is known about the present status of the Gabela forests themselves. The fact that the Gabela Bush-shrike has recently been discovered to inhabit farmbush, as well as intact forest, gives some grounds for optimism about its prospects for survival.

Braun's Bush-shrike (L. brauni) *and the **Gabela Bush-shrike** are both confined to tiny areas of escarpment forest in Angola. Both are Endangered. First discovered in 1930, and rediscovered in 1960 at Gabela, the Gabela Bush-shrike was lost again until the 1990s. The fact that it has recently been found to inhabit farmbush, as well as intact forest, gives grounds for optimism about its survival.*

Genus *MALACONOTUS* Swainson, 1824

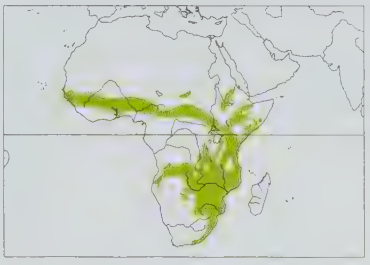
1. Fiery-breasted Bush-shrike

Malaconotus cruentus

French: Gladiateur ensanglanté **German**: Blutbrustwürger **Spanish**: Gladiador Cruento

Taxonomy. *Vanga cruenta* Lesson, 1831, Cape of Good Hope; error = Cape Coast, Ghana.
Sometimes treated as part of the superspecies formed by *M. blanchoti*, *M. monteiri* and *M. lagdeni*; nominate race of *M. monteiri* has been thought to be a colour morph of present species; largely sympatric with *M. lagdeni*, so best regarded as separate species. Geographical variation not understood: of five races named, based on extent and depth of orange or red suffusion of breast, and on size (slightly decreasing from W to E), only "nominate" (Sierra Leone E to SE Nigeria), *gabonensis* (SW Cameroon and Gabon) and *adolfifriederici* (PRCongo, S Central African Republic, N & E DRCongo and W Uganda) possibly worthy of recognition. Most or all populations, however, exhibit individual variation in amount of yellow/orange/red/scarlet below, and species probably polymorphic, rather than polytypic. Treated as monotypic.
Distribution. Sierra Leone E, discontinuously, to SE Nigeria, SW & S Cameroon, Gabon, N & SW PRCongo, S Central African Republic, N & E DRCongo (S to Itombwe) and W Uganda (Semliki Forest).
Descriptive notes. 23–25·5 cm; male 68–79·5 g, female 70–91 g. A large, powerful bush-shrike with a heavy, hooked bill, a deep indentation in cutting edge behind hook, three nasal and five rictal bristles on each side of bill. Two colour morphs, yellow and red, with some intermediates. Has forehead, lores and surrounds of eye white, crown, nape and ear-coverts grey, sharply demarcated from red, orange or yellow throat, and merging into olive-green on mantle, back, wing, rump and tail; tertials black, broadly tipped yellow, alula and primary coverts blackish; tail rounded, yellow-tipped, with broad black subterminal band; chin, throat and breast variably scarlet, red, orange or yellow; belly and undertail-coverts yellow; in W of range (E to Nigeria) throat and breast mainly yellow (except on Mt Nimba, in N Liberia, where uniform, with small area of pale orange on breast), many in Cameroon (also some in Sierra Leone) have orange-yellow chin, orange-red throat and breast, orange upper belly, brilliant yellow lower belly, flanks, thighs and undertail-coverts, but in Kumba (SW Cameroon) half of population yellow-orange and half red-orange; in Gabon and DRCongo, most have brilliant orange chin and throat, bright red-orange or scarlet breast, and bright yellow belly and undertail-coverts, paler at side; iris pale blue-grey or greyish-white; bill black; legs grey to dark blue-grey. Sexes alike. Juvenile is like adult, but forehead to hindneck and ear-coverts buff-brown, underparts initially fluffy, chin and throat white, breast pale greyish-yellow, belly pale yellow, black band in tail narrow; later, throat orange, black-and-yellow pattern in tertials dull; later still, crown tawny, upperparts uniform dark olivaceous brownish-grey, with white lores or, at least, white spot above each nostril, underparts as for adult but flanks and belly buff-grey. Voice. Song 4–10 short, resonant, hollow-sounding "hoh" notes, like voice of Hairy-breasted Barbet (*Tricholaema hirsuta*), at rate of 10 in 16 seconds, soon repeated. Characteristic call a hard, sharp accelerating trill, "krrrièèèk"; other calls include excited, rolling "rrrourourou", sometimes in flight, also sharp "kik-ik-ik", and harsh rasping and chattering notes. Also clicks bill and makes "fripping" sounds with wings.

Habitat. Lowland forest from sea-level to 1500 m, less commonly to 1900 m (in DRCongo). In Liberia, primary forest along rivers and forests with more open canopy bordering inundation zones, abandoned farms, secondary forest and (on Mt Nimba) ridge forest; in Ghana and Nigeria, undergrowth in secondary forest, forest edges and well-wooded gardens; in Gabon, gallery forest, regen-



erating woods 3–5 years old in forest clearings, and thick cover in unkempt plantations; in N DRCongo, all strata in closed dry forest and canopy of open forest.
Food and Feeding. Eats beetles (Coleoptera), cicadas (Cicadidae), grasshoppers and crickets (Orthoptera), mantises (Mantidae), butterflies and moths and their larvae, pupae and eggs (Lepidoptera), and small tree-frogs; small seeds found in stomachs; captives accept small vertebrates and pieces of meat. Often in canopy; lower down, likes tangled curtains of creepers and dense undergrowth; often at edges of forest paths, sometimes on ground. Forages by creeping through and searching leafy vegetation, moving rather ponderously; may remain motionless for 10 minutes before moving on; joins mixed-species foraging parties. Holds prey underfoot and uses bill to tear it apart.
Breeding. Few data. In W Africa calls all year (mainly Sept–Apr), breeding apparently Jun–Apr, with oviduct eggs in Jun and Nov in Cameroon, courtship and copulation Oct and dependent young Nov in Liberia, and nest-building Feb in Gabon; in E DRCongo (Itombwe) about Mar–Jul and Oct–Nov; in breeding condition in Jul in Uganda. Thought to be territorial; two or three males at a time sing from high in canopy; four individuals, presumed to be two pairs, seen in apparent territorial display together, with much hooting, upward head-pointing and bill-snapping. Nest-building spells last c. 20 minutes, in early morning, each collecting and building trip taking 1·5–2 minutes; one female brought material found 10–15 m away, drooped and vibrated wings, male approached her and the two moved to nest, where she worked material in; nest a shallow bowl, loosely built of dry vines, small twigs, leaf petioles, grass stems or weed stalks and maize "silk", lined with rootlets, or a platform of large dead twigs and the bowl then lined with vegetable fibres and dead leaves; sited low down in small branches or in tangle of vines, or on fork 4 m up in cocoa tree. Clutch 2–3 eggs; no information on incubation and nestling periods.
Movements. Resident.
Status and Conservation. Not globally threatened. Uncommon in limited ranges in Sierra Leone and Guinea (Ziama Massif), but in Liberia frequent S of 7° N and locally common in N, where common at 800–1500 m on Mt Nimba; in Ivory Coast, common in Danane–Nimba–Taï area and locally frequent in Abidjan–Bouaké–Maroué region; in Ghana, absent from wetter forests in SW but not uncommon elsewhere in forest zone and outliers to N (Chama, Mampong, Amedzofe, Akropong, Tafo); in Togo, recorded only in SW (near Misahöhe); in Nigeria, not uncommon in SW, but elsewhere recorded only in Niger delta (where uncommon) and at Ikom; widespread and frequent to common in Cameroon and Gabon; local in PRCongo (Kouilou Basin, Odzala National Park, rare in Nouabalé-Ndoki National Park); in Central African Republic only in Lobaye Prefecture; in DRCongo, only a few scattered records in N, several old records near Buta, in NE, also local and uncommon in E from Semliki S to Kivu and frequent in Itombwe; in Uganda, confined to Bwamba lowlands at c. 700 m and said to be common in 1960s, but no records since. A shy, skulking species, easily overlooked except when calling; likely to be commoner than it appears, with a less discontinuous range than currently suggested. Adaptable, inhabiting not only mature lowland forest but also thick secondary growth and well-wooded farms and gardens adjacent to forest. In Liberia, seems to be less common in primary forest than in secondary forest (and to forage lower down in latter, where doubtless easier to find); six calling individuals along 2 km of ridge forest on Mt Nimba. Pair has home range of 6–10 ha in closed-canopy forest (Gabon). In Ivory Coast thought to be much less common than formerly, and throughout W Africa its numbers have no doubt diminished greatly with accelerating clearance of forests in recent decades.
Bibliography. 2. Grey-headed Bush-shrike

Malaconotus blanchoti

French: Gladiateur de Blanchot **German**: Graukopfwürger **Spanish**: Gladiador Cabecigrís

Taxonomy. *Malaconotus blanchoti* Stephens, 1826, Senegal.
Forms a superspecies with *M. monteiri* and *M. lagdeni*, with *M. cruentus* sometimes included in same group; has been regarded as conspecific with *M. monteiri*. All races intergrade at common boundaries; size decreases clinally from N to S. Seven subspecies recognized.
Subspecies and Distribution.
M. b. blanchoti Stephens, 1826 – Senegal E to N Cameroon.
M. b. catharoxanthus Neumann, 1899 – N Cameroon E to Ethiopia (N and W of Rift Valley), Eritrea, Uganda and W Kenya.
M. b. approximans (Cabanis, 1869) – Ethiopia (S and E of Rift Valley), Somalia, Kenya and N Tanzania.
M. b. interpositus E. J. O. Hartert, 1911 – Angola, SE DRCongo (Katanga) and N & W Zambia (Mporokoso; North-Western Province).
M. b. citrinipectus Meise, 1968 – SW Angola and extreme N Namibia (Cunene valley and N Ovamboland).
M. b. hypopyrrhus Hartlaub, 1844 – from Rwanda, Tanzania and C & S Zambia S to NE Namibia (Caprivi Strip), N & E Botswana, Zimbabwe, S Mozambique and E South Africa (near Durban).
M. b. extremus Clancey, 1957 – coastal South Africa from S of Durban S to St Francis Bay.
Descriptive notes. 23–26 cm; male 73–84 g, female 65–99 g. A large bush-shrike with robust, strongly hooked bill, upper-mandible notch blunter than in large forest-dwelling congeners; two nasal bristles and four rictal bristles on each side of bill. Nominate race has line from nostril to eye white or whitish, chin and throat brilliant cadmium-yellow; otherwise, head and mantle to tail olive-green, tail narrowly tipped pale yellow (up to 3 mm deep on outer two feathers); small outer primary wholly blackish, other remiges blackish, outer vanes olive-green proximal to point of emargination and edged yellow distal to it, secondaries narrowly tipped pale yellow, tertials tipped pale yellow (forming series of spots up to 6 mm long); upperwing-coverts olive-green, greater coverts and outer median coverts broadly tipped pale yellow in triangular or axe-head shape; breast brownish-orange, more so at side (amount and depth of orange varying considerably), belly brilliant yellow, thighs olive-green and yellow, vent and undertail-coverts yellow; underside of tail greyish-olive, tip pale yellow, shafts yellow; underside of remiges pale silvery grey, inner vanes of all except outermost primaries edged pale yellow, underwing-coverts and axillaries sulphur-yellow, leading edge of wing bright yellow; iris orange or light yellow (perhaps varying geographically); bill black or black-brown; legs bluish-grey. Sexes alike. Juvenile is like adult, but mottled brown on head, paler yellow on underparts, bill light grey, iris yellow (in areas where adult iris orange) or pale yellow (where adult yellow).

Races vary in colour of underparts (bright yellow to brownish-orange) and in size: *catharoxanthus* is like nominate, but underparts generally uniform bright yellow, side of breast sometimes with brown wash; *approximans* has tawny-orange on underparts deeper in shade and more extensive, forming gorget enclosing yellow throat and extending well on to flanks; *interpositus* has breast with less brown-orange suffusion; *citrinipectus* has fore throat and breast lemon-yellow (not cadmium-yellow); *hypopyrrhus* is very like nominate, but wing and leg slightly shorter; *extremus* has top of head, nape and hindneck darker grey (less bluish) than nominate, upperparts and wing and tail darker green (less yellowish). Voice. Male song or advertising call a series of spooky, drawn-out whistles on one pitch, "uuuuuuuuh", "whoooooooo" or "hawwwwww", mournful, ventriloquial, slightly quavering, whistle starts softly, becomes louder and stops abruptly, is repeated up to 50 times at intervals of 1–5 seconds, and often given by two birds in antiphonal duet; some notes shorter, with falsetto ending, "whoooo-up" or "hawwwww-ip", or grating and ringing, "wraaaaaaanh", or thinner and squeakier, "wheeu"; whistle may be preceded by soft notes (audible only at close range), and whistles sometimes accompanied by clicking; series may have distinct break in middle, the second set being of higher-pitched "pheeeeeeu" notes. Female occasionally duets with 4–5 harsh drawn-out "skeeeeer" or "skwaaar" rasps. Alarm a loud, explosive "squok-squok" or "squok-tot-squok-tot" (can be given in dive-bombing flight); contact call a soft, plaintive, querulous mewing, "phouu-phouu"; female solicits with quivering wings and soft, buzzing "zzhoreer-zzhoreer" call. Makes "fripping" sounds with wings, and threatens with loud bill-snaps followed by short, soft "klip-klip-phoou".
Habitat. Thick woody growth and bushes in open savanna woodland, keeping to tangled growth, creepers, branch masses and dense foliage within a few metres of ground, including canopy of small trees: microphyllous, thorny woodland, shrubby pasture, dense riparian woods, riverine forest and thickets. In NW Nigeria inhabits old woodland, dry or wet, with very thick undergrowth and dominant trees African mahogany (*Khaya senegalensis*) and kapok (*Ceiba pentandra*) and palms *Borassus*, *Raphia* and *Elaeis*. In Ethiopia lives in woods at 180–1800 m; in Eritrea in riverine woods, especially with tamarinds (*Tamarindus indicus*), and mixed woods below 1210 m. In NE DRCongo occurs in plantations of Ceará rubber (*Manihot glaziovii*), and in Rwanda in galleries of *Acacia polyacantha*; resident in eucalypt (*Eucalyptus*) plantations in Swaziland and occurs near neem (*Azadirachta*) in Nigeria, but generally rare in exotic vegetation. In Zimbabwe typically in brachystegia (*Brachystegia*) woodland, commonest in riparian fringing forest with tall acacia trees, sometimes within lowland evergreen forest; uncommon in semi-arid savannas. In Somalia has predilection for acacias but lives in all types of woodland, including fragmented forest, riverine woods and scattered trees. Everywhere can occur in large gardens and parks, and sometimes nests close to houses.
Food and Feeding. Large arthropods and small vertebrates: locusts and grasshoppers (Acrididae), mantises (Mantidae), bees and wasps (Hymenoptera), particularly eumenid mason wasps, beetles (Coleoptera), termites (Isoptera), dragonflies (Odonata), caterpillars and moths (Lepidoptera) and worms (Annelida); small chameleons (Chamaeleonidae), geckos (Gekkonidae) and other lizards, snakes up to 60–70 cm long, frogs, rodents, bats, also birds and their eggs and nestlings. Forages at all levels in vegetation c. 12 m tall, up to canopy; hops and bounds nimbly, in crouched posture, along and between branches and through twigs, diligently checking leaves for insects, peering about and even twisting head upside-down; may pay more attention to branches than to leaves when foraging; tends to work its way upwards in a tree. Sometimes forages in leafless shrubs, and descends to ground to take worms or swarming termites; also hawks insects in flight, fluttering up to catch one with audible snap of bill. Often raids bird nests; attempts to catch a small bird by pursuing it through vegetation. Appears to kill and dismember prey at favourite or special places, from where it takes prey to mate on nest; one consumed a Yellow-fronted Canary (*Serinus mozambicus*) by wedging it firmly between two upright twigs in a mopane tree (*Colophospermum*) and tugging with the bill until a piece came away, the pieces being swallowed instantly regardless of size; when remains of canary came adrift and fell to ground, the bush-shrike dived after and retrieved it. One individual wedged large pupa into broken end of branch, tore it open by using hook at tip of bill, and ate bits of it piecemeal; another wedged items including caterpillars, small frogs and small nestling birds. Small prey items can be held under one foot while being torn apart. A gecko was beaten against a branch to kill it, then eaten piecemeal; seen to kill large moth by pulling its wings off and beating it against a branch or the ground, before swallowing it whole; one individual killed a single-striped grass mouse (*Lemniscomys rosalia*) the same weight as itself (75 g) and carried it for 11 m; one hopped purposefully into a house, flew up to a cluster of mason wasps on ceiling and ate them all, then flew to another cluster outside and quickly consumed them, too. One individual gave up harassing a large flap-necked chameleon (*Chamaeleo dilepis*) c. 30 cm long. Sometimes caches food item. Joins mixed-species foraging flocks in S African winter, although sometimes is mobbed by small birds.
Breeding. Breeds mainly in Jun–Jul in Gambia, Jan–May in Ghana, Feb–Sept in Nigeria; Mar–Jun in Sudan, Ethiopia (once in Dec) and Horn of Africa, and Jul–Dec in E Africa; Sept–Oct at Lubumbashi, in DRCongo; Aug–Sept in Angola, Aug–Feb (mainly Sept–Oct) in Zambia, Sept–May (mainly Oct–Nov) in Malawi, Sept–Jul (mainly Sept–Nov, especially Oct) in Zimbabwe, and Aug–Jan in South Africa; single-brooded. Monogamous. Territorial; singing male holds body sleeked and inclined, tail hanging vertically down, and head bowing downwards with each call; in low-intensity alarm or threat, bird adopts hunched, crouched posture with back feathers raised, calls, opens bill and sways head menacingly from side to side. Courtship involves conspicuous chasing of one partner by the other; in display-flight, male frips wings and fans tail between short glides when it utters whistle call. Nest (or, at least, lining) built by both sexes, male may collect twigs and pass them to female; a shallow, loosely knit, rather untidy, circular platform or bowl 15–17 cm wide, made of twigs up to 5 mm in diameter and 25 cm long, lined with tendrils, dry leaves, bits of soft or strong grass and fibrous roots, placed usually c. 4 m up near top of small deciduous tree with

On following pages: 3. Monteiro's Bush-shrike (*Malaconotus monteiri*); 4. Lagden's Bush-shrike (*Malaconotus lagdeni*); 5. Green-breasted Bush-shrike (*Malaconotus gladiator*); 6. Uluguru Bush-shrike (*Malaconotus alius*).

spreading branches, e.g. *Cassia abbrevita*, fig (*Ficus*), *Strychnos spinosa* or *Parinarium mobola*, either out on side branch or in fork in upright stem, but always where many spreading twigs to support and screen it; often in clump of mistletoe (*Loranthus*); sometimes old nest of dove (Columbidae), sparrowhawk (*Accipiter*) or Grey Go-away-bird (*Corythaixoides concolor*) used; once destroyed nest of African Thrush (*Turdus pelios*), taking material presumably for its own nest; territory c. 50 ha, occupied probably throughout year. Clutch 2–4 eggs, usually 3; incubation by female, sitting very tight, fed on nest by male, period 15–17 days; nestling period c. 20–21 days. In clutches of 4 eggs no more than three seem ever to hatch; three young at 14 days or two at 20 days can be far too big for nest, and one or two may fall from it and die, although often three young do fledge successsfully.

Movements. Probably mainly sedentary, but in Mali moves N with the rains; arrives Bamako in Mar and departs Oct, arrives Ban Markala May and departs Oct. The most N records in Nigeria tend to be in rains; present in W National Park, in SW Niger, only in Oct–May; occurs on Ghana coast only in dry season. Suggestion of movements in Uganda and in S Africa, but clearer evidence required.

Status and Conservation. Not globally threatened. Uncommon to fairly common in savanna woodland throughout sub-Saharan Africa except for the Horn, Congo Basin and the SW. Density in N South Africa (former Transvaal) less than 1 pair/200 ha. In South Africa appears to be commonest in medium-density woodland and less common in dense woods or open savanna. In Nigeria sometimes killed for the traditional-medicine (fetish) market.

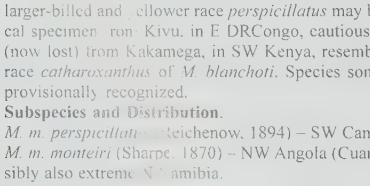
3. Monteiro's Bush-shrike

Malaconotus monteiri

French: Gladiateur de Monteiro **German**: Monteirowürger **Spanish**: Gladiador de Monteiro



Taxonomy. *Laniarius monteiri* Sharpe, 1870, Dande River, Luanda, Angola.

Forms a superspecies with *M. blanchoti* and *M. lagdeni*, with *M. cruentus* sometimes included in same group; has been regarded as conspecific with *M. blanchoti*, and nominate race has been considered to be a colour morph of *M. cruentus*. Barely known in Cameroon, where supposedly larger-billed and yellower race *perspicillatus* may be only a colour morph of *M. gladiator*; historical specimen from Kivu, in E DRCongo, cautiously attributed to *perspicillatus*; single specimen (now lost) from Kakamega, in SW Kenya, resembled both nominate race of present species and race *catharoxanthus* of *M. blanchoti*. Species sometimes treated as monotypic. Two subspecies provisionally recognized.

Subspecies and Distribution.

M. m. perspicillatus Reichenow, 1894 – SW Cameroon (Mt Cameroon).

M. m. monteiri (Sharpe, 1870) – NW Angola (Cuanza Norte, Cuanza Sul, possibly Huambo); possibly also extreme N Namibia.

Descriptive notes. 25–26·5 cm. A large bush-shrike with a very heavy, hooked bill. Nominate race has lores and small but distinct area around eye white, the white sometimes extending backwards as well-delineated superciliary stripe and with shorter, upcurving subocular stripe; head dark grey, merging into olive on mantle and sharply delineated from bright lemon-yellow throat; rest of upperparts, including tail, bright olive-green, uppertail-coverts with narrow yellow tips, rectrices tipped pale yellow; upperwing olive-green, tertials, greater coverts and most median coverts broadly tipped pale yellow; underparts brilliant yellow, breast more or less suffused with tawny-orange, flanks olive-green (largely concealed beneath spreading yellow belly feathers); underside of remiges shiny dark grey with broad pale yellow inner edges and bases, underside of tail olive-grey; iris greenish-ochre or bluish-grey; bill black; legs slate-blue. Differs from very similar *M. blanchoti* mainly in having eyes dark grey (not yellow), pale face patch more extensive. Sexes alike. Juvenile undescribed. Race *perspicillatus* very poorly known, type specimen has heavier bill and is paler yellow below than nominate, the breast without orange wash. Voice. Call of one individual duetting with *M. gladiator* was a mournful whistle of 5 notes without inflections at end, repeated five times; probably indistinguishable from voices of *M. gladiator* and *M. blanchoti*. Makes "klip-klip" snapping or rattling with bill.

Habitat. In Angola, inhabits montane and submontane riverine, gallery and coffee forests and secondary scrub along the escarpment, and may extend into lowland forest; lusher lower seaward slopes (of Mt Njelo, S of Gabela, in Cuanza Sul) where forest merges with abandoned and regenerating shade coffee plantations; degraded secondary forest, old coffee plantations and primary forest at Kumbira Primero, near Conda (Cuanza Sul). In Cameroon, found in primary montane forest at 1000–1450 m.

Food and Feeding. No information.

Breeding. No information.

Movements. Presumably sedentary.

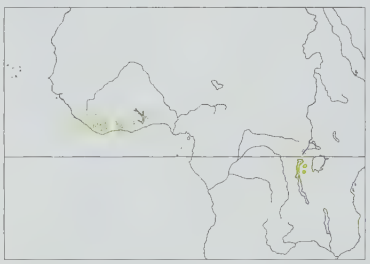
Status and Conservation. Data-deficient. Restricted-range species: present in Cameroon Mountains EBA and Western Angola EBA. Very poorly known species; elusive and formerly thought to be very rare. In Angola, six or seven historical specimens and a few sight records up to 1957, from R Dande near Luanda, Dondo, Mucoso, N'dalatando, Gabela, Quipeio, "Bucaso" (perhaps Buçaco), Quitondo and Canjala (12° S); in 2001–2003 and 2005, in Cuanza Sul, found to be locally surprisingly common in Kumbira Forest, on Mt Njelo (near Conda), where several heard while calling simultaneously and one photographed, in near-pristine forest and degraded secondary scrub, and in 2005 reported as widespread, if uncommon, from R Dande S to Assango, Tondo and Gungo (11°50' S). In Namibia, an individual thought to be of nominate race of present species was collected at Okombambi (R Cunene valley) in 1963. In Cameroon, no records on well-worked Mt Cameroon since 1894, when type specimen of race *perspicillatus* collected (in Buea); individual with characters of present species seen in 1992 in same tree as *M. gladiator* on Mt Kupé, where one was glimpsed in 1997 on Max's Trail; one or two seen at 1250 m at L Edib, in Bakossi Mts, in 1997. Specimen, now lost, said to have been obtained in Kakamega Forest, in SW Kenya, in 1932; individual attributed to this species obtained at Kanzenze, in E DRCongo, in 1905. Widespread destruction of forest in Angola has doubtless compromised the survival prospects of this bush-shrike, which seems always to have been thinly distributed.

Bibliography. Andrews (1994), Anon. (2008d), Bannerman (1939a), Bowden (2001), Bowden & Andrews (1994), Butchart (2007), Butchart & Stattersfield (2004), Chapin (1954), Clancey (1957,1980a), Cohen *et al.* (2004), Collar & Stuart (1985), Collar *et al.* (1994), Dean (2000b), Demey (1997, 2003), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fishpool & Evans (2001), Fry *et al.* (2000), Fuchs *et al.* (2005), Hall (1960a, 1960b), Hall & Moreau (1970), Hall *et al.* (1966), Harris & Franklin (2000), Hawkins (1993), Mackworth-Praed & Grant (1973), Mills & Dean (2007), Moreau & Southern (1958), Prigogine (1984b), Quantrill (2006), Reichenow (1894), Ryan *et al.* (2004), Sekercioglu & Riley (2005), Serle (1954), Sibley & Monroe (1990), Sinclair & Ryan (2003a, 2003b), Sinclair *et al.* (2004), van Someren (1932), Stattersfield & Capper (2000), Stuart (1986), Traylor (1962, 1963), White (1962), Williams (1998), Zimmerman *et al.* (1996).

4. Lagden's Bush-shrike

Malaconotus lagdeni

French: Gladiateur de Lagden **German**: Lagdenwürger **Spanish**: Gladiador de Lagden



Taxonomy. *Laniarius lagdeni* Sharpe, 1884, "Ashantee" (Kumasi), south Ghana.

Forms a superspecies with *M. blanchoti* and *M. monteiri*, with *M. cruentus* sometimes included in same group; voice suggests that it is closest to *M. cruentus*, with which it overlaps in range. Two subspecies recognized.

Subspecies and Distribution.

M. l. lagdeni (Sharpe, 1884) – SE Sierra Leone E to Ghana, possibly to Togo.

M. l. centralis Neumann, 1920 – E DRCongo, W Uganda and W Rwanda.

Descriptive notes. 24·5–25·5 cm; male 84–97 g. Nominate race has forehead to hindneck and side of neck uniformly dark grey, mantle to tail bright olive-green, tail rounded, outer three rectrices tipped bright yellow; upperwing with black flight-feathers, olive on outer webs, upperwing-coverts black, broadly tipped bright yellow, tertials olive-green with yellow tips and wide subterminal black band; brilliant yellow below, throat and upper breast strongly suffused with orange, paling to yellow on lower breast, flanks olive-green (largely concealed beneath spreading yellow belly feathers); underwing-coverts and axillaries bright yellow, underside of flight-feathers shiny dark grey with pale yellow inner edges; iris bluish-grey; bill black, two nasal and four rictal bristles on each side; legs slate-blue. Sexes alike. Juvenile has forehead and cheek to upperparts, including wings and tail, dark greyish-brown, tertials narrowly tipped grey and with blackish subterminal band, chin and throat white, breast white with greyish tinge, centre faintly dappled, sides greyer, upper belly white in middle, grey at side, lower belly, thighs and undertail-coverts warm buff; bill pale grey-brown or horn at first, later becoming blackish. Race *centralis* is very like nominate, but usually has much less orange on throat and upper breast. Voice. A mournful, quavering, drawn-out "whoooooo" or "uuuuuuuh", 0·5–0·7 seconds long, sometimes falsetto at end and disyllabic, "whoooo-up", repeated up to 14 times at intervals of 3–5 seconds; also low, soft "hoh", usually repeated four times at one-second intervals, lower than similar call of *M. cruentus*; pair may call in duet, female's "hoh" synchronous with male's "whoooooo"; also, a more melodious whistle, "heejwoo, heeet-huuuu", mournful "hoop, hooooo" (second note longer and lower), quavering "wip, haww", grating raucous "chaarr-chaarr" and "chrrr", and loud staccato "kkk-k-k-kkk". In E Ghana gives 4–5 soft whistles at rate of one per second, each rising slightly in pitch; in Ivory Coast calls include a whistle like that of African Golden Oriole (*Oriolus auratus*); in Sierra Leone repertoire much more complex, with long whistles and broken whistles; in Rwanda calls just like those of *M. blanchoti*. Reacts readily to voice playback and to human imitations, by falling silent for some minutes, giving rattles, and then singing repeatedly. Makes loud flapping noises with wings when agitated, and may snap bill.

Habitat. Dense creepers in evergreen rainforest, in W Africa at 100–700 m and in E of range at 1400–3300 m (mainly 1900–2700 m); commonest at height of 10–30 m in undisturbed forest, also in lightly logged and even much-disturbed forests. Found also in gallery forest, secondary growth near forest edges and clearings, and open grassy woods at high elevations.

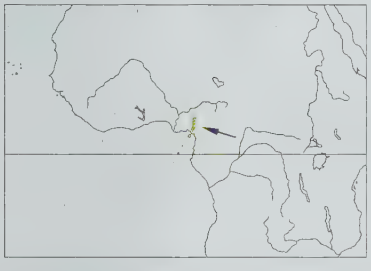
Food and Feeding. Insects, including katydids (Tettigoniidae); also small vertebrates, including a frog, a 10-cm-long *Agama* lizard, and a Blue-throated Brown Sunbird (*Cyanomitra cyanolaema*). Forages in middle strata and in open parts of canopy, mainly at 10–30 m. Main method is gleaning of branches 5–30 mm thick; beats large insects vigorously against perch. Predatory, and small birds warn of its approach, but commonly found in mixed-species foraging flocks of insectivorous birds and often in company of *Chlorophoneus multicolor*.

Breeding. Various evidence indicates approximate seasons Jun–Jul in Liberia, Oct–Jan in Ivory Coast, Dec to at least Feb in DRCongo, and Mar in Uganda; in W Africa, sings in Jan and Feb (although one sang only twice in 5 days) and silent in Jul. Nest built by both sexes, once approaching it while carrying long, very thin fibres and singing in duet as they did so; only one nest examined, a bulky bowl of dry leaves and bracken placed 3·5 m up in fork of small tree in dense secondary growth in abandoned clearing; two uninspected nests were hidden in leafy regrowth on top of broken-off tree c. 6 m tall. Single clutch known was of 2 eggs; in Liberia, two fledglings were guided each by one adult for c. 35 days. No other information.

Movements. Appears to be entirely sedentary.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. In Sierra Leone, uncommon in Gola Forest, formerly probably more widespread. In Liberia, widely distributed but uncommon, known from c. 16 lowland high-forest locations; population estimated to be c. 6000 pairs, with densities locally of 1–3 pairs/2 km². In Ivory Coast, known only from Taï, Mopri

and Yapo Forests. Single old record in Ghana, but possibly occurs in Nini-Suhien National Park and, in SE, recently found in Kyabobo forests, on Togo border; possible presence in Togo suggested by a sight record by Pagala–Ghana road in 1990. In DRCongo, uncommon in Ruwenzoris, Kivu Volcanoes at c. 2400 m (Kibumba, Bitashimwa, Kamatembe, Mt Karisimbi), and S to Itombwe highlands (where uncommon) at 1390–2710 m (Kiliza, Kitongo, Luiko, L Lungwe, Mayamoto, Mianga and Mikenge). In Uganda, scarce at 2200–2700 m in Ruwenzoris and Virunga Volcanoes, but may be locally quite common in Bwindi-Impenetrable Forest. In Rwanda, uncommon in Gishwati Forest; rare in wetter Nyungwe Forest, where only two records in five months, at Uwinka at 2500 m and S of it at 2300 m; recorded also near Mt Bigugu. Poorly known over much of range; elusive, and may therefore be commoner than the sparse data suggest. On the other hand, continuing destruction of forest habitats is bound to affect the species adversely, even though it may have moderately wide habitat tolerance.



Bibliography. Allport *et al.* (1989), Anon. 5. Green-breasted Bush-shrike

Malaconotus gladiator

French: Gladiateur à poitrine verte **German**: Grünbrustwürger **Spanish**: Gladiador Pechiverde
Other common names: Cameroon Mountain/Gladiator/Cameroon Bush-shrike

Taxonomy. *Laniarius gladiator* Reichenow, 1892, Buea, Mount Cameroon, Cameroon.
Closely related to *M. cruentus* and the superspecies formed by *M. blanchoti*, *M. monteiri* and *M. lagdeni*. It has been argued that present taxon, restricted to W Cameroon and extreme SE Nigeria, is no more than a colour morph of *M. monteiri*, an Angolan near-endemic of questionable occurrence in W Cameroon, and, conversely, that a specimen and two sightings of *M. monteiri* from Mt Cameroon and Mt Kupé relate to colour varieties of present species. Monotypic.
Distribution. SE Nigeria (Obudu Plateau and Cross River National Park) and W Cameroon (Bamenda-Banso Highlands, Bakossi Mts, Mt Kupé, Mt Nlonako, Rumpi Hills, Dikume Balue, and Mt Cameroon above Bonenza and Buea).

Descriptive notes. 25–28 cm; 99 g. A large, green bush-shrike with powerful, deep, hook-tipped bill. All of head down to hindneck, side of neck and malar area rather dark grey; rest of plumage mostly olive-green, underparts slightly brighter than upperparts; primaries blackish, narrowly edged olive; alula feathers, primary coverts, greater coverts, tertials, secondaries and inner primaries narrowly tipped yellowish-olive; iris light grey or greyish-white; bill black; legs grey or blue-grey. Sexes alike. Juvenile undescribed. VOICE. Song, audible for at least 1 km, of 3–10 drawn-out, mournful, ventriloquial, low-pitched whistles, each 1–1·5 seconds long, at rate of 1 whistle every 1·5–2 seconds; sometimes whistles end with a falsetto note, and may be shorter and given at faster rate; whistle-song of four types, (1) 5–10 whistles on one pitch, (2) shorter series at same pitch, each whistle ending with upward inflection, "hooooooooo-lwe", (3) combination of preceding two types, and (4) undulating series of whistles at slightly different pitches; in Bamenda Highlands said to have thinner, more muffled whistle than that heard farther S. Call a harsh rasping, at same length and rate as the whistles; one call, thought to be by female, is of up to 5 raucous, tearing "haaarrrr" notes that may be given in duet with (male's) whistles; also, a harsh "chit-chipaa", buzzy "tziktzu" sounds, unmusical chattering, and loud bill-snapping or bill-rattling. Voice very like those of *M. monteiri* and *M. blanchoti*; whistles perhaps slightly longer and "haaarrrr" lower-pitched than in *M. monteiri*. Can readily be attracted close by voice playback or by imitation of whistle, when it becomes agitated and can respond by drumming with bill on branch or may glide into another tall tree and then call.
Habitat. Wet, gloomy primary and secondary montane evergreen forests, often on steep, dissected terrain, at 950–2300 m; also in tree-fern groves, thick second-growth forest canopy along mountain streams, and forest underplanted with subsistence crops. Mainly in high canopy, sometimes down to 10 m or even 2 m above ground; in Bakossi Mts strictly confined to canopy, although readily brought to edges of clearings by voice playback.
Food and Feeding. Insects, including large green locusts (Acrididae), apparently hunted in canopy by gleaning. Occurs singly and in pairs.
Breeding. Gonads slightly hypertrophied in Dec. No other information.
Movements. Resident.
Status and Conservation. VULNERABLE. Restricted-range species: present in Cameroon Mountains EBA. Rare in most of small global range. Fairly common at 1100–1400 m in Bakossi Mts, where at least six territorial birds or pairs found in Apr 1998 in less than 1 km² of forest–grassland mosaic near Kodmin, also common near L Edib, on nearby Mt Kupé at 1100–1950 m and Mt Nlonako at 1400–1600 m. Elsewhere in W Cameroon, recorded S to Rumpi Hills (1300 m, and Dikume Balue at 1520 m) and Mt Cameroon (S slopes above Bonenza at 950–1350 m, and above Buea at 1375–1800 m), and N to Bamenda-Banso Highlands (near Bambulue at 2080 m, Bali-Ngemba Forest Reserve at 1700 m, forest patches between Mbengwi and Tinachong, and Mt Oku at 2200–2300 m). Bali-Ngemba population thought to be healthy; rare in Kilum-Ijim forests at c. 2250 m on Mt Oku, where conservation projects have proceeded for 20 years, but species recorded only in 1984 and 1998. Among the bird species of greatest conservation concern, for which BirdLife International's Kilum-Ijim Forest Projects and, in 1991, Mount Kupé Forest Project were initiated. Mid-altitude forests are largely degraded by logging, firewood collection, and clearance for agriculture and grazing. Loss of forest on Mt Oku and on Obudu Plateau continues at a great rate, although a small patch of Obudu forest has been protected.

6. Uluguru Bush-shrike

Malaconotus alius

French: Gladiateur des Uluguru **Spanish**: Gladiador de las Uluguru
German: Schwarzkappenwürger
Other common names: Blackcap/Black-capped Bush-shrike

Taxonomy. *Malaconotus alius* Friedmann, 1927, Bagilo, Uluguru Mountains, Tanzania.
Differs from congeners in slightly smaller size, black head, brown eye, degree of sexual disparity, and perhaps also voice, and was thought by some possibly to be related to Malagasy vanga family (Vangidae), rather than to current family. Recent studies of nuclear and mitochondrial DNA, however, strongly support its placement within present genus. Monotypic.
Distribution. Uluguru Mts, in E Tanzania.

Descriptive notes. 23–24 cm. Medium-large bush-shrike with huge, powerful, hook-tipped bill. Male has forehead to nape, hindneck and side of neck glossy black, sharply defined all around; upperparts, including wing and tail, uniformly olive-green, concealed parts of remiges blackish; chin and throat bright yellow, breast yellow with green tinge and belly yellow in mid-line, both merging to olive-green at sides, and flanks and thighs olive-green, vent and undertail-coverts greenish-yellow (some individuals have underparts below breast entirely green); axillaries, underwing-coverts and underside of remiges bright yellow, underside of tail olivaceous grey; iris reddish-brown; bill black; legs bluish-grey. Female is like male, but underparts duller and greener. Juvenile undescribed; one identified as such in the field differed from adults in being duller, with crown greyer. VOICE. Distinctive, strident, far-carrying series of low-pitched disyllabic whistles, "huw-teew" or "wu-chiew", second note higher and downslurred; also a series of rhythmic multisyllables, "kokok-teew", "wokwok-teew-teew", "ku-ku-kua-kua"or "chi toktokchii,toktok-chii...". Calls of one individual may be answered by another. Responds to playback of voice.
Habitat. Densest foliage in canopy of submontane and montane forest, from 1300 m to 2100 m.
Food and Feeding. No information.
Breeding. Immature seen in Jul. No other information.
Movements. Presumed sedentary.
Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in Tanzania–Malawi Mountains EBA. Confined to forest on Uluguru Mts, where elusive and rare. N Uluguru is a narrow ridge 25 km long, the highest peak at 2360 m, with Mt Lupanga at N end rising to 2138 m and only 2 km from town of Morogoro; S Uluguru, also 25 km long but up to 17 km wide, is largely an 1800-m plateau, rising to 2668 m (Mt Kimhandu). Forest cover was c. 300 km² in 1955; by 1980s luxuriant humid evergreen submontane forest at 800–1500 m had been largely cleared for cultivation; submontane forest, with canopy height of 30–50 m, gradually gives way to damper montane forest, with canopy height of 10–30 m, between 1500 m and 1850 m, above which the N ridge and S plateau are clothed in wet moss forest. Forest areas had been reduced to c. 220 km² in 2000; remaining forest now nominally protected in two reserves, Uluguru North and Uluguru South Forest Reserves, formerly adjoining but now separated by 1·5 km of farmland. This species is found mostly in N Uluguru, where encountered in 1981 and 1982 at 1300 m on Mt Lupanga and, particularly, 7 km to S at c. 1800 m near Bagilo. During two months of fieldwork in 1993, three or four territories were found on E slopes of N Uluguru and total population estimated at 1000 pairs. In detailed survey in 1999–2000 several birds found in Uluguru North Forest Reserve, an area of 83·6 km², which was estimated to hold c. 1200 pairs, mainly at 1200–1700 m. In what is presently mainly farmland, one individual of this species was seen in 1948 at Bunduki (1500 m), now a tiny and badly damaged forest reserve between N & S Uluguru. In S Uluguru, one individual found in 1981 at 2100 m. The 1999–2000 survey failed to encounter any in Uluguru South Reserve, then 164·3 km² in extent, but in 2007 a pair was located by call playback at 1739 m, near Bunduki (and only 3·4 km from nearest record in N Uluguru), and on same day another was found 400 m from the pair, at 1885 m. One member of the pair was seen a month later. Lower slopes of Ulugurus have been heavily exploited by the dense local human population; submontane forest has been subject to greatest destruction, a trend continuing up to at least 2000. A three-year conservation action plan was initiated in 1999 by RSPB and EU, in collaboration with local organizations and communities. While lower forests continue to be modified by underplanting with banana and other cash crops, the resilience of this bush-shrike's congeners to forest habitat modification suggests that it may yet sustain itself.

Genus *TCHAGRA* Lesson, 1831

7. Brown-crowned Tchagra

Tchagra australis

French: Tchagra à tête brune **German**: Dorntschagra **Spanish**: Chagra Coroniparda
Other common names: Three-streaked Tchagra(!), Brown-headed Tchagra/Bush-shrike; Souza's Tchagra (*souzae*)

Taxonomy. *Malaconotus australis* A. Smith, 1836, north of Kurrichane, northern South Africa.
Forms a superspecies with *T. jamesi* and *T. tchagra*; has hybridized with former. Additional named races are *littoralis* (described from Changamwe, in Kenya) and *congener* (Neu-Helgoland, Songea, S Tanzania), both synonymized with *minor*, and *frater* (Bangwa Mts, W Cameroon), subsumed in *emini*. Nine subspecies recognized.
Subspecies and Distribution.
T. a. ussheri (Sharpe, 1882) – Sierra Leone E to SW & S Nigeria.
T. a. emini (Reichenow, 1893) – SE Nigeria S to lower R Congo, E to N & E DRCongo, S Sudan, Uganda, W & C Kenya, Rwanda and NW Tanzania.
T. a. souzae (Bocage, 1892) – SW PRCongo S to C Angolan plateau (S to N Huíla), E to S DRCongo (to upper Katanga) and N Zambia (near Ndola).
T. a. ansorgei (Neumann, 1909) – W Angola (S Cuanza Norte and Luanda S along coast and escarpment to C & S Huíla and E Namibe).
T. a. bocagei da Rosa Pinto, 1968 – SE Angola (C Cuando Cubango).
T. a. minor (Reichenow, 1887) – SE Kenya, Tanzania (except NW), Zambia (except Ndola and extreme SW), Malawi, N Zimbabwe and N & C Mozambique (S to R Save).
T. a. rhodesiensis (Roberts, 1932) – SE Angola (Cuando Cubango), NE Namibia (along R Okavango E to Caprivi) and NW Botswana.
T. a. damarensis (Reichenow, 1915) – extreme SW Angola, Namibia (except NE), Botswana (except NW), SW Zimbabwe (W & NW Matabeleland) and N South Africa (S to N Northern Cape and W Free State).
T. a. australis (A. Smith, 1836) – SE Zimbabwe (in Sabi valley and SE lowveld), NE South Africa (S to N KwaZulu-Natal), S Mozambique (Sul do Save) and E Swaziland.

Descriptive notes. 17·5–20 cm; male 35–40 g and female 31–44 g (*emini*), male 30–46 g and female 30–33 g (*ussheri*), male 30–33 g and female 27·5–34 g (*minor*). Nominate race has forehead to nape brown, narrow black lateral crownstripe extending back and broadening along side of nape, long pale buff superciliary stripe bordered below by black stripe through lores and behind eye; hindneck, mantle and inner scapulars brown, outer scapulars rufous with blackish-brown feather centres, rump and uppertail-coverts greyish-brown; central tail feathers olive-brown with narrow, evenly spaced, dark greyish bars, other tail feathers black with white tip, white 1–2 mm deep on T2, increasing to c. 11 mm on inner web of outermost rectrix (T6), on which white also extends back along outer web as long narrow wedge; remiges blackish-brown, outer webs of primaries rufous, outer webs of secondaries rufous at base and edges, tertials broadly edged rufous, alula dark brown, outer web of largest feather edged white; median and lesser upperwing-coverts rufous-chestnut, coverts at bend of wing white; ear-coverts and side of neck light brown, cheek greyish-buff; below, dull buff, chin and throat paler, breast and flanks darker grey; axillaries and underwing-coverts buff, large cinnamon-buff area on underside of flight-feathers (formed by pale inner borders); iris purplish-brown with pale inner rim, lower eyelid featherlets white; bill black; legs slate-grey or blue-grey. Distinguished from very similar *T. tchagra* mainly by smaller size and shorter and less robust bill (bill 21 mm long, as against 31 mm); from *T. jamesi* by larger size, different head pattern and somewhat darker plumage. Sexes alike. Juvenile and immature are like adult, but head pattern less distinct, plumage more grey-buff below, throat and breast faintly mottled, tail feathers tipped pale buff, bill horn-brown, eyes greyish dark brown. Races vary relatively little, mainly in size and in coloration of underparts and, to lesser extent, of upperparts: *rhodesiensis* is somewhat paler above and more tawny-buff below than nominate; *damarensis* is paler and greyer above than previous, paler tawny-buff below, with little grey on breast and sides, also slightly larger; *emini* is warmer brown above, with hindneck, mantle and inner scapulars tawny-brown, much paler below, underparts greyish-white with buff tinge, breast and flanks darker grey with brown tinge, undertail-coverts pale buff; *ussheri* is similar to previous, but slightly paler brown, less tawny, above and clearer grey, less buffy, below, also slightly smaller (on average c. 3 g lighter); *minor* also is similar, but slightly paler brown above and whiter below, with less grey on breast and sides, also smaller (on average 5–6 g lighter); *souzae* is richer brown above and darker grey below, differs from all other races in having brown centres of inner scapulars and tertials merging with rufous edges; *ansorgei* is like *emini* above but deep tawny-buff below; *bocagei* resembles last, but upperparts darker. Voice. Territorial song generally given in flight, preceded or accompanied by loud wing-fripping. In W Africa male's song a jaunty series of liquid, descending notes, "tree-tree-treeutreeuu-treeuu…", usually delivered in display-flight and preceded by wing-fripping; in Gabon, PRCongo and DRCongo male's flight song, duration c. 6 seconds, is quite different, one type starting with high, thin note that turns into hard trill and ends with a series of rapid "chup" notes, decelerating and descending scale as it progresses, "wheeeeeeeee-rrrrrrrrrrrrrrupupupchupchupchupchupchup", another type beginning with decelerating rattle and ending with c. 12 downslurred whistles, "ratttatatatatatatatataataa-chyoo-chyoo-chyoo-chyoo...", and in third type whistles may be omitted and rattle a steady churr on one pitch; in E & S Africa male sings a series of 8–30 (usually c. 12) liquid double whistles descending the scale, becoming progressively longer, loudest in middle and dying away at end, "chi-cheeya-cheeya-chooyu-chooyu-chooyu…" or "weeo, wewo-wo, wee-wo-kew-kew-kew-tu-tut-tu-tu"; female sometimes responds in duet with soft, nasal "cheru-cheru-cheru..."; variable, sometimes notes wheezy rather than clear whistles. Song from perch a harsh "jwee-jwee-jwee-jweeu-jweeu-jweeu…"; also a conversational medley of buzzy notes and trills interspersed with *Oriolus*-like "quooeeoo". Contact calls "jwee", "jip", "toptop", a hard trill, a hoarse "jaw" and a rasping medley; alarm "chuk-chuk..."; several other notes described, including a courtship song of nasal "pitcheuu-pitcheuu" and tearing, trilling whistles.
Habitat. Thickets in variety of bushy, wooded savannas, mainly at low and medium altitudes. Forest-savanna edges, abandoned forest clearings; gallery forests in N DRCongo, scrub with Solanaceae and derelict farmland in Liberia; also old cultivations and gardens, and brachystegia (*Brachystegia*), mopane (*Colophospermum*) and other broadleaf woods; bracken briar, elephant grass (*Pennisetum purpureum*) and bushes at edges of bamboo at 1800 m in Malawi and 2250 m in E DRCongo; thickets in arid acacia (*Acacia*) thornbush in SW of range; in Zimbabwe avoids brachystegia and favours nearby valleys with rank forest-edge secondary growth.
Food and Feeding. Mainly insects, including grasshoppers and nymphs, and crickets (Orthoptera), moths and caterpillars (Lepidoptera), tenebrionid and other beetles (Coleoptera), mantids and their egg cases (Mantidae); also spiders (Araneae), and a few small lizards; once a hairless *Leggada* mouse, pulped and disembowelled, fed to nestling. Forages largely on ground beneath bushes, running about and hopping as it searches bases of plants, low branches and foliage; occasionally takes insect in flight. Often in mixed-species foraging flocks. Less arboreal than *T. senegalus*; skulking and retiring, and seldom perches for long in the open.
Breeding. Season May–Jun in Ghana, Mar and Aug–Oct in Cameroon, Aug–Feb in Gabon, Dec in Sudan; Aug–Nov in Angola, Oct in SE DRCongo (Katanga); Sept and Dec–Apr in Uganda, Dec–Oct (mainly Feb–Jun) in Kenya and NE Tanzania, Oct–Jun (mainly Nov–Mar) in rest of Tanzania; Sept–Mar in Zambia and Malawi, Sept–Feb (mainly Oct–Dec) in Zimbabwe, Sept and Nov in Mozambique; in South Africa, Sept–Apr (mainly Oct–Dec) in N but Oct–Nov in KwaZulu-Natal; probably single-brooded. Male defends territory with repeated song flights, first zigzags up bush or small tree to top, where it often sings, posturing and swinging tail, then makes steep upward flight with loud bursts of wing-fripping to a few metres above vegetation, raises head, erects crest, usually fluffs rump feathers and fans tail (white terminal spots prominent), and glides somewhat jerkily down, often landing 20–60 m from take-off place; several individuals can display excitedly together, flying from bush to bush, tails cocked and flicking, repeatedly fripping wings and making "chuk-chuk" and other calls. In courtship male postures in front of female while giving variety of complex calls; he bows, stretches body up, with bill pointing upward, cocks, fans and flicks tail, and makes side-to-side movements of body. Nest, built by both sexes in c. 7 days, a shallow, thin-walled cup of fine twigs, rootlets, leaf stems and coarse grass, lined with finer grass and rootlets, sometimes with feathers, bound on outside with spider web; well concealed c. 1 m above ground on fork of shrub. Clutch 2–4 eggs, average 2·3 in E Africa and 2·4 in S, laid at intervals of 24–48 hours; incubation by both sexes, mainly by female, fed on nest by male, often beginning with first egg laid, period 13–16 days; male returning to nest performs display-flights, which seem to signal nest-relief; chicks fed by both parents, nestling period c. 15–16 days; young remain with parents in family party for at least 5 months, in Malawi becoming independent probably at 6–7 months. Nests sometimes destroyed by rats (*Rattus*), mongooses (Herpestidae), snakes and ants (Formicidae). Longevity more than 6·5 years.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Widespread and locally common over vast range. In S Mozambique (Sul do Save), density varies from less than 5 birds/100 ha to 8 birds/100 ha, according to woodland type; in N South Africa, 1 pair/20 ha in acacia woodland and 1 pair/25 ha in broadleaf woodland; in Swaziland, 2·5–15 birds/200 ha in various habitats. In Kalahari (Botswana), 68 birds seen in transect counts in a dry season following good rains, 34 in next wet season, when rains poor, and only four in following dry season, when area was drought-stricken. Susceptible to disturbance when breeding.

8. Three-streaked Tchagra

Tchagra jamesi

French: Tchagra de James **German**: Somalitschagra **Spanish**: Chagra de James
Other common names: James's Tchagra

Taxonomy. *Telephonus jamesi* Shelley, 1885, Goolis Mountains, Somalia.
Forms a superspecies with *T. australis* and *T. tchagra*; has hybridized with former. Two subspecies recognized.
Subspecies and Distribution.
T. j. jamesi (Shelley, 1885) – extreme SE Sudan, NE Uganda, S Ethiopia, Somalia, N & E Kenya (except coast) and extreme NE Tanzania.
T. j. mandanus (Neumann, 1903) – islands of Lamu and Manda and adjacent Kenya coast (W to Witu and R Tana delta).
Descriptive notes. 16–17 cm; male 22–30 g, two females 26–27 g, unsexed 24–32 g. Nominate race has crown and side of head greyish-brown, narrow black median stripe from bill to nape, black lores and line behind eye, poorly demarcated greyish-white superciliary stripe; upperparts greyish-brown, mantle and scapulars with olive tinge; central tail feathers greyish-brown with fine dark bars, rest of tail blackish, rectrix T2 with small triangular white spot at tip, T3–T6 with white at tips increasing in size towards shorter outer feathers, narrow white wedge on outer web of T6; primaries and secondaries dark brown, base of outer webs of primaries and entire outer webs of secondaries

On following pages: 9. Southern Tchagra (*Tchagra tchagra*); 10. Black-crowned Tchagra (*Tchagra senegalus*); 11. Marsh Tchagra (*Tchagra minutus*); 12. Sabine's Puffback (*Dryoscopus sabini*); 13. Pink-footed Puffback (*Dryoscopus angolensis*); 14. Red-eyed Puffback (*Dryoscopus senegalensis*); 15. Black-backed Puffback (*Dryoscopus cubla*); 16. Northern Puffback (*Dryoscopus gambensis*); 17. Pringle's Puffback (*Dryoscopus pringlii*).

rufous, tertials brown, alula dark brown, feathers with white outer webs; primary coverts brown with rufous outer webs; greater coverts rufous, innermost ones with brown centres, median and lesser coverts rufous; chin and throat buffish-white, underparts grey-buff, darker on breast and flanks, whiter on belly; axillaries and underwing-coverts pale grey, inner borders of remiges pale brown; iris dark brown, ring of white or silvery dots surrounding pupil; bill black; legs slate-grey, blue-grey or olive-green, soles white. Sexes alike. Juvenile and immature are like adult, but stripes on head blackish-brown, side of crown paler and buffier, tail more pointed, white tips tinged buff, breast, belly and flanks buffier, upper mandible slaty, lower mandible slaty with horn base. Race *mandanus* is a little paler than nominate, black crownstripe wider, underparts sandier and less ashy, belly whiter. Voice. Male song in display-flight, preceded by mechanical wing-fripping, a series of emphatic downslurred whistles descending the scale, "wi-weo-weo-weo-weo", "tui-tui-tui-tui-tui…" or "chweeo-chweeo-chweeo", like song of *T. australis* but slightly higher-pitched, individual notes more distinct; whether female ever joins in is not known. Scolds with nasal "chuwaa" and "cherraa-cherraa"; frips wings.

Habitat. Semi-desert, with thickets of dense low thorn-scrub in arid and semi-arid acacia (*Acacia*) bushland and *Commiphora* woodland; wind-stunted aloe (*Aloe*) bushes. From sea-level to 1100 m in Kenya, to 1200 m in Ethiopia.

Food and Feeding. Insects, including cockroaches (Blattodea), mantis egg cases (Mantidae) and moths (Lepidoptera); possibly preys on chicks in Red-billed Quelea (*Quelea quelea*) colonies. Shy and skulking; creeps about in low, dense woody cover but can forage up to 4 m above ground in acacia trees; probably feeds largely on ground. Joins mixed-species foraging flocks in dense cover.

Breeding. Poorly studied. Season Dec in S Sudan, Mar–Apr in Somalia, and Mar–Jul (mainly Apr–May) in S Ethiopia; May on Kenya coast and Manda I (race *mandanus*). Territory advertised with conspicuous song flight, in which bird ascends with wing-fripping, then glides down with tail held fanned; apparently, same flight used for courtship. Nest a small, shallow, compact cup made of dry grass stems, twigs and bark fibres interwoven with some spider web, lined with small rootlets; placed 1–3 m up on fork in thorn bush, often an isolated one. Clutch 2–3 eggs; incubation by both sexes. No further information.

Movements. Resident.

Status and Conservation. Not globally threatened. In SE Sudan, fairly common in Natoporoputh Hills; rather uncommon in Ethiopia; in Somalia, locally common and widespread but absent from most of NE and coastal areas N of 4° N. In Kenya, locally common N & E of highlands, S to Kerio valley, L Bogoria, Samburu, Meru and Tsavo; local in Turkana, confined to regions near Sudan border. Rare in Uganda, where only about five records, near Kenya border in and to N of Mount Moroto Forest Reserve. Only just enters NE Tanzania (near Mkomazi).

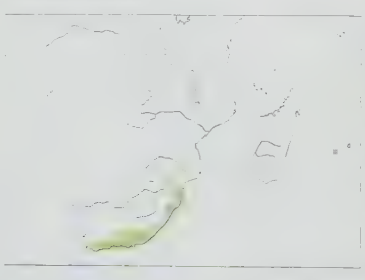
9. Southern Tchagra

Tchagra tchagra

French: Tchagra du Cap **German**: Kaptschagra **Spanish**: Chagra de El Cabo
Other common names: Levaillant's Tchagra, Tchagra Shrike

Taxonomy. *Thamnophilus tchagra* Vieillot, 1816, "Senegal … to Cafferland" = Gamtoos River, South Africa.



Forms a superspecies with *T. australis* and *T. jamesi*. Three subspecies recognized.

Subspecies and Distribution.

T. t. natalensis (Reichenow, 1903) – NE South Africa (E Mpumalanga and KwaZulu-Natal) and W Swaziland.

T. t. caffrariae Quickelberge, 1967 – Eastern Cape from KwaZulu-Natal border S to area of R Great Fish.

T. t. tchagra (Vieillot, 1816) – S South Africa from S Western Cape E to S Eastern Cape (E to Uitenhage region).

Descriptive notes. 20–22 cm; 38–54 g. Nominate race has crown rich dark brown, broad whitish superciliary stripe, black lores and black stripe behind eye (lower eyelid feathers white); upperparts dull brown, rump tinged greyish; central tail feathers dark grey-brown with many, regular, narrow dark bars, remaining rectrices blackish with white tip, white increasing in size outwards to 11 mm on inner web of outermost feather, which has long white wedge along outer web; remiges, primary coverts and greater upperwing-coverts dark olive-brown, outer webs fringed bright rufous, median and lesser coverts dark rufous; ear-coverts and cheek pale grey-brown; chin and throat greyish-white, underparts grey, darker and olive-tinged on side of breast and flanks; underwing-coverts and axillaries dusky grey-brown; iris very dark brown; bill black; legs slaty or bluish-grey. Differs from very similar *T. australis* mainly in larger size and longer and more robust bill (bill 31 mm long, as against 21 mm). Sexes alike. Juvenile is like adult, but upperparts duller, more olive-tinged, underparts buff-tinged, supercilium and tips of tail feathers buffy, tail more pointed, lower mandible with pale base. Race *caffrariae* has crown chestnut-brown, superciliary stripe buffy, flanks, thighs and undertail-coverts olive-tinged, also bill 1·5 mm shorter than that of nominate; *natalensis* has crown redder still than previous, upperparts brighter, underparts much paler, also is slightly smaller than nominate (wing 3–5 mm shorter, bill 2·5–3 mm shorter). Voice. Song of male, delivered in flight and preceded by wing-fripping, a trill followed by short stuttering, croaking notes and then loud, liquid, progressively longer whistles, usually 10–20 (but up to 30), on one pitch and seeming to decelerate as notes lengthen, "trrrrr-itititititi-tyi-tyi-tyi-tewp-tewp-tewp-tewp…"; slower version has no preliminary trill, only a few short notes and then a long series of loud even-pitched whistles, "tyio-tyi-wheeeoo-wheeeoo-wheeeoo-wheeeoo-hooee-hooee-hooee-tooiyup-tooiyup-toooiyup…". After male alights from display-flight the whistles may continue, and male often utters tearing "tzzerrr-tzzerrr" or "sskwirrr…", like calls of *Dryoscopus* species; similar call sometimes given by female when singing at same time as male. Common call a harsh "tschagra"; in aggressive interactions, a complex medley of purring, trilling and tearing sounds, as well as wing-fripping; alarm a searing "neeeaaa"; contact call a quiet "twet" when two individuals foraging close together, a louder harsh "tzzerrr" when farther apart.

Habitat. Ecotonal scrub between grassland and montane, riparian, gulley and coastal forest; dense littoral bush, edges of and clearings in coastal dune-forest, tangles of *Lantana*, brush piles around rural cultivation, dry *Euphorbia* forest and thickets of *Acacia cyclops*; in drier country inhabits thornveld and dense *Acacia* riverine scrub; locally in bracken and scrub between forest and grassland at 1100–1275 m.

Food and Feeding. Insects, including beetles (Coleoptera), corn crickets (Orthoptera) and larvae; also berries and small molluscs. Forages on ground, where it runs and hops about, flicking over debris in manner of a *Turdus* thrush; also searches for food low down in dense low vegetation.

Breeding. Season Sept–Dec in KwaZulu-Natal and Aug–Mar (mainly Sept–Nov) in Western Cape and Eastern Cape; sometimes double-brooded. Advertises and defends territory by wing-fripping followed by song flight (sometimes song from perch) generally low over bushes, often circling; ascends rapidly, fripping wings, rump feathers held fluffed out, at top of ascent head held high and crest raised, then glides down with tail broadly fanned, whistling loudly, and on alighting gives harsh "chok-chok-chok" (often followed by more whistles); in intense territorial threat frips wings excitedly, fans tail, moves body jerkily, or makes slow side-to-side movements of head and body, bows, and cocks and flicks tail. Courtship little known, appears similar to territorial threatening. Nest, built probably by both sexes, a broad, shallow, thin-walled cup made of plant fibres, rootlets and twigs, lined with fine rootlets and sometimes hair; placed on twig fork, or sometimes on top of nest of another bird species, seldom more than a metre above ground and well concealed in *Carissa*, *Rhus*, *Olea* or *Sideroxylon* thicket, or often in isolated bush or small, dense and tangled solitary tree; territory c. 4 ha. Clutch 2–3 eggs, usually 2; role of sexes in incubation not known, sitting bird unusually confiding, incubation period 15·5–16 days; chicks fed by both parents, nestling period 13–15 days. Nest sometimes parasitized by Jacobin Cuckoo (*Clamator jacobinus*).

Movements. Resident.

Status and Conservation. Not globally threatened. Uncommon and local in N of range, commoner in S. In SW Cape occurs W to Hermanus and Robertson and N to Beaufort West; common in Little Karoo; fairly common in S & E Cape but sparse in Transkei and Pondoland; in KwaZulu-Natal sparse and local along coast and inland up to 600 m, N to Lebombo Mts at Ingwavuma, in Swaziland; along Drakensberg Escarpment, extending over it and into C lowveld at Eyrie and Graskop, in Mpumalanga. Reported also from Inhaca I, in extreme S Mozambique. In Tierberg drainage-line woods in E Western Cape karoo vegetation, recorded in 20% of 276 1-km transect counts. Likely to have been affected adversely by continuing destruction or modification of coastal dune-forest, but appears to have benefited considerably from spread of such exotic trees as *Acacia cyclops* and of woody growth encroaching on to grassland near forest, as in East London area; some evidence of expansion of range in last 30 years.

Bibliography. Clancey (1964a, 1971a, 1980a), Cyrus & Robson (1980), David & Gosselin (2002b), Dean & Milton (2001), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fishpool & Evans (2001), Fry *et al.* (2000), Ginn *et al.* (1989), Hall & Moreau (1970), Harris & Arnott (1988), Harris & Franklin (2000), Harrison *et al.* (1997), Hockey *et al.* (1989), Lawson & Edmonds (1983), Mackworth-Praed & Grant (1963), Maclean (1993), Maclean & Vernon (1976), Markus (1972), McCleland (1999), Milstein (1999), Parker (1994, 1999), Priest (1948), Quickelberge (1967), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Sonnenschein & Reyer (1984), Steyn (1996), Tarboton *et al.* (1987), Uys (1989), Uys & Macleod (1967), White (1962), Winterbottom (1962).

10. Black-crowned Tchagra

Tchagra senegalus

French: Tchagra à tête noire **German**: Senegaltschagra **Spanish**: Chagra del Senegal
Other common names: Black-headed Bush-shrike/Tchagra, Black-capped Bush-shrike, Hooded Tchagra; Moroccan Tchagra (*cucullatus*)

Taxonomy. *Lanius senegalus* Linnaeus, 1766, Senegal.

Closely allied with the "*T. australis* superspecies", yet completely sympatric with it. Race *remigialis* intergrades with *nothus* around L Chad. Some geographical variation trivial and clinal; race *warsangliensis* sometimes subsumed in *habessinicus*. At least 17 races have been described; *pallidus* synonymized with nominate and *timbuktanus* with *nothus*, also *camerunensis*, *sudanensis* and *rufofuscus* subsumed in *armenus*, and *mozambicus* and *confusus* in *orientalis*. Ten subspecies currently recognized.

Subspecies and Distribution.

T. s. cucullatus (Temminck, 1840) – Morocco E to N Tunisia and NW Libya.

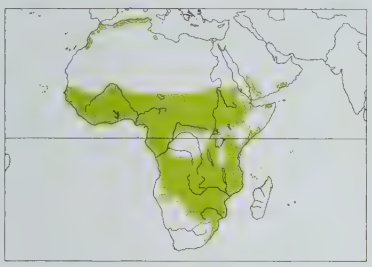
T. s. senegalus (Linnaeus, 1766) – S Mauritania S to Liberia, E to S Mali (S from Mopti), Nigeria (except far N), S Chad and Central African Republic.

T. s. nothus (Reichenow, 1920) – borders of Sahara from C Mali E to L Chad.

T. s. remigialis (Hartlaub & Finsch, 1870) – L Chad E to W & C Sudan (Darfur, Kordofan and C Nile Valley).

T. s. armenus (Oberholser, 1906) – S Cameroon E to N DRCongo, SW Sudan (Bahr el Ghazal) and Uganda, S in W to Angola (S to W & C Huíla and Cuando Cubango) and, in E, to Kenya (except coast), Tanzania (except E lowlands), N Zimbabwe, Malawi and NW Mozambique.

T. s. habessinicus (Ehrenberg, 1833) – S Sudan (E from Imatong Mts), Ethiopia, Eritrea, Djibouti and NW Somalia.



T. s. percivali (Ogilvie-Grant, 1900) – SW Saudi Arabia, W & E Yemen and S Oman.

T. s. warsangliensis S. R. Clarke, 1919 – Warsangli area of N Somalia.

T. s. kalahari (Roberts, 1932) – S Angola (E Huíla E to SE Cuando Cubango), N Namibia, SW Zambia, Botswana, NW Zimbabwe, and N South Africa (North West Province and W Limpopo).

T. s. orientalis (Cabanis, 1869) – S Somalia, coastal Kenya, E Tanzanian lowlands, Mozambique (except Tete region), Zimbabwe (except N & NW), NE & E South Africa and Swaziland.

Descriptive notes. 19·5–23 cm; 42–53 g (*armenus*), 48–55 g (*orientalis*). Nominate race has crown, lores and stripe behind eye black, long broad superciliary stripe very pale buff to whitish; hindneck, mantle and inner scapulars pale brownish, outer scapulars blackish-brown with broad rufous fringes, rump grey, uppertail-coverts greyish-brown; strongly graduated tail (c. 95 mm long), central feathers dark greyish-brown with evenly spaced narrow dark bars, remaining feathers black with broad white tip, white c. 5 mm deep on T2, c. 180 mm deep on inner web of outermost rectrix (T6), latter with long white wedge on outer web; primaries and secondaries are blackish with narrow rufous outer edges,

tertials black with broad bright rufous edges, upperwing-coverts rufous; side of head and neck tawny-brown, grey-brown towards throat; pale grey below, whiter on chin, middle of throat, belly and undertail-coverts, darker on side of breast and flanks; underwing-coverts and axillaries pale rufous, inner edges of flight-feathers pale buff; iris greyish-mauve, some birds with ring of tiny white dots around pupil; bill black; legs grey. Sexes alike. Juvenile is like adult, but crown mottled brown and blackish, stripe behind eye dark brown, supercilium and cheek buffy, tail buff-tipped and more pointed, underparts buffier, bill grey-brown, base of lower mandible paler. Races vary mostly in tone of plumage, in size and in tail length: *nothus* is rather larger and longer-tailed than nominate, also paler, greyish-brown above, white chin, throat, belly and undertail-coverts, pale grey breast and flanks; *remigialis* is paler still, very pale tawny-brown above, wings pale rufous, almost white below, buff tinge on breast and flanks, underwing-coverts white; *armenus* is slightly darker and more tawny-brown above and darker grey below than nominate; *habessinicus* is like previous but darker and greyer, with supercilium narrower; underwing-coverts greyish; *warsangliensis* is like last, but upperparts still darker and greyer, cheek greyer, wing 8–13 mm shorter than in other races; *orientalis* resembles *armenus*, but cheek and ear-coverts browner, less greyish, and underparts slightly paler; *kalahari* is like preceding race, but slightly paler and greyer above, supercilium paler buff, underparts whiter; *cucullatus* is large (wing 92 mm), with tail very long (118 mm), has upperparts darker and greyer-tinged than *armenus*, cheek and ear-coverts darker grey-buff, underparts darker and greyer, underwing-coverts dark cinnamon; *percivali* is distinctive, upperparts and underparts uniform dark grey, but chin and throat white, differs from all other races in lacking any vestige of black or rufous on scapulars and in having central tail feathers black (not grey-brown), supercilium white, tertials unpatterned. VOICE. Song of male a series of rich, lilting, mellow, warbling whistles, sweeter, slower and more deliberate than those of congeners, descending scale and becoming slower: "whee, hooee, heeyoo, hyooo, hooey..."; much individual, seasonal and geographical variation (e.g. two populations 120 km apart in Morocco have substantially different songs). Song of female a hard, rattling, descending trill, given in duet before, during or after male's song; other duets are (presumed female's) chatter and (presumed male's) single, loud, slurred whistle, "trrrrr-hooeeeyou-trrrrr" or "chchchch-huweeyee-chchchch". Race *cucullatus* male has three main songs, i.e. territorial song of 1–3 whistles followed by three descending phrases each of 3 falling notes, a similar song but not descending (each phrase with first 2 notes on same pitch and third note lower-pitched and almost disyllabic), and up to 10 sonorous, mournful, descending whistles; female *cucullatus* sings only third song type; there are strong local dialects. Aggressive interactions and territorial threats involved counter-singing and complex, excited duetting with explosive, whooping whistles, rolling trills, bubbling, tearing and clashing sounds, and much wing-fripping; one bird may give throaty "chrrrrrwee", other replying with low drawn-out "whooooo". Emits "chuk-chuk" notes in mild alarm, harsh tearing sounds in intense alarm.

Habitat. Wide variety of open grassy situations with bushes, thickets and small trees. In Morocco scrubby semi-desert, dry open forest, plantations, gardens, *Argania spinosa* woodland, *Thyula* scrub, dense macchia, bushy slopes and ravines in foothills, stands of olives (*Olea*), holm oaks (*Quercus ilex*) and *Cistus*; in W Africa, sparse acacia (*Acacia*) and *Salvadora* scrub, farmland, suburban gardens, riverine forest; in Ethiopia, mixed forest of olive, juniper (*Juniperus*) and *Podocarpus* at up to 3000 m, and in lowlands semi-desert thornbush, acacia and broadleaf savannas. From sea-level to 1900 m in Cameroon, 1650 m in Uganda, 2300 m in Eritrea and 3000 m in Ethiopia. In S Africa, occurs from sea-level to 1400 m in light deciduous woodland with underlying rank grass, brachystegia (*Brachystegia*) and mopane (*Colophospermum*) woods, bushveld, overgrown eucalypt (*Eucalyptus*) plantations, and coastal thickets.

Food and Feeding. Eats mainly insects, including grasshoppers (Acrididae) up to 6 cm long, crickets (Gryllidae), beetles and their larvae (Coleoptera), caterpillars, wasps (Hymenoptera), cicadas (Cicadidae), termites (Isoptera), mantises and nymphs (Mantidae); also small fruits, including *Lycium* berries; also worms (Annelida), spiders (Araneae), scorpions (Scorpiones), snails (Gastropoda), frogs, tadpoles, small lizards and snakes. Regurgitates pellets of c. 8·5 × 13 mm. Forages on ground under cover of woody growth and low down in vegetation. Hops, leaps, lopes and runs about on ground, searching slowly and carefully, flicking aside debris with bill in manner of a *Turdus* thrush; pulls dung apart; jumps up to take insect from low vegetation. Creeps around in bushes, searching trunks, branches and foliage; hammers snails off branches and eats them on the ground. Carefully wipes large hairy caterpillars on the ground before consuming them. Sometimes takes aerial prey. Joins mixed-species feeding flocks.

Breeding. Season May–Jun in Morocco and Apr–May in Tunisia; Aug in Mauritania, Jul in Senegal and Oct–Nov in Gambia; in Ghana, Apr–Jun in S and Jul–Sept in N; Jun–Jul in SW Niger and Feb–Sept (mainly Jul–Aug) in Nigeria; Aug–Nov in Sudan, Apr–Jul in Ethiopia, May in Oman; Sept–Nov in E & S DRCongo, Feb, May–Jun and Aug in Uganda, all year (mainly in early rains) in Kenya and N Tanzania; Aug–Oct in Angola, Sept–Jun (mainly Oct–Nov) in Zambia, Oct–May in Malawi, Sept–Mar in Mozambique, Dec in Botswana, Aug–Apr (mainly Sept–Dec) in Zimbabwe, and Sept–Feb (mainly Oct–Dec) in South Africa. Male defends breeding territory for much of year, advertises it by singing in display-flights, rising steeply to height of 10–15 m, fripping wings loudly and repeatedly as he does so, head held up and tail depressed, at highest point raises crest, and then glides down in arc of as much as 60 m, with intermittent jerky movements, singing lilting whistles and fanning tail widely before alighting; occasionally female accompanies male in similar flight and may call in duet; rival males conduct vigorous song-duels on ground or in bush, dominance established vocally and, at perch, by height which upstretched bird can reach. Courtship involves same display-flights; female joins male in duet, often zigzagging up through bush to perch upright just below him; pair performs elaborate duets while in steeply upright posture and variously cocking, lowering, rotating and sometimes fanning tail, moving head and body slowly from side to side, and bowing; several males may chase one female. Nest built by both sexes, a shallow compact cup made of rootlets, fine twigs and tendrils, lined with grass stems and finer rootlets, sometimes bound with spider web on rim and decorated with dry leaves or snakeskin, sited up to 6 m (mainly c. 2 m) above ground in horizontal or vertical fork in bush or small tree; territory 4–25 ha, often c. 10 ha. Clutch 1–4 eggs, usually 2–3; two egg types in Nigeria (see page 76); incubation by both sexes, mainly by female, which sits very tight, relieving male alights in nest tree and works his way up (or down) to nest, partners exchange calls for up to 2 minutes before she leaves, incubation period 12–15 days; chicks fed by both parents, nestling period 14–16 days; fledged young remain with parents for several months.

Movements. Resident; some evidence of local movements in NW Africa, in extreme N parts of range in W Africa, and in Malawi.

Status and Conservation. Not globally threatened. Generally common. Uncommon to locally common in Morocco and Algeria, commoner in Tunisia; in Morocco, density in *Thyula* scrub 8 pairs/km², in macchia 2·7 pairs/km², in woodland 1·3 pairs/km². Fairly common and widespread in SW Arabia wherever light woodland occurs. In sub-Saharan Africa, common and locally almost abundant throughout most of vast range; density in Odzala National Park (PRCongo) and Limpopo Province (N South Africa) c. 4 pairs/km²; in four Swaziland acacia savannas, respectively 25, 33, 58 and 150 birds/10 km². Population in S Mozambique (Sul do Save Province) possibly in excess of 500,000 individuals. Many of this species are killed for traditional medicine, e.g. in Benin (for supposedly improving memory) and in Nigeria (where claimed to aid talent).

11. Marsh Tchagra

Tchagra minutus

French: Tchagra des marais **German**: Sumpftschagra **Spanish**: Chagra Marismeña
Other common names: Blackcap Bush-shrike, Black-capped Shrike/Bush-shrike, Blackcap(ped)/Little Blackcap Tchagra, Lesser/Little Tchagra/Shrike/Bush-shrike; Anchieta's Tchagra, Southern Blackcap (*anchietae*, *reichenowi* and *remotus*)

Taxonomy. *Telephonus minutus* Hartlaub, 1858, Ashanti, Ghana.
Somewhat aberrant species, sometimes treated in a monotypic genus *Antichromus* or *Bocagia*; differences from congeners moderately notable genetically, but morphologically and biologically no greater than differences among species within other malaconotid genera. Nominate sometimes separated from other races as a distinct species. Races *anchietae*, *reichenowi* and *remotus* intergrade where they meet; whether nominate and *anchietae* also do so is not known. Four subspecies recognized.

Subspecies and Distribution.
T. m. minutus (Hartlaub, 1858) – Sierra Leone E discontinuously to lower R Congo, N & E DRCongo (S to NW shores of L Tanganyika), S & E Sudan, Ethiopia, W Kenya and NW Tanzania.
T. m. anchietae (Bocage, 1869) – Angola, S & SE DRCongo, N Zambia, SW Tanzania and N & W Malawi.
T. m. reichenowi (Neumann, 1900) – E, C & S Tanzania (coastal lowlands S to R Rufiji, and inland in S Dodoma, Morogoro, Iringa and Songea).
T. m. remotus Clancey, 1959 – SE Malawi, N & W Mozambique and E Zimbabwe.

Descriptive notes. 15–19 cm; male 25–38 g, female 30–37 g, unsexed 32–41 g. A rather small, large-headed, thickset tchagra with comparatively short graduated tail; bill shorter and relatively wider than that of congeners. Male nominate race has glossy black head, whitish cheek, dark rufous-brown mantle, back and upperwing, rump slightly greyer; scapulars black, innermost with rufous inner web, outermost with rufous outer web and tip; tail blackish, feather tips buff, narrow on central pair and increasing in depth outwards, T5 with 5 mm of buff at tip, T6 also with buff outer margin; chin white, throat buffy white, underparts rich ochre; large rufous-buff area on underwing formed by broad inner borders of flight-feathers; iris pinkish-brown or reddish-brown; bill black; legs dark grey. Female is like male, but has striking, well-defined superciliary stripe from base of bill to above ear-coverts. Juvenile initially (one week after leaving nest) looks almost white-headed, has forehead, crown and nape white, dusky stripe through eye, broken blackish lateral crownstripe above white supercilium, with throat, side of head and hindneck very pale buff, eye black, bill bluish-grey with yellowish cutting edges; later is like female but supercilium buffy white, crown streaked and mottled, mantle and scapulars with blackish streaks, tail dark brownish-black, underparts buffier, bill horn-coloured, base of lower mandible paler, eye grey-brown; immature plumage transitional between those of juvenile and adult, buffy supercilium becoming black on male and white on female. Race *anchietae* is like nominate, but scapulars dark rufous-brown (concolorous with back and wings), wing on average 3 mm longer; *reichenowi* is like previous but less richly coloured, black crown separated from rufous of mantle by buffish-white hindneck, buff tail-feather tips greyish subterminally, same size as nominate; *remotus* resembles last, but slightly paler and larger. VOICE. Song of male, in display-flight preceded by muffled wing-fripping, is short, cheery whistled "tuwee-twer-tuweet" or "chee-chu-chweeoo" (nominate race), or "tuweetilweuu" (*remotus*) or trilling "pirree ti-weep peeeu" (*anchietae*); female often responds in duet with nasal "cherrrruu"; in territorial aggressiveness, songs of both sexes often followed by discordant, rapid "tzzerrr-tzzerrr, tzzrrrr-tzzrrrr" notes. Alarm "klok", "tchup" or repeated harsh "tzik"; contact call a softer "tzik-tzik" by male, answered with nasal bleating by female.

Habitat. Rank waterside vegetation with moist grassy hollows, scattered bushes and elephant grass (*Pennisetum purpureum*); edges of marshes, papyrus (*Cyperus papyrus*) swamps and coastal lagoons; streamside reeds, damp forest borders, abandoned cultivation with regenerating scrub; sugarcane and maize crops. In Ethiopia long rank grass with scattered trees and bushes, in particular *Hyparrhenia*, in combretaceous woodland; also in cotton and coffee plantations; in PRCongo common in dambos with patches of *Jardinea* and *Clappertonia*. Mainly at low altitudes, but at higher

elevations (up to 2150 m) in Zambia and Malawi inhabits bracken briar; occurs at up to 2000 m in E Africa, 1800 m in Cameroon and 1450 m in Zimbabwe.
Food and Feeding. Quite large insects, including grasshoppers (Acrididae), beetles (Coleoptera), dragonflies (Odonata) and bugs (Hemiptera). Forages low down in vegetation, while clinging to reeds and grass stems; searches trunks, branches and foliage. Sometimes feeds on ground, and hawks insects in flight.
Breeding. Not well studied. Season Sept in Ghana, Jun–Jul in Nigeria and Oct in Sudan; various evidence indicates breeding in Feb–Jun and Sept in Uganda; May–Jun and Nov in Kenya and N Tanzania; Oct in Angola; in DRCongo, Jul–Oct (Uele) and Sept–Mar (Katanga); Nov–Dec in Zambia, Nov in Malawi, Nov–Mar in Zimbabwe, and Dec–Mar in Mozambique. Monogamous and territorial. In mornings and evenings perches boldly for long periods on tall grass stem or bush up to 5 m high, in upright posture with tail depressed a little; territorial male rises in air with muffled wing-fripping, at apex raises head and crest and sings while gliding back to perch with tail fanned; female may join male in giving less elaborate song flight; in aggressive territorial interactions song flights made repeatedly, singing combined with calls; in bushes males, sometimes with a female, move about excitedly, bowing, swaying body jerkily from side to side, cocking tail and flicking wings. Courtship apparently involves same song flight, male fluffing out rump feathers and chasing female, both sexes making nasal mewing calls. Nest built by both sexes, a deep, thin-walled cup made of thin, pliant, interlocking rootlets, woody stems and tendrils, sometimes bound on outside with a little spider web, often decorated copiously with fragments of snakeskin, sometimes lined with fine grass, moss and down; sited 0·8–1·8 m above ground in upright fork in bush, fork partly incorporated into sides of nest; nest can be reused for second brood; pair lives throughout year in territory of c. 1 ha. Clutch 1–3 eggs, usually 2–3; incubation by both sexes, in subequal spells of 40–60 minutes; no information on duration of incubation and nestling periods. Nests probably occasionally parasitized by Black Cuckoo (*Cuculus clamosus*), begging juvenile of which was seen to be accompanied by individual of present species in Benin.
Movements. Resident, perhaps also partially migratory; most records in N part of W African range are in rains, May–Sept.
Status and Conservation. Not globally threatened. Generally uncommon, and frequent or common only locally, within its very large but discontinuous range. This species' evident dependence on swamps suggests that it may be at risk locally and regionally in drought conditions and as a consequence of drainage and water management. Has not been recorded on Kenya coast for decades, and in W of that country no longer occurs in Nairobi, Thika, Murang'a or Nandi areas; presently confined to W of Rift Valley in areas above 1000 m altitude with annual rainfall exceeding 1000 mm. Considered "critically endangered" in Zimbabwe; in 1997, a section of prime habitat, a 4·5-km vlei near Wamba, in Eastern Highlands Tea Estate, was dammed for irrigation, destroying 3·5 km and reducing this species' population from 50 individuals to only 24; in 1998, the remaining 1 km of vlei was taken over for sugar cane and root crops, and by late 2000 only one pair remained; in 1997 there were 12–14 birds in nearby Katiyo Tea Estate, and they, too, had disappeared by 2002 after vlei was planted with bananas and root crops; in 1999, BirdLife Zimbabwe began an educational conservation programme in Honde Valley involving 23 schools, and by 2003 population of this tchagra had increased from two to ten birds.

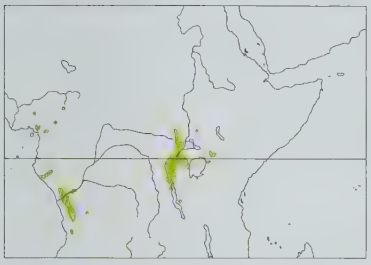
Genus *DRYOSCOPUS* Boie, 1826

12. Sabine's Puffback

Dryoscopus sabini

French: Cubla à gros bec **German**: Dickschnabel-Schneeballwürger **Spanish**: Cubla de Sabine
Other common names: Large-billed Puffback

Taxonomy. *Thamnophilus sabini* J. E. Gray, 1831, Sierra Leone.
Differs from congeners in bill morphology, and has diagnostic whistle call. Two subspecies recognized.
Subspecies and Distribution.
D. s. sabini (J. E. Gray, 1831) – Sierra Leone E to S Nigeria.
D. s. melanoleucus (J. Verreaux & É. Verreaux, 1851) – Cameroon S, discontinuously, to N Angola and patchily in NE, C & S DRCongo.



Descriptive notes. 18–19 cm; male 31–44 g, female 32–39. Distinctive puffback with long, robust bill, culmen flat-convex and wide between nostrils; remiges curved, wing very rounded. Male nominate race has forehead to mantle and scapulars, also uppertail-coverts and tail, black with dark blue gloss; back and rump contrastingly white (plumage long, very dense and fluffy); upperwing black, less glossy and less bluish than mantle; entire underparts white, underwing-coverts and axillaries white, underside of remiges slaty black, underside of tail glossy black; iris dark brown; bill greyish-black, upper mandible pale bluish-grey except for black tip and cutting edges; legs blue-grey. Female has forehead, crown, nape and hindneck medium grey, merging into olive-grey on mantle, warm rufescent brown on back and scapulars, and rufous on rump, tail and wing; back and rump plumage thick and fluffy (although less so than male's); pale grey or whitish above eye, joining with narrow white ring around eye; sometimes a short, narrow pale line above lores; lores grey, ear-coverts grey-brown with thin whitish shaft streaks; chin, throat, breast, flanks, and sides of belly and undertail-coverts uniformly pale rufous, centre of belly and vent snow-white; underwing-coverts and axillaries pale rufous, underside of remiges dark grey and of rectrices pale brown; bare parts as for male. Juvenile is thought to be like female; immature male like adult female, young male moulting into adult plumage replaces feathers on upperparts irregularly, has blotchy mix of grey and black feathers on head, of rufous and black feathers on back, tail and wings, and rufous and white patches on underparts. Race *melanoleucus* is almost identical to nominate, but has tail shorter, average 61·5 mm (nominate average 73 mm), and tail of female is slightly darker than that of nominate female. Voice. Song a series usually of 5–15 notes on descending scale, at first short, thin, clipped and high-pitched, like squeaky bicycle pump, gradually becoming longer, louder and somewhat ringing, ending abruptly, "tsee-tsu-tsu-tsu-tsu-tew-tew-tew-tew-teewp-teewp-tewp", very like song of Yellow Longbill (*Macrosphenus flavicans*); short song of 5–6 notes also likened to songs of Gabon Woodpecker (*Dendropicos gabonensis*) and of Olive-green Camaroptera (*Camaroptera chloronota*); song can be of far more than 15 notes, lasting 2–3 minutes. Also nasal rasping "tzrrrrr", "tzwee-tzwee" or "tzrrreeeeu", and has varied repertoire of harsh calls, including loud clicking notes, descending "cheeerrrrr" or "trtrtrtrtr" rattle lasting up to 4 seconds, short "djip", disyllabic "tuk-rrraaa'" or "di-rrrrraaaaa", also contact call "krriéé"; in aggression a grating, upslurred "jooway". Almost in duet, one individual can give hard rattle and mate joins in before it has ended, this often given in flight with much wing-fripping.
Habitat. Canopy of tall primary forest, logged and secondary forests, riparian forest and swamp-forest, edges and thick growth in clearings, old African mahogany (*Khaya ivorensis*) plantations, and suburban gardens with tall timber; often in canopy of emergent trees and in curtains of hanging lianas.
Food and Feeding. Insects, including grasshoppers and crickets (Orthoptera), beetles (Coleoptera), moths and large caterpillars (Lepidoptera), and termites (Isoptera). Keeps at heights above ground of 20–45 m, mainly 30–35 m, hardly ever descending into middle strata. Forages by gleaning conspicuously on twigs and vines and under leaves in outermost branches, examining them closely. In pairs; commonly in mixed-species foraging flocks.
Breeding. Almost unknown. In Liberia, enlarging gonads in Jun, Aug–Sept and Nov, and courtship display seen Aug and Oct–Nov; in Ghana, courtship display in Jul; in Nigeria, courtship display in Jun, enlarged gonads in Oct; in Gabon, family parties seen at end of short dry season and in following wet season. Courtship consists of wing-fripping flights during which white rump feathers puffed out.
Movements. Resident.
Status and Conservation. Not globally threatened. Locally fairly common to rare. Estimated densities of 2–5 pairs/km² in Liberia and 8–10 pairs/km² in Gabon. Uncommon in Sierra Leone, where records from Bo, near Matotaka, and in Sugarloaf Forest, also in logged and primary forest in Gola Forest; eight birds seen in two years in 1930s. Not uncommon in Liberia, where recorded at 35 localities from coast at Cape Mount and Harbel to Nimba highlands and Wologizi range. In Ivory Coast, known from tall forests from Taï and Ayamé to Lamto, Yapo, Daloa, Bossematié, and Anguédédou and Banco National Park (near Abidjan); frequent in the last and in Taï Forest National Park, Yapo and Bossematié. In Ghana, not uncommon from Sunyani, Kumasi and Tesano to forests in extreme SW, including Kakum, and on coast at Axim, Cape Coast and Accra; in 1870s was said to be very common in some areas; in 2005, found to be common in six selectively logged reserved forests, frequent in two others and uncommon in seven more. Single record (on R Gonobé) in Togo; in Benin, recorded twice in Niaouli Forest. In Nigeria, uncommon from near Lagos to Ibadan, Ife, Omo Forest Reserve, Benin and Umuagwu. In Cameroon, frequent at Kumba and Mt Kupé at 850–1300 m, common in Rumpi Hills Forest Reserve, uncommon in Korup National Park, and scarce in Mbam-Djerem National Park; records from Mbonge and SE to R Dja. Uncommon in Gabon S to Lopé National Park, but frequent to common in SW, in Loango and Moukalaba-Doudou National Parks. In PRCongo, common in Nouabalé-Ndoki National Park, frequent in Odzala National Park; in Central African Republic, recorded only in SW (Haute Sangha). Uncommon in Angola in forests of Cabinda, and recorded also from upper R Cuango R in Lunda Norte. Rare in DRCongo, where known from at least seven localities in NE and Ituri, including Avakubi, Ngayu and Mawambi, from Mbandaka and upper R Maringa (on equator), and from at least five places in Kasai, including Kabambaie, Tshikapa and Ngombe.

13. Pink-footed Puffback

Dryoscopus angolensis

French: Cubla à pieds roses **German**: Rotfuß-Schneeballwürger **Spanish**: Cubla Patirrosada

Taxonomy. *Dryoscopus angolensis* Hartlaub, 1860, Bembe, Loanda Province [= Uíge], Angola.
Apparently most closely allied to *D. sabini*, juveniles of the two being strikingly alike and females very similar to each other in plumage. Race *boydi* not well defined, possibly represents clinal variation and perhaps better merged with nominate. Four subspecies recognized.
Subspecies and Distribution.
D. a. boydi Bannerman, 1938 – extreme SE Nigeria and W Cameroon.
D. a. angolensis Hartlaub, 1860 – S Gabon, S PRCongo, SW DRCongo and NW Angola.
D. a. nandensis Sharpe, 1900 – extreme S Sudan, NE & E DRCongo, W & S Uganda, extreme NW Tanzania, W Rwanda and W Kenya.
D. a. kungwensis Moreau, 1941 – Mt Kungwe Mahale (Mahare), in SW Tanzania.
Descriptive notes. 15–17 cm; 35–40 g. Distinctive puffback with bill comparatively short (shorter than head), quite slender, and not strongly hooked. Male nominate race has forehead to upper mantle black with dark blue gloss, lores, upper cheek and ear-coverts dull greyish-black; lower mantle dark grey, scapulars, back and rump mid-grey to pale grey (white feather bases can show through), uppertail-coverts dark grey; tail very dark brown, feathers structurally barred blackish; upperwing uniformly dark greyish-brown; chin and throat greyish-white, grading into pale grey on

breast and flanks, belly almost white in middle, thighs, vent and undertail-coverts pale grey; underside of tail and underside of flight-feathers shiny dark grey, underwing-coverts and axillaries pale grey or whitish; iris dark brown, edge of sclerotic membrane bright cobalt-blue or violet-blue, rim of eyelids dusky with dark red tinge; bill black; legs pale pink-violet or lilac-grey, claws grey. Female has forehead, crown, hindneck, lores, upper cheek, upper ear-coverts, side of neck and upper mantle uniformly bluish-grey, merging into olive-brown on lower mantle and scapulars; back and rump olivaceous grey, uppertail-coverts olive-brown, tail greyish-brown; lower cheek and lower ear-coverts rufous-buff, slightly streaky; chin, throat, breast and upper flanks light orange or rufous, lower flanks and thighs pale rufescent brown, belly white, greyish-white or creamy white, undertail-coverts whitish or pale rufous; underwing-coverts and axillaries bright rufous, underside of flight-feathers glossy dark grey with inner border of feathers proximally pale rufous; underside of tail ochreous brown; bare parts as for male, but lower mandible pale. Juvenile is like female, but upperparts duller, mantle with olive-brown wash, underparts tawnier, bill pale, eyes brown, legs pinkish-brown. Race *nandensis* male is like nominate, but forehead, crown, nape, lores, upper cheek and upper ear-coverts dull blackish-grey, grading through hindneck into glossy bluish-black on upper mantle, female identical to nominate female; *kungwensis* resembles previous, but male has greyer crown and neck; *boydi* male has slightly greyer head than nominate male and is a little smaller. Voice. Not very vocal. Variety of harsh, clipped calls, "jack", "djik", "chit-tup" and "jyoop-jyoop"; also a short, hard dry trill, perhaps the same as a reportedly harsh churring or jarring "tzik-tzzik" contact call given by both sexes; emphatic, grating "tchew" or "cheow" repeated unevenly up to 30 times; three males chasing each other gave loud "krrraa" rattles preceded by "pik pik".

Habitat. Mature montane forest at intermediate altitudes, but sometimes down to sea-level, also old second growth; also young, scrubby secondary growth and edges and interior of coffee forest; up to 2500 m.

Food and Feeding. Insects, mainly beetles (Coleoptera), also grasshoppers (Acrididae) and caterpillars. Keeps mainly in foliage high up in trees, although often comes down to middle levels of forest. Hops through and gleans foliage on large subcanopy branches, usually silently, moving much like a large sylviid warbler. Usually in pairs, sometimes singly; commonly joins mixed-species foraging flocks.

Breeding. Barely known. Birds in breeding condition in Apr in Cameroon; various evidence of breeding in Jan, Apr–Jun and Nov in E DRCongo (Itombwe) and in Jan, Mar and Sept in Uganda. Nest a substantial lichen-covered cup, incorporating spider web, one placed c. 7 m up in dense foliage on creeper-covered dead tree; a female carried large clump of green moss to presumed nest 8–13 m above ground in Bwindi Impenetrable Forest, in Uganda. No other information.

Movements. Resident. Records on Cameroon coast suggest that part of Mt Cameroon population may move to lower levels in non-breeding season.

Status and Conservation. Not globally threatened. Locally common to uncommon. Range highly fragmented, with main centres in W Cameroon, NW Angola, Rift Valley mountains, and isolated montane outliers. Few records in Nigeria, from Mambilla Plateau (Ngel Nyaki forest), Obudu Plateau and Cross River National Park. In Cameroon, occurs at sea-level at Limbe (Victoria), uncommon on Mt Cameroon at 700–1280 m, fairly common on Mt Kupé at 760–1950 m, common to abundant on Mt Nlonako at 1200–1750 m and at Dikume Balue (Rumpi Hills) at 1000–1700 m, and quite common in Bali-Ngemba Forest Reserve at 1700–1800 m; known also from Bafeng, Ngaoundéré, Yoko, Yaoundé and Lolodorf. Single record in Gabon, at Mouila in 1984; at lower R Congo (S PRCongo and W DRCongo), not uncommon in Mayombe (Col de Bamba, Temvo, Makaia Ntete), inland to Thysville; in Angola, locally common in provinces of Zaïre, Cuanza Norte and Malanje (Bango), S to Gabela, in Cuanza Sul. In Sudan, recorded only in Imatong Mts, where uncommon at 2400 m. In E DRCongo, widespread from Arebi, in N, to Baraka, in S; common in Itombwe Highlands at 1170–1830 m, and near Baraka at 2200–2300 m. In Uganda, common in Bwindi Impenetrable Forest, elsewhere local and uncommon at 900–2500 m from Kibale S to Mabira and Malabigambo; also on Mt Elgon. In Rwanda, found at up to 2300 m in W Nyungwe Forest. In Kenya, confined to Kakamega and Nandi Forests, where uncommon; an old record from Kenyan side of Mt Elgon at 2400 m; reported also from Tugen Hills. In Tanzania, recorded at Minziro Forest Reserve, in NW, and at Mt Kungwe, in W. Reports of this species' presence in N Central African Republic (Manovo-Gounda Saint Floris National Park) require corroboration.

Bibliography. 14. Red-eyed Puffback

Dryoscopus senegalensis

French: Cubla aux yeux rouges **Spanish**: Cubla Senegalesa
German: Schwarzschulter-Schneeballwürger
Other common names: Black-shouldered Puffback

Taxonomy. *Sigelus senegalensis* Hartlaub, 1857, "Senegal"; probably = Gabon.
Forms a superspecies with *D. cubla*. Monotypic.

Distribution. From W & SE Nigeria very patchily S to NW & NE Angola, discontinuously E to N Central African Republic, NE DRCongo, W Uganda and Rwanda.

Descriptive notes. 16–18 cm; 23–34 g. Male has forehead to mantle, scapulars and upperwing black, glossed dark blue, back and rump white (plumage dense and capable of erection), uppertail-coverts glossy bluish-black, tail glossy black; entire underside white with cream wash (patchily greyish where dark grey feather bases show between white feather tips), chin with many filoplumes 5–8 mm long; underwing-coverts and axillaries white, underside of flight-feathers greyish-black; iris orange-red; bill black; legs grey. Distinguished from very similar *D. sabini* mainly by somewhat smaller size, shorter and less deep bill with less prominent hook at tip, and paler eyes. Female is like male, but has white stripe from nostril to above eye, lores black, upper cheek white (not

black), lower mantle, scapulars, wing and tail dark greyish-brown, back and rump smoky mid-grey, or mantle sometimes glossy black, rump sometimes white; 29 females examined, from R Dja (Cameroon) four have white rump and five have grey rump, from Efulen (Cameroon) three have white-and-grey rump and two grey rump, four from E DRCongo have white or pale grey rump, and eleven are intermediate, also two females from Kumba (Cameroon) have grey mantle and two have black mantle, most R Dja females have black mantle, most from Victoria (Cameroon) have grey mantle, others are intermediate. Juvenile male (almost fully fledged) is like adult male in colour, but plumage fluffy; immature male seems to be exactly like adult female. Voice. Vocal, but keeps hidden. Male's song a rolling snore lasting up to 2 seconds, beginning with tearing sound, loudest in middle and then dying away, "tzzzzrrrree-eeawrrrrr", or ending with single "jit" (possibly given by a second individual); female sometimes joins in with snapping and scolding notes, "chrraaay", or with softer, rasping notes like those of a *Ploceus* weaver, "tsap-tsap-tsap-tsap". Another male song is shorter, upslurred "djit-djurrreeee" or "djit-jijurrreeeeya". Male's territorial call, from perch and in flight, a loud, explosive "kyow", "chyow" or "ptiou", frequently repeated, or monotonous "chew-chew-chew..." or "tzew-tzew-tzew..."; the loud "chyow", high-pitched and downslurred, can be repeated on same pitch up to 20 times, at rate of 2 notes per second; also utters fast, dry, harsh rattle or ratchet-like note, and loud clicking "tik-tik-tik-tik...". Makes wing-fripping sounds in flight.

Habitat. Inhabits secondary forest, large thickets, forest clearings and gallery forests; less common in very open forest; keeps chiefly in canopy of tall, isolated trees, also in smaller trees in old clearings. At M'Passa, in Gabon, commonest in thin woods with open spaces and in isolated trees left in clearings; also in cacao and avocado (*Persea americana*) plantations, and in clearings in primary forest, although not in primary forest itself. In Lopé National Park, also in Gabon, inhabits gallery forest and small forest patches; penetrates primary forest, but only a short distance from edge.

Food and Feeding. Prey includes beetles (Coleoptera), bugs (Hemiptera), orthopterans and their eggs, dictyopterans, termites (Isoptera), large caterpillars, a spider (Araneae) and a tiny frog. Occupies mainly middle and upper levels of vegetation, but sometimes lower levels at forest edge; forages 10–25 m above ground, sometimes higher, rarely lower. Occasionally flies up to hawk a flying insect. Occurs in pairs and in family parties of three or four individuals; often in mixed-species flocks.

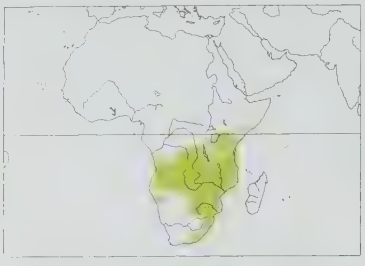
Breeding. Season Feb, Aug and Nov in Cameroon and Dec–Mar in Gabon; in breeding condition throughout year and nestling found in Sept in NE DRCongo; breeding condition Jul–Sept and Nov in Uganda. Strongly territorial; male regularly traverses territory in canopy, fripping wings and singing as he flies from tree to tree, quite often raising puff of white rump feathers, aggressive towards *Malaconotus bocagei* in its territory. Such flights serve also as courtship, and occur during nest construction and incubation stages. Nest built by female, accompanied by displaying male, a small, compact cup made of fine rootlets and vegetable fibres held together with spider web, externally covered uniformly and entirely with pieces of lichen; placed 4–16 m above ground on multiple horizontal fork in middle of or near end of branch. One clutch was of 2 eggs; incubation by female only, period 16 days; chicks brooded by female, male passes food items to her for delivery to young, chicks fed also by both parents during independent short nest visits; no information on duration of nestling period; fledglings remain with parents almost until the next nesting attempt.

Movements. Resident.

Status and Conservation. Not globally threatened. Rare to locally common. Density of 2–4 pairs/10 ha in N Gabon. Only three records from Nigeria, at Oshogbo and on Obudu Plateau. In Cameroon, very common at Kumba, frequent on Mt Kupé at 750–1300 m, abundant in Mbam-Djerem National Park, and record at Bali (Bamenda Highlands); widespread in S, and reported as abundant at Bonga in 1920s. In Gabon, widespread in N from R Ogooué (Ogobai) and R Moonda (Mondah) E at least to M'Passa, and throughout Lopé National Park; recorded at Mimongo, Kango, Cape Esterias and Mbigou, and frequent around Mouila. In PRCongo, common in more humid parts of Odzala National Park, common in Bomassa region of Nouabalé-Ndoki National Park, and widespread in Mayombe; frequent in Bamingui-Bangoran National Park, in Central African Republic. In DRCongo, widespread in NE (Uele), and possibly extends right across N part of country from NW (N PRCongo border); common in Ituri and Semliki, uncommon in Irangi Forst near Kahuzi-Biega National Park; occurs also W of Bukavu, and in SW DRCongo in region of lower Congo valley, downstream from Kwamouth. In Uganda, old records from Ruwenzoris and formerly not uncommon in Bwamba lowlands, but no recent records; pair seen in Shava Valley, in Rwanda. Not uncommon in Angola, where found in Cabinda and in N Lunda Norte (e.g. Dundo).

Bibliography. Bannerman (1939a, 1953), Bates (1911, 1930), Bobo *et al.* (2006), Borrow & Demey (2001), Bowden (2001), Britton (1980), Brosset & Érard (1986), Carswell *et al.* (2005), Chapin (1954), Christy & Clarke (1994), Dean (2000b), Dowsett (1990), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire (1990, 1997a, 1997b), Dowsett-Lemaire & Dowsett (1999, 2000), Elgood *et al.* (1994), Érard (1987), Fishpool & Evans (2001), Friedmann & Williams (1971), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Franklin (2000), Kizungu (2001), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1973), Prigogine (1971), Quantrill & Quantrill (1998), Rand *et al.* (1959), Rodewald *et al.* (1994), Sargeant (1993), Schouteden (1969), Serle (1965), Short *et al.* (1990), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Stevenson & Fanshawe (2002), Traylor (1963), White (1962).

15. Black-backed Puffback



Dryoscopus cubla

French: Cubla boule-de-neige **Spanish**: Cubla Dorsinegra
German: Schwarzmantel-Schneeballwürger
Other common names: Southern Puffback, The Puffback; Zanzibar Puffback (*affinis*)

Taxonomy. *Lanius cubla* Latham, 1801, Cape of Good Hope, South Africa.
Forms a superspecies with *D. senegalensis*. Only "pure" individuals of race *affinis* seem to occur on Zanzibar and adjacent mainland coast; from coastal S Somalia S to C Tanzanian coast (Dar es Salaam) many are pure *affinis*, but others, especially inland, have variable amounts of white in scapulars and wing, and exhibit extensive intergradation with *nairobiensis* and *hamatus*. Race *okavangensis* intergrades with *hamatus*. Proposed race *chapini*, described from Newington (E Mpumalanga), in NE South Africa, is subsumed in *hamatus*. Five subspecies recognized.

Subspecies and Distribution.
D. c. hamatus Hartlaub, 1863 – N Angola, SE & E DRCongo, N & W Zambia, SW Kenya (W of Rift Valley, to Kavirondo Gulf), Tanzania (except NE), Malawi, Mozambique, E Zimbabwe, and

lowland NE South Africa (Limpopo Province S to extreme N & NE Free State and N KwaZulu-Natal) and Swaziland.
D. c. nairobiensis Rand, 1958 – E of Rift Valley in Kenya (S from Archer's Post, E to Mt Endau, Kibwezi, and Tiva and Voi rivers) and NE Tanzania (S to Kilosa, E to Usambara Mts).
D. c. affinis (G. R. Gray, 1837) – S Somalia and coastal lowlands of Kenya (extending inland to Bura and Shimba Hills) and Tanzania (S to R Rufiji), including Zanzibar I and Mafia I.
D. c. okavangensis Roberts, 1932 – S Angola, Zambia (S from Balovale) and W Zimbabwe S to N Namibia, N & E Botswana and N South Africa (R Molopo, in N North West Province).
D. c. cubla (Latham, 1801) – SE South Africa (S KwaZulu-Natal S along coast to E Western Cape).

Descriptive notes. 16–18 cm; male 19–36 g and female 21–30·5 g (nominate), male on average 6 g less and female 4 g less (*nairobiensis*), male on average 3 g and female 4·5 g heavier than nominate (*affinis*). Male nominate race has forehead to mantle, lores, narrow line under eye, ear-coverts and side of neck glossy bluish-black; back and rump white, feathers dense and quite long (capable of being fluffed up into hemispherical shape), uppertail-coverts and tail glossy black; flight-feathers black, edged white, narrowest on primaries, tertials broadly edged white, greater primary coverts black, narrowly edged and tipped white, all secondary coverts black, broadly edged and tipped white; throat and entire underparts creamy greyish-white; underwing-coverts and axillaries white, underside of flight-feathers shiny dark grey; iris bright red to orange-red to orange-yellow (colour appears to vary between habitats, e.g.orange-red in montane forest and red in woodland populations); bill black; legs grey. Female is like male, but less intensely black, with white areas creamy (rather than snowy), rump greyish and feathers shorter than male's; eyes bright orange or yellow-orange, upper mandible black, lower mandible blue-grey or pale grey for variable portion from base, legs blue-grey. Juvenile is like female, but feathers of upperparts blackish-grey with buff tips, rump grey-brown, chin to undertail-coverts initially fluffy and dull white, turning buff soon after young leaves nest; immature like adult female above, has throat, breast and usually belly orange-buff, finely vermiculated, eyes brown at first, becoming yellowish-orange, bill blackish-grey, paler below. Race *okavangensis* male is like nominate but white edges of wing feathers broader, underparts whiter, eyes red, female like nominate but feathers of forehead and mantle edged greyish, rump pure grey (rather than creamy) and lores pale buffy (not blackish); *humatus* male resembles previous but scapulars broadly edged white (large white shoulder patch) and underparts almost pure white, female like nominate but lores whitish; *nairobiensis* male has wings blacker than last (white edges of all feathers narrow) and white scapular patch less conspicuous, female with lores dusky (not whitish); *affinis* male is distinctive, has scapulars and wings all black, female almost or entirely without white in scapulars and wings and with lores dusky. Voice. Male song a percussive click followed by loud, clear whistle, "dzlit-toweeeyoo" or "tzr-t'weeeyo", sometimes second part pure and shrill, "zzt-wheee"; repeated up to ten times in c. 10 seconds; female often responds instantly in duet with tearing "chizzzrrrrr", loud "cheeerrrr" or nasal "wraanh"; sometimes female sings first and male responds in near-synchronous duet, "jeeeez-tweeeyu". Also whistles a repeated upslurred "tu-tu-wee" or downslurred, ringing "tywe-tyew-tyew". Courting male calls "chak-chak-chak" in flight; frips wings and clicks bill in flight. Many other calls, in variety of clicks, snores, chatters and whistles often in conversational medley, like a *Lanius* shrike.

Habitat. Canopy of dense savanna woods and forest edges, less commonly in sparse woodland; occasionally in open acacia (*Acacia*) savanna, especially where modified by bush encroachment. Inhabits also evergreen montane forest, dense riverbank woods, coastal forest and mangrove; in South Africa commonly in plantations of black wattle (*Acacia mearnsi*) and in well-wooded parks and gardens; in Tanzania in gardens and coffee plantations; in N Malawi tall submontane forest at 2000 m. Sea-level to 2200 m.

Food and Feeding. Eats beetles (Coleoptera), large numbers of caterpillars, ants (Formicidae), termites (Isoptera), also *Salvadora* fruits and *Acacia* buds. Food items given to nestlings include butterflies and moths (Lepidoptera), noctuid and saturnid moth caterpillars, long-horned grasshoppers and crickets (Orthoptera), dragonflies (Odonata), beetles, larvae, worms and small lizards; once a stick-insect (Phasmida) 115 mm long and from which legs had been removed. Forages mostly in upper canopy of trees, moving swiftly and silently in horizontal posture, gleaning from foliage and wood; explores galls and pods at end of branch while momentarily hanging upside-down; sometimes comes lower, and descends to the ground in pursuit of falling prey. Occasionally hawks for flying insects. Forages singly and in pairs. Commonly joins mixed-species foraging flocks, e.g. in Zambia found in 61% of bird parties in one area and 36% in another; in Serengeti National Park (Tanzania), often in parties including *Laniarius erythrogaster* and *Malaconotus blanchoti*.

Breeding. Fledglings in Oct in Somalia; in Kenya, season Jan–May, Jul, Sept–Oct and Dec (mainly Apr) inland, Sept and Dec near coast; Jan–Mar in N Tanzania and Jul–Dec on Zanzibar; birds with active gonads in Oct in Angola; breeds Jul–Dec and Mar (mainly Sept, then Oct–Nov) in Zambia; in all months except May (peak Sept–Nov) in Zimbabwe, Oct and Mar in Mozambique, and Feb and Oct–Nov in Botswana; in South Africa, mainly Sept–Jan (peak Nov–Jan) in Limpopo and Oct–Dec in KwaZulu-Natal; single brood per season. Monogamous; one pair remained together for four seasons. Territorial all year; male advertises and defends territory by calling repeatedly (up to 60 times) while perched in exposed position in upright posture on top of tree, with crest and throat feathers slightly raised, tail half-fanned; male signals territorial threat by counter-singing rapidly with whistles and tearing sounds, female joining in with scolding calls; in high-intensity interactions calling speeds up and rises in pitch, then male clicks bill stridently, often during descending, bouncy flight with wings whirring, head held up, tail fanned, and back and rump feathers fluffed out into dense snow-white hemisphere about size of golfball or small powder puff; on alighting, male crouches, with head and foreparts down, and sways slowly from side to side; female clicks bill and occasionally fluffs rump feathers. Male courtship display seems to be just the same as territorial display: short flights with bill-clicking, whirring wings, fanned tail and puffed-out rump; male chases female, pair flying with loud wing-fripping, bouncing swiftly through branches, then male approaches mate in head-down posture, swaying body, with tail fanned, and white rump puff so erect that it almost envelops slightly drooping wings, female bends down and partly opens wings, male mounts her. Nest built by female alone (see page 76), male sometimes brings material, work takes about ten days; a small, neat, deep cup made of dry grass, roots and thin strips of bark, bound with spider web and some plant down, sometimes decorated on outside with pieces of lichen, dry leaves and bark, and lined with fine wiry dry grass; well hidden in upright fork 2–15 m above ground in tree; territory size c. 4 ha in dense lowland woods; on Nyika Plateau (Malawi) at 2000 m pairs occupy all forest patches of 7·5 ha or more and at Zovotchipolo (2200 m) two forests of 8·5 ha and 12 ha each held one pair. Clutch 2–4 eggs, in Zambia generally 3–4; incubation mainly by female, fed on nest by male, male relieves her for short periods (both sexes initiate nest-relief, by calling), period 13 days; chicks brooded by female, she feeds them with food delivered to her by male, later fed by both parents, both also remove faecal sacs, nestling period c. 18 days; young out of nest continue to beg from and are fed by parents for at least three weeks, and juveniles appear to be tolerated in parental territory until next nesting season; up to 15 individuals, all or most juveniles, sometimes congregate noisily in trees, displaying rump feathers, calling, wing-fripping and chasing. Nests occasionally parasitized by Klaas's Cuckoo (*Chrysococcyx klaas*), and possibly by African Emerald Cuckoo (*Chrysococcyx cupreus*) and Black Cuckoo (*Cuculus clamosus*). Nestlings sometimes killed by ants. Individual ringed as adult survived for further 10 years 8 months.

Movements. Resident; ringing recoveries all within 10 km of ringing site.

Status and Conservation. Not globally threatened. Generally common. In Somalia, fairly common in lower Jubba and lower Shabeelle valleys and in extreme S; frequent to common in Kenya, where widespread from sea-level up to 2200 m, almost entirely S of equator. In Tanzania, seemingly local in W half, including Minziro Forest (in NW), Zinza area (S of L Victoria), mesic woodlands near L Tanganyika, and probably much of Kigoma and Tabora provinces; widespread in E half, including on Zanzibar and Mafia I. Widespread in SE DRCongo S from S Kivu and E from Kasai, and common and widespread throughout Zambia, Zimbabwe, Malawi and Mozambique. Common in much of Angola, but absent from NW & SW; frequent to common in N Namibia, N & E Botswana, most of NE & E South Africa and throughout Swaziland.

16. Northern Puffback

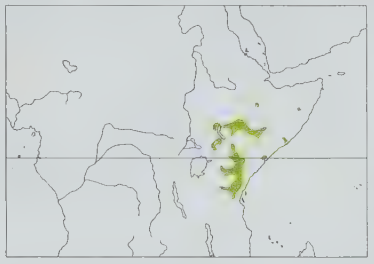
Dryoscopus gambensis

French: Cubla de Gambie **German**: Gambia-Schneeballwürger **Spanish**: Cubla del Gambia
Other common names: The Puffback, Common/Gambian Puffback/Puffback-Shrike

Taxonomy. *Lanius gambensis* M. H. C. Lichtenstein, 1823, Senegambia.
Considered to form a superspecies with *D. pringlii*, the two being very alike in plumage and having parapatric ranges (some sympatry in S Ethiopia). In E range, size decreases clinally from N (Sudan) to S (Itombwe); race *erwini* rather poorly differentiated, sometimes subsumed in *malzacii*. Five subspecies recognized.

Subspecies and Distribution.
D. g. gambensis (M. H. C. Lichtenstein, 1823) – extreme S Mauritania and Senegambia E to W Cameroon and Gabon.
D. g. congicus Sharpe, 1901 – SW PRCongo, SW DRCongo and NW Angola (Cabinda).
D. g. malzacii (Heuglin, 1870) – E Cameroon, S Chad, Central African Republic, SW Sudan, NE DRCongo, Uganda, W Kenya, Rwanda, N Burundi and NW Tanzania.
D. g. erythreae Neumann, 1899 – Eritrea, Ethiopia and E Sudan (Sennar).
D. g. erwini Sassi, 1923 – Itombwe, in E DRCongo.

Descriptive notes. 18–19 cm; male 30–37 g, female 25–40 g, male on average 2–2·5 g heavier than female (*malzacii* and *erwini* combined). Male nominate race has forehead, lores and narrow line under eye back to ear-coverts, hindneck, side of neck and mantle glossy bluish-black; back and rump greyish-white (plumage long, dense and erectile), uppertail-coverts and tail glossy black; primaries blackish-brown, narrowly edged pale grey, secondaries and tertials blackish-brown, edged and tipped greyish-white, greater primary coverts black, very narrowly pale-edged, secondary coverts brownish-black, broadly edged and tipped greyish or buffy white; entire underside creamy greyish-white; underside of flight-feathers shiny dark grey, underwing-coverts and axillaries white; iris bright orange or red; bill black; legs grey. Female has forehead, crown, upper cheek, ear-coverts, nape, hindneck and side of neck medium grey, upperparts greyish-brown, uppertail-coverts dark brown, tail brownish-black; flight-feathers dark brown, edged rufous, upperwing-coverts dark brown with grey bases, mainly fringed pale rufous or greyish-white; chin to breast and upper flanks pale creamy rufous, merging into white in middle of belly and vent, rest of underparts pale rufous, washed brownish; upper mandible black, lower mandible blue-grey or pale grey for variable portion from base, eyes bright orange, legs blue-grey. Juvenile is similar to immature, but chin and throat white, lower throat with cream wash; immature (both sexes) is like female, but mantle feathers tipped pale rufous, flight-feathers, scapulars and upperwing-coverts broadly fringed rufous, chin and throat rufous, underparts white, feathers fluffy, grey bases showing through patchily. Races differ mainly in plumage of females: *congicus* female is deeper rufous below and flanks more uniformly rufous than nominate; *malzacii* female has forehead, crown and hindneck very dark brown (not grey) and mantle and back dark brown (not greyish-brown), underparts slightly paler than nominate, and colour from chin to flanks and undertail-coverts more uniform; *erythreae* female is almost male-plumaged, but upperparts dark chocolate-brown where male bluish-black, and underparts usually creamier; *erwini* is smaller than nominate, and may differ from *malzacii* in bill colour (black in male, but proximally grey in female) and eye colour (orange-red in male, orange in female). Voice. No particular courtship or territorial song known, and pair-members do not sing in antiphonal duet. Contact and other calls include loud, explosive whistles, harsh rasping sounds, strident clicking; makes wing-fripping sounds. Main call a harsh whistle, single or double or repeated rather slowly: "tchrep-tchrep", "tyoop", "tyoo-yoo", "chip-chipchip" or "churc-churp…", and rasping "zhrraanh" or "zhiuu"; also slow, harsh "wrrich, wrrich", nasal "krim, krim", high-pitched querulous "weer-weer" interspersed with nasal disyllabic whistles; calls often accompanied by strident chattering and clicking; alarm a repeated, sharp "tuk, tak…" and (when bird held in hand) prolonged metallic trilling.



Habitat. Dense mesic savanna woodland, also thickets, mangroves, wooded farmland, bamboo groves and well-timbered gardens. In Liberia, forest–grassland mosaic to 1500 m altitude, and secondary growth, forest edge and mangrove on and near coast; in Nigeria favours shea-butter trees (*Vitellaria paradoxa* = *Butyrospermum parkii*); in Eritrea lives at up to 1540 m in wet woodlands, *Combretum*, and riparian figs (*Ficus*) and tamarinds (*Tamarindus*), but never in pure acacia (*Acacia*) woods. Lowlands in W Africa; highlands to 3000 m altitude in E Africa.
Food and Feeding. Insects, including beetles (Coleoptera), Lepidoptera (including caterpillars) and Orthoptera; a few plant buds. Keeps in tree canopy, moving rapidly but stealthily among the branches, descending to tops of tall undergrowth; pulls appendages (moth wings and orthopteran legs) from insect prey before consuming them. Forages singly and in pairs; retiring, secretive and easily overlooked.
Breeding. Poorly known. Season Aug in Mauritania and Jun–Sept and Dec in Gambia; in Liberia, males display in Sept–Oct and Mar–Apr; breeds Apr–May and probably later in Ghana, about May–Jul in Togo, and apparently Apr–Jun, Sept–Oct and Dec in Nigeria; Apr in Ethiopia, Jan in Kenya, and Apr, Aug and Oct in E DRCongo (Itombwe); in breeding condition in Mar–Oct and Dec–Jan in Uganda. Appears to be monogamous and territorial. In courtship very vocal and demonstrative, male flies from tree to tree, with white back and rump feathers puffed out to cover back and base of wings. Nest a compact cup made mainly of fine strips of bark, the outside plastered with spider web, lined with fine rootlets or with very fine bark strips and plant down, placed c. 20 m above ground in multiple fork of tree. Clutch 2–3 eggs. No other information.
Movements. Resident; suggestion of migration through Gabon.
Status and Conservation. Not globally threatened. Frequent to common in N tropical woodlands, ranging N to upper Guidimaka valley in S Mauritania, great bend of R Niger in Mali (where scarce), W National Park in Niger, Abéché in Chad, Jebel Marra foothills in W Sudan and Blue Nile valley to about Singa in E Sudan, and highlands to about Asmara in Eritrea. Ranges S in W Africa to N limits of rainforest zone. Density of 10–12 birds/km² in Chilomo Forest, in Ethiopia. In Somalia, several records at Ged Deeble (in NW) in 1918 and 1958. Scarce in Mbini and Gabon (M'Passa, Lékoni, Mouila and Tchibanga); in PRCongo, rare in Odzala National Park but widespread S from Léfini; in Angola found only in Cabinda, where not uncommon, but an old nest record from N'dalatando. In DRCongo, common in N Uele, sparse in Ituri and Kivu, frequent in lowlands in Semliki valley and to 2150 m in Ruwenzoris and 3000 m on Kivu Volcanoes, and quite common in Itombwe Highlands at 1850–2830 m; widespread to at least 2000 m throughout Uganda, except for area S of Masaka and E of Mbarara; in Kenya, frequent to common at 900–2200 m, near Moyale and from Marsabit, Mt Nyiru, Mt Loima, Horr Valley, Cheranganis, Kapenguria and Elgon S to Bondo, Ng'iya, Nandi, Elmenteita, Lake Nakuru National Park and Laikipia Plateau, E to N Uaso Nyiro valley. In NW Tanzania recorded from Ngara (near Rwanda) and Kibondo (near Burundi); in Rwanda from Zaïre-Nil crest at 1700–2600 m and Kibungu region (in SE) at 1300–1750 m; records in N Burundi. Threats to this species are characterized by those facing the avifauna of the Hwimo area of W Nigeria, where, as a result of increasing human population, new land is continually being taken for farming and house-building; trees are systematically felled and burnt, and hunting is widespread, farmers carrying home-made guns and children wielding catapults. Corpses of this bush-shrike are commonly present in traditional medicine markets in Benin.

17. Pringle's Puffback

Dryoscopus pringlii

French: Cubla de Pringle **German**: Zwerg-Schneeballwürger **Spanish**: Cubla de Pringle

Taxonomy. *Dryoscopus pringlii* F. J. Jackson, 1893, Mauungu Wilderness and between Tsavo and Kufumika Road, Kenya.
Considered to form a superspecies with *D. gambensis*, the two being very alike in plumage and having parapatric ranges (some sympatry in S Ethiopia). Birds of this species in Ethiopia, having greyer underparts, may represent a distinct race; further study required. Currently treated as monotypic.
Distribution. S & E Ethiopia, C & S Somalia, NW, NE & C to SE Kenya and NE Tanzania.

Descriptive notes. 13·5–14 cm; male 19–22·5 g, female 13–20·5 g. Male has forehead and lores back to hindneck, side of neck, mantle and scapulars glossy bluish-black, back medium grey, rump whitish, uppertail-coverts glossy black; tail black, tips of feathers T2–T5 greyish-white, outermost rectrix with greyish-white tip and outer edge (2 mm deep); upperwing dark brown, primaries with narrow grey-buff outer edges, inner secondaries and tertials with whitish outer edges and tips, greater primary coverts with narrow white or whitish edges, greater and median secondary coverts with broader (1–2 mm wide) white or whitish edges and tips; chin and throat creamy or greyish-white, grading into pale grey on breast and pale brownish-grey on flanks; belly white (at least in middle), thighs grey, vent and undertail-coverts whitish; underside of flight-feathers shiny grey, underwing-coverts and axillaries white; underside of tail grey, feathers fringed whitish; iris dark red; bill black, basal half of lower mandible pale horn; legs grey-black. Female is rather nondescript, being greyish-brown above, lores and cheeks buffy whitish, narrow white ring around eye, rump whitish (when brown feather tips displaced), tail uniformly brown, pale creamy or greyish-buff below, grading to white on belly and undertail-coverts, with thighs pale brown; upper mandible black, lower mandible mostly or entirely whitish, legs blue-grey, soles pale greyish. Juvenile is like female but duller and buffier; immature like adult female, but head and mantle mottled brownish, eyes crimson, legs purplish. Voice. Poorly known. Song short, low-pitched, harsh and monotonous. Calls include rasping, nasal "cheee-tzrrrr", rapidly repeated "zitiitzitiitziiiit", and "chup-chup-chup"; repeated sharp "keu" often given by several birds together; and a low-pitched churr.
Habitat. Arid and semi-arid acacia (*Acacia*) and *Commiphora* scrub, bushland and woodland; lowlands, generally below 1000 m.
Food and Feeding. Insects, including caterpillars. Active gleaner in microphyllous foliage, moving through undergrowth or low trees; in Tsavo (Kenya), forages in woodland bushes, not trees, at average height of c. 2 m above ground. Often in mixed-species flocks.
Breeding. Little known. Laying recorded once in Nov in Kenya. Nest a deep, neat cup, one moulded on to horizontal branch and anchored to vertical twig c. 120 cm above ground in *Commiphora* sapling, another was basket-like, thin-walled, 7 cm wide and 6 cm deep, made of horizontal grass stems woven among vertical ones, turned inward at top to give neatly rounded lip, placed in multiple fork near top of a 2-m acacia bush. Clutch 2 or 3 eggs. No other information.
Movements. Apparently resident.
Status and Conservation. Not globally threatened. In Ethiopia very uncommon in S (in Yavello, Arero and elsewhere), with only five or six old records and twelve modern ones; old, isolated record near Kololo (C Ethiopia). Uncommon in Somalia, where eight old records and seven recent ones in S (S of 3° N), also an old isolated record N of Bacaadweyn (NC Somalia). Uncommon and local in Kenya, with small population SW of L Turkana (in upper Turkwell valley and Karasuk Hills), records from Moyale and Mandera, seven pre-1970 records along seasonal watercourses from about North Horr and W & SE of Marsabit to Kinya, N & S of Benane and near Adederata; main range from about Barsalinga and Archer's Post S to Meru National Park, Kora Nature Reserve, Kitui, Mtito Ande and Tsavo National Parks, and S into extreme NE Tanzania at L Jipe, Lembeni, Mkomazi Game Reserve and Usambara lowlands S to 4° 20' S; also isolated Tanzanian records from near Manyara and N of Morogoro. Scarcity of this species may be more apparent than real, and it is not considered to be at risk. Nonetheless, it would be prudent to discover much more about this bush-shrike as the basis for future conservation measures.

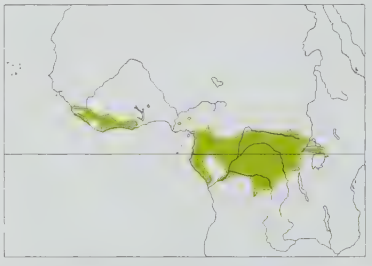
Genus *LANIARIUS* Vieillot, 1816

18. **Sooty Boubou**



Laniarius leucorhynchus

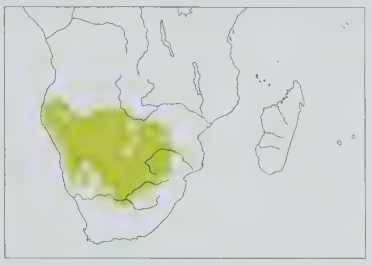
French: Gonolek fuligineux **German**: Schwarzwürger **Spanish**: Bubú Sombrío

Taxonomy. *Telophonus leucorhynchus* Hartlaub, 1848, Elmina, Ghana.
Recent DNA analyses indicate that this species may be as closely related to the black-and-scarlet S African *L. atrococcineus* as it is to the similarly all-black low-latitude *L. poensis*, *L. fuelleborni* and *L. funebris*. Monotypic.

Distribution. Sierra Leone and SE Guinea E to SW Ghana and N Togo, and SE Nigeria E to extreme SW Sudan (Bengengai) and Uganda, S to extreme NW & NE Angola (Cabinda, N Lunda Norte) and C DRCongo.

Descriptive notes. 21–22 cm; male 51–57 g, female 44–45 g. Male is jet-black with faint violet or blue gloss; feathers of lower back and rump very full, long and soft; underside of primaries dark brown; iris dark red-brown or very dark red (DRCongo), or perhaps brown-black (W Africa); bill black; legs blackish or dark slaty bluish. Female is the same as male, but without gloss. Juvenile is like adult, but mantle to rump, wings and side of breast dark chocolate-brown with almost a maroon wash; immature like adult, but bill whitish to ivory-white, changing to adult black rather blotchily, and sometimes has very faint pale spots on crown. Voice. Sings often, all year; pair sings in duet,

which thought to serve for both contact and territorial proclamation, duetting frequency increasing when another pair in vicinity; singing or calling initiated by either sex and appears not to vary regionally (songs in S DRCongo just like those in Rwanda and Uganda). Male song low, hollow whistles, almost pure but with slight burry quality, quavering or ringing, varying from "ooooooooo" (1 second long) that starts and ends softly and becomes louder in middle, repeated after 1-second pause, to a series of four whistles, "oo-oo-woo-woo", the last two louder; a series of similar but shorter whistles at rate of two per second, either continuously or in groups of four; series of 10 notes, the last 7 faster than the initial 3, lasting c. 2 seconds, series repeated after 1-second pause; fast series of hollow whistles at rate of eight per second, either continuous or in groups of 11 notes separated by short gaps; fast "hohohohohoho..." series of up to 50 notes. Faster songs sound like song of White-spotted Flufftail (*Sarothrura pulchra*) in same forests. Male song sometimes answered by female, either synchronously or antiphonally, with low, harsh, scolding "skaaaa" or "hzzrrrrrit-hzzrrrrrit", or vibrating, trembling, hoarse "zzhrrrraaaaazzhrrrraaaaa" (like sound of cloth being slowly but forcibly torn), or drawn-out plaintive "hweeeew" whistle. Other vocalizations are a bubbling or gurgling "blopblopblop" or "blpblpblpblp" seemingly during foraging, also described as 9–10 low clicking "cli" notes; twanging, nasal "tzzaa-naa-naa-naaa" in territorial threat and courtship; sharp, harsh "tik" and "hoik" notes in alarm.



Habitat. Dense undergrowth near lowland rainforest and in savanna woodland, to 900 m in Liberia and 1400 m in Uganda. Impenetrable liana-covered tangles, rank vegetation, dense thickets and thick herbage in coastal shrubland, open swamp vegetation, thickets in mixed papyrus (*Cyperus papyrus*) marsh, low swamp-forest, riparian forest, wooded islands and banks of large rivers and lakes, bushy farmland, young secondary growth, forest clearings and edges, gallery forest and remnant stands of forest in savanna. Enters primary forest along borders of watercourses, old forest tracks, and where opened up by windfalls and storm damage; in *Cynometra* forests in Uganda.
Food and Feeding. Orthoptera, butterflies and caterpillars (Lepidoptera), mantises (Mantidae), cicadas (Cicadidae), beetles (Coleoptera), large wasps (Hymenoptera), ants (Formicidae), spiders (Araneae) and snails (Gastropoda). Forages close to ground or, occasionally, up to 15 m or more above it; secretive, keeping in thickest tangles, moving through them with ease in small jumps. Forages in pairs, and sometimes solitarily or in family parties.
Breeding. Nest-building in May in Guinea; birds in fresh plumage and extended singing in Aug–Nov, nest with eggs in late Oct, females with enlarged ovaries in Nov and Mar, and carrying nest material in Mar in Liberia; breeds Dec–Jan in Gabon; enlarged ovaries Mar and Nov in Cameroon, Feb, Jun and Aug in DRCongo, and Jul in Uganda. Territory thought to be defended by singing. Nest a quite large, loosely structured open cup on base of intertwined twigs, rootlets and dry, thin, woody climber stems or tendrils; placed on multiple vertical fork 2–3 m above ground in bush in forest clearing, in vegetation c. 1 m above water, in thick ornamental tree in middle of clearing, or in young secondary growth; territory seems to be as large as 6–8 ha. Clutch 2 eggs; incubation by female alone; no information on duration of incubation and nestling periods; young out of nest accompanied by both parents.
Movements. Resident.
Status and Conservation. Not globally threatened. Rare throughout much of W Africa, although locally frequent, probably overlooked; frequent or common in well-investigated parts of Congo Basin. In Guinea, uncommon around Ziama Massif and Mt Nimba; in Sierra Leone, several old records from R Little Scarcies and elsewhere W of 12° W, more recently only in SE quarter (W to Bo); in Liberia, not uncommon along coast and in interior from Lofa County and Nimba to Zwedru, and common at Ganta; not uncommon in Ivory Coast S from Yapo, Lamto and Béoumi. In Ghana, recorded regularly at Akropong (in Akwapim) and irregularly at Cape Coast, Kakum Forest, Kumasi (where formerly common) and Tafo; sight record at Fazao, in Togo. In Nigeria, not uncommon around Umuagwu, once five together near Bashu, and occurs in Cross River National Park. In Cameroon, rare in Korup National Park but farther E recorded from numerous localities in Bitye, Efulen, Olounou and Zoulabot areas; frequent N to Mbam-Djerem National Park. Records in Central African Republic in Bai Bakalonga and along R Babonga in Dzanga Reserve, in Lobaye Prefecture and Bangui area, and along R Mbomou valley at DRCongo border; in Sudan, known only from Bengengai. Widespread and common in Gabon except in S, where uncommon in Gamba area and rare in Moukalaba-Doudou National Park; in PRCongo, common in Nouabalé-Ndoki National Park, Odzala National Park and Léfini Réserve, locally common in Mayombe, but almost absent from Goumina and some other areas. Widespread and locally frequent in DRCongo, where very common around Niangara. In Uganda, locally common in Bwamba area, elsewhere in S only about six records; one collected in Kenya (Kaimosi Forest) in 1931, but no records since; status in Rwanda uncertain. In Angola, not uncommon in Cabinda and N Lunda Norte.
Bibliography. van den Akker (2003), Angehr *et al.* (2005), Ash (1990), Bannerman (1939a, 1951, 1953), Bates (1930), Bobo *et al.* (2006), Borrow & Demey (2001), Brosset & Érard (1986), Carswell *et al.* (2005), Chapin (1954), Cheke & Walsh (1996), Colston & Curry-Lindahl (1986), Dean (2000b), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire (1990, 1997a, 1997b, 1997c), Dowsett-Lemaire & Dowsett (1991, 1999, 2000), Elgood *et al.* (1994), Érard (1987), Field (1979), Fishpool & Evans (2001), Friedmann & Stager (1969), Fry *et al.* (2000), Gatter (1997), Germain & Cornet (1994), Green & Carroll (1991), Green & Rodewald (1996), Grimes (1987), Hall & Moreau (1970), Halleux (1994), Harris & Franklin (2000), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1960, 1973), Marchant (1953), Nguembock *et al.* (2008), Nikolaus (1989), Prigogine (1971, 1984c), Rand (1951), Rand *et al.* (1959), Ripley & Bond (1979), Ripley & Heinrich (1966), Serle (1965), Serle & Morel (1977), Short *et al.* (1990), Sibley & Monroe (1990), Sinclair & Ryan (2003a), van Someren (1916), Sonnenschein & Reyer (1984), Stevenson & Fanshawe (2002), Thiollay (1985), Thorpe (1972), Tomlinson (1950), Traylor (1963), White (1962), Young (1946), Zimmerman *et al.* (1996).

19. Crimson-breasted Shrike

Laniarius atrococcineus

French: Gonolek rouge et noir **German**: Rotbauchwürger **Spanish**: Bubú Pechirrojo
Other common names: Crimson-breasted Gonolek/Boubou, Burchell's/Black-and-crimson Gonolek

Taxonomy. *Lanius atrococcineus* Burchell, 1822, Spuigslang Fontein (confluence of Vaal and Orange Rivers), South Africa.
Multiple genetic studies indicate that this species represents a single, deep branch in phylogenetic tree of present genus, only very distantly related to the other scarlet bush-shrikes. Until recently was regarded as forming a superspecies with *L. barbarus*, *L. erythrogaster* and *L. mufumbiri*, and as being closest to and sometimes conspecific with *L. erythrogaster* (calls apparently identical, and responds to voice playback of latter). Monotypic.
Distribution. Kalahari Basin and adjoining hardveld regions: S Angola, SW Zambia and W & S Zimbabwe S to Namibia (except W & S: Namib and Karoo), Botswana (except parts of N & C) and N & C South Africa (N & C Limpopo Province S to N Northern Cape and NW Free State).
Descriptive notes. 22–23 cm; 40–56·5 g. Has lores matt black, forehead to hindneck and side of head, and upperparts, jet-black and strongly glossy (gloss bluish in some lights); back and rump plumage full, soft and fluffy, black with mainly concealed white blotches; uppertail rounded or slightly graduated, glossy black, outermost rectrix sometimes with white triangular mark up to 6 mm deep at tip; upperwing glossy black, long white stripe formed by white outer lesser coverts, most median coverts, inner three greater coverts (outer two all white, innermost one with white outer web and black inner web), and white outer edges (2–3 mm wide) on inner three secondaries; chin to flanks and undertail-coverts brilliant crimson-red (slightly paler in arid regions), sharply demarcated from black of side of head and neck, thighs black; underside of tail glossy black, underwing-coverts and axillaries black; iris dark violet or grey-brown with narrow pale violet ring; bill black, mouth black; legs black. Rare yellow morph has chin to flanks and undertail-coverts bright daffodil-yellow. Sexes alike. Juvenile has top of head and mantle blackish-brown with fine rufescent-buff bars, back, rump and lesser wing-coverts dark brown with broader pale bars (formed by buff feather tips), flight-feathers dark brown, median and greater wing-coverts buffy white with

dark brown subterminal bars, uppertail-coverts and tail black with narrow rufous tips, chin to breast evenly and finely barred with buff and blackish, belly and flanks evenly and more broadly barred likewise, undertail-coverts crimson; when moulting from juvenile to immature plumage, first belly and flanks become crimson, then centre of breast does so (leaving large brindled brown patches on sides of breast and in middle of lower breast and upper belly), then chin and throat and sides of breast and then entire underparts become crimson, except for thighs and small patch in middle of lower breast. Voice. Wide repertoire of loud, explosive, hollow, ringing whistles by male and harsh grating, snarling or tearing sounds by female, usually in duet delivered at remarkable speed. Male territorial call, given solo or in duet, a high-pitched, explosive "quipquip" whistle given twice; duetting female intervenes instantly with harsh, scratchy "tzui" or "tjerr", the pair producing what sounds like a single song, "quipquip-tzui-quipquip"; antiphonal song can also sound like "pyop-zulwi-pyop", "weeyu-jaweer-weeyu" and "cho-zer-chop"; male can intervene in double female call, "jawaaa-beeyu-jawaaa" or each sex alternates without discernible pause, "beeyu-jawaaa-beeyu-jawaaa" or "tyotyo-ziluwaa-tyotyo-ziluwaa"; sometimes male and female calls are synchronous, when sound defies transliteration; single bird can utter complete duet sequence after losing mate. Other calls are a pure, high-pitched, 3-note whistle, "pee, yee, yoo"; male's ringing trill "torrrr" answered by female's grating "djuzhu", or male's dry "tirrrrr" answered by tearing "zaaaa"; alarm signalled with hard "qwip", and when ground predator or perched hawk nearby a slowly repeated harsh "tik tik..."; short-range contact call a soft, low-pitched churring; distant contact maintained by duetting; male invariably gives one or more soft "chop" notes just before leaving roost, female responding with "tsui" in duet. Breeding birds silent during nest-building and incubation; calling and duetting resume after eggs hatch, some pairs then much more vocal than others.
Habitat. Thornveld with scattered clumps of small trees, particularly woodland dominated by acacia (*Acacia*) and *Baikiaea*; keeps to densest vegetation.
Food and Feeding. Beetles (of families Carabidae, Tenebrionidae and Cerambycidae), beetle larvae, ants (Formicidae), caterpillars, termites (Isoptera), heteropteran bugs, spiders (Araneae); some small fruits and seeds also taken, and once birdtable peanuts husked and broken into small pieces. Ants a favourite prey when bird feeding on ground. Young fed with small moths (Lepidoptera), grubs, and once a 50-mm centipede (Chilopoda). Forages among branches and foliage but mainly on tree trunks, hopping around, inspecting rough bark and peering under loose pieces of bark; zigzags up through bush, bouncing rapidly from branch to branch; commonly comes to ground, where hops with very upright posture, wingtips pointing down and tail horizontal and jerking up at each bounce; sometimes runs. Flicks aside bits of vegetable matter in manner of a *Turdus* thrush; occasionally flycatches. Once seen to attack a bat (Chiroptera), dislodging it from behind bark; in captivity, kills other small birds. Often forages alongside *L. aethiopicus*, sometimes in same bush. Pair invariably joins flock of Southern Pied Babblers (*Turdoides bicolor*) passing through its territory and forages opportunistically with them; forages also with Arrow-marked Babblers (*Turdoides jardineii*), with Hoopoes (*Upupa epops*) on ground and with Common Scimitarbills (*Rhinopomastus cyanomelas*) low in trees.
Breeding. Season Sept–Apr, mainly Oct–Nov; often double-brooded, and some pairs make four nesting attempts in a season. Territory occupied all year, male advertises and defends it by singing from crown of thorn tree; territorial pairs counter-sing, and interact with excited body-bowing, side-to-side movements and tail-jerking, rivals sometimes counter-singing across territorial boundary for several minutes; once two opponents jerked tail up and down and then flew and struck each other's breast; breeding pair generally co-exists peacefully with other small birds, but will occasionally harass a pair of weavers (Ploceidae), paradise-flycatchers (*Terpsiphone*) or barbets (Capitonidae). Courtship involves some chasing of female by male in tree, bouncing and zigzagging through branches in tandem, tails jerking with each bounce; male also pursues female in flight, wings making fripping sounds, or male glides briefly with head held up. Nest built by both sexes, work usually taking five days, a rather untidy, poorly bound, quite bulky but weak open cup (trampled into flat platform by time young ready to leave), made largely of shreds of fibrous bark from branches and trunks of acacia trees, strips (some up to 25 cm long) added to nest by each bird in turn, lined with rootlets, dry shreds of weed stalks and strips from maize leaf, base of nest secured to substrate with spider web, most nests built in fork c. 3 m up in *Acacia karroo* tree; territory 2·4–7 ha in one study, mean 12 ha in another, usually surrounded by natural boundaries (e.g. open thicket surrounded by grassland). Clutch 2–3 eggs, average 2·8; incubation from first, second or third egg, period c. 16·5 days; chicks brooded and fed by both parents, brooded continuously for 5 days, no longer brooded at 11 days (even during rain), nestling period 18·5–19·5 days; 28 days after leaving nest fledglings still keep close to parents but forage independently, and are remarkably quiet and unobtrusive; roost in same tree as parents, family-members all sleeping in different places in tree. Nests heavily parasitized by Black Cuckoo (*Cuculus clamosus*). Breeding success variable, often poor: in brood of three, two chicks often die in nest, once because of infection by mites (*Ornithonyssus bursa*); in one study only seven broods fledged from 66 clutches, and in Nylsvlei (Limpopo Province, in South Africa) only one young fledged from 13 clutches; inexplicably, half of nests destroyed by their owners, before or after eggs laid. Longevity moderate: ringed juvenile recovered after 8 years 3 months.
Movements. Resident; some local wandering in austral winter.
Status and Conservation. Not globally threatened. Frequent nearly everywhere in range, commonest in well-developed acacia woodland and bushveld and in NW part of C Kalahari; absent from apparently suitable thornveld habitat in N lowveld of South Africa. Yellow morph rare: seen only twice in Zimbabwe and once in Botswana. Densities in former Transvaal (South Africa) of 1 pair/4–5 ha in optimal habitat and 1 pair/9–12·5 ha in suboptimal habitat. In Botswana, 2 birds/10 ha in E and 1 bird/ha in Okavango; in one year when region was drought-stricken, only one quarter as many birds as in previous year after good rains.

20. Mountain Boubou

Laniarius poensis

French: Gonolek de montagne **German**: Rabenwürger **Spanish**: Bubú Montano
Other common names: Mountain Sooty Boubou

Taxonomy. *Dryoscopus poensis* Alexander, 1903, Mount St Ysabel, Bioko.
Has often been treated as conspecific with *L. fuelleborni*, but the two differ in plumage (particularly of juvenile), in bill size and vocally. Recent genetic studies strongly suggest that the two, although more closely allied to each other than to the other black boubous (*L. leucorhynchus* and *L. funebris*), are not conspecific and do not form a superspecies. Considerable vocal differences between E race *holomelas* and W races (nominate and *camerunensis*) suggest that former may be better treated as a separate species. Three subspecies currently recognized.
Subspecies and Distribution.
L. p. camerunensis Eisentraut, 1968 – extreme SE Nigeria and W Cameroon.
L. p. poensis (Alexander, 1903) – Bioko I (Fernando Póo).
L. p. holomelas (F. J. Jackson, 1906) – NE & E DRCongo, W Uganda, W Rwanda abd NW Burundi.

Descriptive notes. 18 cm; male 39–49 g, female 30–36 g, unsexed 40–54 g (*camerunensis*), male 38–45 g and female 38–47 g (nominate). Nominate race is entirely dark glossy black with blue reflections; wing strongly decurved at tip, tail somewhat decurved at tip; iris bluish-black; bill and legs black. Sexes alike in plumage, male on average longer-winged and longer-tailed than female. Immature has upperparts dull black, without blue or violet gloss, and underparts matt black. Race *camerunensis* is like nominate in plumage, but larger; *holomelas* is like previous, but less glossy. Voice. Noisy, repertoire varied in each region, and main calls and songs differ substantially between regions; variety of whistles, harsh tearing and rattling sounds uttered generally in duet. Lacks liquid, rhythmic song of *L. fuelleborni*. Nominate race poorly known: duet consists of "vuik" (attributed to male), immediately followed by "eng" (attributed to female). Race *camerunensis* exhibits much individual variation, with loud whistles, trilling, snoring, clicking and rattling noises, squeals and harsh, grating alarm calls, and duets; commonest duet a grating "whaa-dzu" or "shaaaaa-tsu" by male followed, often instantly, by female's harsh, tearing "tzzzeeerrr"; male may respond with another "whaa-dzu", pair thus producing a three-component song. Male commonly gives "whoo-ee, wee, wit" whistle or repeated short whistles, "wok-wok-wok-wik-wik-wik", or faster "bu-bu-bu" or even faster, bubbling "bobobobo". Duets can be short, a rapidly repeated, abrupt, buzzy "hzz" and nondescript "eng" sound; also a harsh "chik-a-chaka, tk-a-tk, kcher kcher..." sequence; pair (or possibly single bird) utters 1·5-second tearing "whaaa-chuaaaoow"; single calls include "whazzz", longer, nasal "zzhaannh", hard "ckickit-ckickit"; also a repeated nasal, downslurred "jeeoonh..." and a short (0·5 seconds) hollow trill. Commonest vocalization of race *holomelas* a loud, ringing, high-pitched whistle, "heeeeeee", lasting 0·8 seconds, or ascending "hooeeee", given solo or as part of duet, answered by harsh "ti-haarwet" or snoring, rattling "korrrrr" or tearing "tzweeeerrr" by presumed female; also grating, frog-like "t'rrraaanh" answered by short "chyow", and "t'zzheeeh" answered by abrupt "chya"; other calls a tearing "turrrraaaanh" (1·5–2 seconds), scraping "jaaa" and hollow "jowjowjowjow"; in courtship or territorial threat a nasal twanging "zzazanananana"; in alarm a rasping scold; nestling has insect-like begging call.
Habitat. Edges of primary montane forest, dense low shrubby vegetation on steep slopes and in treefall areas, gallery forest and bamboos; at 600–2200 m in Cameroon, and to 3385 m in DRCongo. Occurs alongside *L. leucorhynchus*, at least seasonally, at 430 m on Mt Cameroon.
Food and Feeding. Insects, including beetles (Coleoptera), grasshoppers (Orthoptera) and caterpillars; occasionally snails (Gastropoda), isopod crustaceans and small frogs. Generally in twos, which are not necessarily male and female, often joining mixed-species foraging flocks; follows hunting swarms of *Dorylus* ants on forest floor. Skulks in deepest shade in thickest tangles of leafy, woody vegetation; occasionally comes into view for no more than a few seconds at a time. Forages low down in thick undergrowth and tangled vines and giant ferns; in Cameroon keeps lower in vegetation than *L. atroflavus*, but in Itombwe (DRCongo) sometimes ascends to middle levels of forest.
Breeding. Little known. Season Nov–Jan and Mar (and in breeding condition Oct and Apr) in Cameroon; bird with brood patch in Oct in Uganda; breeds Apr–May or probably Apr–Jul in DRCongo (Itombwe). Only one nest described, a mossy cup built in a cypress tree (Cupressaceae) covered with *Gouania* creepers; clutch 2 eggs. No other information.
Movements. Resident, or perhaps a small-scale vertical migant. Recorded down to 430 m at Ekona (Mt Cameroon), suggesting post-breeding descent.
Status and Conservation. Not globally threatened. Generally common and vocal, but very poorly known. In Nigeria, common on Obudu and Mambilla Plateaux and known from Gotel Mts. In Cameroon, abundant on Mt Cameroon at 700–1400, common at 1400–1950 m, and uncommon at 600–700 m (but once abundant at 500 m); abundant at Dikome Balue (in Rumpi Hills) at 1000–1700 m, on Mt Kupé at 1200–2000 m (recorded down to 950 m), on Mt Nlonako at 1200–1750 m; common on Mt Manenguba at 2100–2200 m, and occurs at 2200 m on Mt Oku, in Bamenda Highlands. On Bioko I, common at Pico Basilé at 1200–2100 m, with most records at 1500–1800 m, and in S highlands at 750–1800 m. In DRCongo, found in mountains from W of Mahagi and Kasenye (L Albert) S to Mt Kabobo; common in Itombwe Highlands at 1170–2450 m and on Mt Kabobo, uncommon on Idjwi I (L Kivu). In Uganda, quite common in Bwindi Impenetrable Forest; in Ruwenzoris uncommon at 2100 m, common at 2400 m and 3000 m, very common at 2700 m. In Nyungwe highlands, in Rwanda, commoner above 1950 m than below that level.

21. Fülleborn's Boubou

Laniarius fuelleborni

French: Gonolek de Fülleborn **German**: Fülleborn würger **Spanish**: Bubú de Fülleborn
Other common names: (Fülleborn's) Black Boubou, Sooty Boubou(!)

Taxonomy. *Dryoscopus fülleborni* Reichenow, 1900, Usafua, north of Lake Nyasa, south Tanzania.
Has often been treated as conspecific with *L. poensis*, but the two differ in plumage (particularly of juvenile), in bill size and vocally. Recent genetic studies strongly suggest that the two, although more closely allied to each other than to the other black boubous (*L. leucorhynchus* and *L. funebris*), are not conspecific and do not form a superspecies. Slightly smaller and slatier-coloured birds from Uluguru Mts described as race *ulugurensis*, but seem barely distinguishable from *usambaricus*. Two subspecies recognized.
Subspecies and Distribution.
L. f. usambaricus Rand, 1957 – Eastern Arc mountains (Usambaras, Ngurus, Ukagurus, Ulugurus), in Tanzania.
L. f. fuelleborni (Reichenow, 1900) – Tanzania S of Uluguru Mts, N Malawi and extreme E Zambia (Nyika Plateau).

Descriptive notes. 18–20 cm; male 46–53 g, female 43–47 g, unsexed 37–53 g. Male nominate race is mostly greyish-black with variable bluish cast, rump plumage very full and soft; upperwing glossy brownish-black, primaries rounded and markedly decurved; iris dark brown; bill and legs black. Female is like male but slightly olive-washed, with dark blackish-grey belly. Juvenile is very dark olivaceous grey-brown above, wings and tail browner, dark greyish-olive below, with yellowish wash on belly and obscure dark olive banding; immature like juvenile, but without barring on belly. Race *usambaricus* is darker than nominate, male black with bluish-grey bloom (particularly on back, rump and belly), glossy jet-black ear-coverts and tail, glossy brownish-black wings, female and immature like male but head less blackish, whole plumage slightly greyer, underparts with faint olivaceous or ochreous wash, also female appears to be considerably shorter-winged than male. Voice. Very vocal, with varied repertoire of rattles, scolds, fluty whistles, grunts and trills. Male and female frequently sing in duet, initiated by either, male uttering loud, liquid, ringing whistles and female rattling trills; male also may sing alone, a descending "whee-whee-whee" or "fweet-fweet-fweet" or somewhat explosive "dududwee" or "to-wheee, to-wheee" or "pu-wheeeng" ending with upslurred note, or repeated "co-wo-roik"; female's trill a rattling "tyurrrrrrrrr..." or "p-r-r-r-r-r-r...", rising sharply at first and then descending and tailing off, less commonly a rapid, liquid 5-note trill, "totowiddlywit". Near-synchronous combination of varied male and female notes produces almost endless variety of duets. Alarm, and calls associated with foraging at ant columns, a grating "zi-zi-zaar", hard, clicking "zutzutzutzu...", scolding "raaj-raaj-raaj..." and grunting "chack".
Habitat. Moist montane and submontane forest, dense undergrowth and regrowth, forest edges, bamboo groves and plantations, at 900–3000 m. In Tanzania found in juniper (*Juniperus*) forest in W Usambaras; in Malawi montane forest, and also in dense montane shrubland 3–4 m tall.
Food and Feeding. Invertebrates, including caterpillars, ants (Formicidae), grasshoppers (Orthoptera) and snails (Gastropoda). Solitary or in pairs; generally shy and skulking. Forages in dense understorey, from near ground up to 16–18 m in tallest trees, also in canopy (8–15 m tall) of low montane forest. Gleans bark and foliage. Occasionally attends ant swarms, without leaving thick cover; one or two individuals often follow swarm of *Dorylus* ants in Usambara Mts, hopping as low as 30 cm above ground in weeds and vines, making short sallies to ground, pecking lianas, stems and leaves, and giving variety of calls.
Breeding. Few details available. Season Dec–Feb in Tanzania, Sept–Jan (mainly Nov) in Malawi, and Nov–Jan in Zambia. Nest a shallow cup made of grass, rootlets and tendrils, placed among creepers or in fork of shrub; territory size 0·6–1 ha in narrow forest patches with plenty of thick regenerating scrub, larger in continuous forest, one territory was occupied for eight seasons. Clutch 1–2 eggs; incubation probably by both sexes (both have brood patch). Among ringing recoveries, oldest individual at least 7 years 4 months (bird ringed as adult). No other information.
Movements. Resident; highly sedentary, longest movement in Malawi only 250 m. Thought to be altitudinal migrant in Nguru Mts (Tanzania), occurring down to 1000 m in Oct.
Status and Conservation. Not globally threatened. Restricted-range species: present in Tanzania-Malawi Mountains EBA. Reasonably common in most of range; in continuous forest 2–3 pairs/10 ha, whereas eight forest patches each of 8–12 ha (totalling 73 ha) contained 18 pairs, i.e. average 4 pairs/ha. In Tanzania, race *usambaricus* common at 1500–2200 m in W Usambaras and at 900–2800 m in Ngurus, Ukagurus and Ulugurus; in Eastern Arc mountains as a whole reported also as scarce at 1100 m, but estimated 20 birds/km² at 1300 m, 40 at 1500 m, 47 at 1750 m and 43 birds/ha at 1980 m. Density of nominate race in S Tanzania less well known, but this race is frequent on Mt Luhombero (Udzungwa Mts) at 1900–2350 m; in Malawi local in Misuku Hills (where commoner with increasing altitude in Matipa), and present throughout Nyika, and N & S Viphya Plateaux at 1170–2500 m; in Zambia restricted to Nyika Plateau at 1900–2200 m. Although not currently at risk, this species could become of conservation concern by virtue of its fragmented, isolated montane-forest distribution.

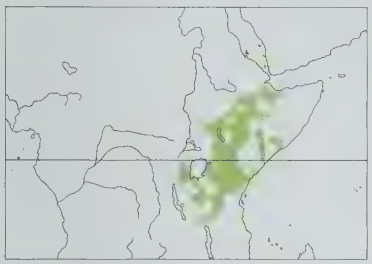
22. Slate-coloured Boubou

Laniarius funebris

French: Gonolek ardoisé **German**: Trauerwürger **Spanish**: Bubú Fúnebre



Taxonomy. *Dryoscopus funebris* Hartlaub, 1863, Meninga ["Unyamwesi area of Tanganyika Territory"], west-central Tanzania.

Recent molecular research indicates that this species constitutes a more recent branch within the genus than do *L. poensis* and *L. fuelleborni* and far more recent one than *L. leucorhynchus*. Race *degener* intergrades with nominate in coastal regions, S Kenya and NE Tanzania (E of Mt Kilimanjaro). Proposed race *atrocoeruleus* (from NE Ethiopia and N Somalia) synonymized with nominate. Two subspecies recognized.

Subspecies and Distribution.

L. f. funebris (Hartlaub, 1863) – NW Somalia and S through C Ethiopia to SE Sudan, SW & extreme E Uganda, Kenya and Tanzania.

L. f. degener Hilgert, 1912 – C & S Ethiopia and S Somalia, SE Kenya and NE Tanzania (E of Mt Kilimanjaro).

Descriptive notes. 18·5–20 cm; male 33–50 g, female 23–55 g. Nominate race has whole head, neck and throat glossy jet-black, grading posteriorly into dark blue-grey on upperparts and breast; rump plumage long and full with white feather bases, some feathers with whitish subterminal spots; uppertail-coverts and tail jet-black; belly and flanks smoky bluish-grey, paler than breast; thighs and undertail-coverts bluish grey-black; iris dark brown; bill and legs black. Sexes alike. Juvenile initially is dark brown above, feathers of forehead, mantle and upperwing-coverts with narrow rufous-buff tips, back and rump plumage full, fluffy, capable of being erected, feathers with rufous tip, dusky subterminal bar, buffy centre and grey base, rump barred rufous and blackish, uppertail-coverts very dark brown with narrow buff tips, tail short, black, underparts buff, rather evenly banded with slate-grey, the dark bands narrow and close on throat, becoming broader and more widely spaced rearwards to undertail-coverts; immature dull black above, forehead, hindneck, and mantle to rump and upperwing-coverts with very narrow rufous barring, underparts evenly banded dark slate-grey and buff, acquires adult plumage at c. 4–6 months (below, dark bluish-grey of adult acquired first on breast, then on side of belly). Race *degener* is slightly paler and smaller than nominate. Voice. Loud, varied; male and female generally sing in antiphonal duet with gong-like notes, ringing fluty whistles and harsh snarling sounds; 24 different duet notes have been identified, varying individually and geographically. Duet has two sex-specific components (one for each sex), each component learnt from a same-sex tutor in first 6–8 months of life (once learnt, individual repertoires do not change); either sex capable of producing elements that belong to other sex's repertoire; mated pair combines elements into set of pair-specific duets which remain constant for life (at least seven years). Duets and repertoires vary regionally; local dialects transmitted from one generation to the next by social learning. Duet generally initiated by male using "male" element, answered instantly by female using "female" element, but either sex can initiate duet with any element; duets often have three elements, either male or female one repeated. Each sex remembers opposite sex's voices as a "silent repertoire", parts of which can remain unsung for lengthy periods and then produced as occasion demands, as "sympathetic singing". A pair uses several different, standard, call–answer sequences and switches between them; in Kenya, males at L Baringo use four structurally different notes in initiating duets, females responding antiphonally with only one, and in repeated duets S of Nairobi a male uttered deep "clak" lasting 0·4 seconds and female chimed in instantly with rising "whee" lasting 0·3 seconds and beginning fractionally before the "clak" finished (so that whole duet lasted less than 0·7 seconds). A pair duets throughout day; intervals between duets seldom exceed 3–5 minutes except around mid-day; at Seronera, in Tanzania, a pair sang 100, 260 and 120 duets per hour in, respectively, morning, afternoon and evening, its duetting time amounting to 1–1·5 hours daily; when one pair-member forages on ground, mate keeps watch from perch several metres above it and the two repeatedly duet. Besides reacting vocally to its mate, individual reacts to same-sex rivals, whether seen or not, by counter-singing. One function of duetting is thought to be pair-bonding; one particular "male" song type functions to achieve breeding synchrony; two other types have territorial purpose (and relative frequencies vary with social correlates); another type appears to be used in mate-guarding; duets used also to maintain long-range contact (short-range contact maintained by soft, very quiet calls). Male generally sings 2–4 low, hollow "clo" notes and female responds instantly with rising "wooeee" or "clerwy" whistle or sometimes with sneezing "kitchu", thus duet sounds like "cloclo-wooeee, cloclo-wooeee" or "woko-clerwy, woko-clerwy" or "woko-kitchu"; also described as "haw-kwee", "chuwee, chuwee", "hortwee, hortwee" or "twi-twi". Male may utter trill instead of whistle, and female may respond with buzzy note, producing duet "wreeee-dzzrrr". Male can sing complete duet by himself; sometimes three birds call together, one making bubbling sound, one "whooeeoo" whistle and third "wheee-e-e". Female also delivers rapid "quick-quick", answered by male's "squee". Occasionally duets with a congener, including *L. aethiopicus* and *L. erythrogaster*. In alarm or excitement gives harsh, loud "kch-kch..." or "tek-tek...", shrill "rrrrh" or guttural churring sounds. Fledglings produce babble quite different from adult vocalizations.

Habitat. Semi-arid thornbush and acacia (*Acacia*) savanna woodland, mainly below 1500 m; from sea-level to 2200 m (mainly below 2000 m) in Kenya, e.g. at 1500–2000 m on Mt Kulal. Thick bushes along watercourses, overgrown cultivation, thorn-scrub, and in Ethiopia evergreen scrub and juniper (*Juniperus*) woods. Keeps to dense bushland thickets with massed tangles of creepers, in Somalia especially shrubs and small trees smothered in creepers (*Cissus rotundifolia*).

Food and Feeding. Mainly invertebrates, including grasshoppers (Orthoptera), mantids (Mantidae), beetles (Coleoptera), caterpillars, termites (Isoptera), ants, bees and wasps (Hymenoptera), small butterflies (Lepidoptera) and ticks (Ixodoidea); occasionally eats *Commiphora* fruits. In wet season, caterpillars form important part of diet of both adults and nestlings. In dry season, forages by hopping on ground in shade under woody cover, searching leaf litter; in wet season, feeds mainly among foliage, searching for caterpillars. Large prey items wiped to and fro against branch before being swallowed. Usually in pairs; skulking, shy and retiring but noisy.

Breeding. Season Apr–Jul in Ethiopia, Apr–May and Oct in Somalia, Nov in Uganda; in Kenya, breeds in long and short rains, Mar–Nov, nesting 1–3 weeks after rainfall; Oct–May in Tanzania. Pair occupies territory throughout year, defends it by duet singing; in three cases of boundary transgressions, intruders were neighbouring pair nesting attempt of which had recently failed; fighting rare; sometimes a third individual present in territory, once a male and two females, both singing (at different times) in duet with male. In courtship male displays by holding himself upright on extended legs, lowering head, swinging body from side to side, then bending forward, lowering wings, raising and fanning tail, and erecting back and rump feathers into mottled, whitish puff above back; makes short flights between bushes, quivering wings rapidly, with puff expanded; in calling display, two birds face each other 30 cm apart for two minutes, presumed male bows with each deep churring call, answered by female with repeated hoarse cough, thrusting down and forward with each note. Nest built usually by both sexes, mainly female (male sometimes not helping at all), construction time 1–7 days, first nest usually taking longer than later ones, a firmly (sometimes loosely) made open cup built of shreds of bark fibre or of fine rootlets and twiglets, many with remains of seed pods and flower bracts still attached, lined with delicate rootlets and dry grass blades, outer wall sometimes covered with spider web; nest rim often trodden down by brood (so that nest shape changes from cup to platform), and one nest so poorly bound that it collapsed under weight of growing young; placed in vertical fork of small tree or on twiggy horizontal branch of large tree growing in middle of thicket of creeper-covered bushes, usually very well hidden; occasionally nest abandoned before completion and another started elsewhere (material taken from first nest); territory size 1·5–3·5 ha, territories contiguous or isolated. Clutch 2 eggs, sometimes 3, laid on consecutive days; if clutch lost, usually makes new nest, up to three attempts in a season; on day after losing first brood, one pair began to build three nests simultaneously; incubation from first egg, by both sexes when clutch completed (female's spells average 41 minutes, male's 48 minutes), nest-relief co-ordinated by duetting, sometimes only female incubates; incubation period 17 days; chicks brooded for up to 7 days, fed by both sexes, nestling period 14–15 days; fledgling fully capable of flight a few days after leaving nest, even though tail still very short, feeds itself but also begs whenever parent approaches. Of 17 nests at L Baringo, in Kenya, none successful: 12 clutches and 5 broods disappeared (most nests remaining untouched); predation by Nile monitor (*Varanus niloticus*) believed responsible.

Movements. Resident.

Status and Conservation. Not globally threatened. Fairly common in SE Sudan (SE of Torit), and occurs between Boya Hills and NE Uganda and NW Kenya. In Ethiopia, common in Rift Valley and to E, in hot low country around E highlands and to SW & S in Gamo Gofa and Sidamo Provinces; common at 900 m S of Mega and between Yavello, Neghelli and Giarso, in moister country at 1200 m around L Margherita, and in evergreen scrub at 1850 m. In Somalia, fairly common in NW (E to 46° E) and common towards Ethiopian border, and quite common in S, mainly in river valleys and near coast. Fairly common in Uganda in NE (Karamoja), uncommon and local in SW (Ankole, Katonga). Widespread and locally common in Kenya, but absent E of L Turkana and in hinterland W of it, absent also in SW (from Kongelai and Kerio valley to Kavirondo Gulf) and much of arid NE & E, and lowlands S of Malindi. Occurs throughout much of interior Tanzania, but absent from SE of Eastern Arc mountains, and scarce in much of W.

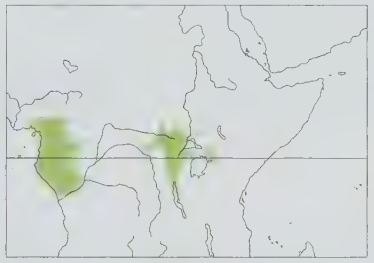
23. Lühder's Bush-shrike

Laniarius luehderi

French: Gonolek de Lühder **German**: Braunscheitelwürger **Spanish**: Bubú de Lühder



Taxonomy. *Laniarius lühderi* Reichenow, 1874, Cameroon.

Forms a superspecies with *L. brauni* and *L. amboimensis*, and all formerly regarded as conspecific. Recent molecular-genetic work indicates that this superspecies is sister to the superspecies formed by *L. aethiopicus* and *L. turatii*. Races intergrade in Ruwenzori Mts (E DRCongo); species sometimes treated as monotypic. Two subspecies tentatively recognized.

Subspecies and Distribution.

L. l. luehderi Reichenow, 1874 – extreme SE Nigeria (Calabar area) and S Cameroon S to NW Angola (Cabinda) and S PRCongo (lower R Congo); extreme S Sudan, NE & E DRCongo, Rwanda and Burundi S to W & E sides of L Tanganyika.

L. l. castaneiceps Sharpe, 1891 – extreme E DRCongo (Ruwenzori Mts), S Uganda and SW Kenya.

Descriptive notes. 18–19 cm; male 30–49 g, female 35–45 g. Distinctive bush-shrike with chestnut cap, round-ended tail (central feather pair 10–14 mm shorter than outer rectrix), and robust bill. Nominate race has forehead and narrow line on side of crown pale cinnamon, merging into chestnut on crown and nape; lores, areas just above and below eye, ear-coverts, side of neck, hindneck, mantle and scapulars glossy black with dark blue or dark green reflections, feathers with grey bases (usually concealed); lower back and rump feathers long, full and loose (overlying rump and uppertail-coverts), dull black with whitish ends and whitish subterminal spot (effect of mottled greyish rump grading to whitish uppertail-coverts); tail black; upperwing black, primaries and outer secondaries with glossy outer webs, inner secondaries, tertials and coverts matt black, but two secondaries with white outer web, and median coverts and some greater coverts broadly tipped white; chin, throat and breast deep cinnamon, rest of underparts white, underwing-coverts and axillaries white; iris dark brown-red; bill black; legs slate-blue or light blue. Sexes alike; neck skin of male thickened and distensible, perhaps linked with throat inflation and decisive head movements when calling. Juvenile is olive-brown above with rufous uppertail-coverts, all finely barred light brown and blackish, no white in wing, has chin and throat pale whitish-grey, underparts olive-yellow with fine dark bars, vent and undertail-coverts unbarred buff, eyes reddish-brown, bill dark grey-brown, legs pale bluish-grey; immature upperparts olive-brown with wide yellowish shoulder streak, tail dull rufous, throat and breast yellowish, rest of underparts whitish, described also as being olivaceous blackish-brown above with obscure paler supercilium, blackish lores and eye mask, primaries and secondaries narrowly edged and tipped rufescent buff, tertials more broadly edged and tipped buffy, upperwing-coverts similarly tipped, chin and throat pale yellowish, merging to orange-rufous on breast and to whitish below, a few thin blackish bars across breast. Race *castaneiceps* differs from nominate only in being rather smaller and paler. Voice. Complex and poorly understood repertoire, regionally variable. Male and female call in duet, using same note or quite different ones; duet a very soft, tremulous, falling "coo" or "keow" by male and low churring "cha-cha-ch-ch..." by female; main calls in DRCongo described as "crrrou" and hoarse "whaw" or "k-kaw" with strange metallic timbre, lasting c. 1 second, answered with dry "k-k-k-k" by presumed female; in Rwanda male gives soft "prru" and guttural "worr" note, female cutting in almost synchronously with harsh, cackling, exclamatory "kè-kè-kè-

kè-kè" or harsh, grating and snoring "wawh-kik-zzha-zzha-zzha"; female's response sometimes an excited slightly crescendo series of cackles, "wawh-kakakekekekikiki", which she may also give unaccompanied as continuous scold; male "coo", "crrrou" and "prru" notes probably same; "keow" and "worr" probably same; "cha-cha", "k-k-k-k" and "kè-kè-kè-kè-kè" probably same; male call lasts 0·2–0·55 seconds, female response starts 0·2–0·25 seconds after male starts, and lasts 0·3 seconds (three "kè" notes) to 0·5 seconds (five notes). With each guttural "crrrou" or "keow", repeated at long, irregular intervals, male bends head and neck forwards, markedly inflates throat and moves head decisively up and down; commonly heard "crrrou" call thought to be used by male for pair contact and territorial advertisement (and described also as a deep, croaking, snoring, hoarse, metallic, guttural and resonant "horrr", "whook" or "worrrrk" with throaty, rolling, frog-like quality). Other duets include liquid whistling "weeo-k'wee" by male and female together; male's explosive, hollow "yo" followed by rapid "yoyoyo", female responding with strident clicks; male's soft, tremulous "keow" answered by female's low, churring "cha-cha" or "chee-uu-graa"; female may respond to male's "crrrou" with harsh "tikk" or long "kssshshsssh". Also utters long "kiurrrr", sharp "tzik, tzik", whistles and harsh notes.

Habitat. Inhabits thick vegetation in abandoned clearings, overgrown plantations and young secondary growth, dense scrub and tall but open secondary forest near lowland towns and villages in forest zone; *Symphonia* gorge forest near PRCongo coast; exceptionally in primary forest (Itombwe, in E DRCongo); sea-level to 2800 m.

Food and Feeding. Mainly caterpillars, especially those in parasol trees, beetles (Coleoptera) and grasshoppers (Orthoptera); also mantises (Mantidae), moths (Lepidoptera), termites (Isoptera), leafhoppers (Cicadellidae), spiders (Araneae), woodlice (Isopoda) and tiny snails (Gastropoda). Forages mainly low down in vegetation and sometimes on ground, but also up to middle levels in trees; keeps in thick, impenetrable cover, but is inquisitive, and can be drawn momentarily into the open. Occurs in mixed-species foraging flocks.

Breeding. Season Sept–Oct in Nigeria, Aug–Oct and Dec in Cameroon, and Sept, Nov–Dec and Feb in Gabon; in DRCongo, in breeding condition in Apr and Jul in NE (Nepoko) and various breeding evidence May–Jul and Oct–Dec in E (Itombwe); Jun–Jul and probably Oct–Nov in Uganda and Kenya. Apparently monogamous and territorial. Nest slight, flimsy, a usually shallow (sometimes quite deep) open cup, loosely made of rootlets, dry weed stems, creeper fibres or thin dry twigs, lined with fine rootlets, sited 1·8–2·5 m above ground on fork well inside small tree, bush or, in Cameroon and Gabon, in the large half-shrubby *Triumfetta*; once on frond of young oil palm (*Elaeis guineensis*) in tangled vegetation. Clutch 1–2 eggs, laying interval 24 hours; replacement laid if clutch lost (once, after egg in first nest disappeared, clutch present only 16 days later in new nest built in palm a few metres away); incubation by both sexes, sometimes by female alone, period c. 15 days; chicks tended by both parents, nestling period c. 15 days.

Movements. None known; probably resident.

Status and Conservation. Not globally threatened. Generally uncommon to not uncommon in W range; common in E. Not uncommon in Nigeria (near Calabar); in Cameroon, widespread in forest zone in SW, common or fairly common in Victoria–Kumba–Dikume Balue area; common and widespread in Gabon, where recorded density of 2–3 pairs/10 ha in secondary growth; in PRCongo, occurs in Odzala National Park, in Nouabalé-Ndoki National Park (near Mombongo), and scarce in Kouilou Basin in SW (from coast E to Mayombe and upstream to Stanley Pool). Possible presence on Bioko I (Fernando Póo) and in Central African Republic not confirmed. In Sudan, common in Imatong Mts (up to 2800 m) and uncommon on Aloma Plateau. In DRCongo, widespread in NE & E (W to between Kisangani and Tshopo Falls), common between R Nepoko and R Bomokandi, and quite common in E (up to 1850 m) S to about Kivu–Katanga border at L Tanganyika; very common in Itombwe Highlands (at 900–2000 m); possibly present along N borders of rainforest, but few early sight records and no recent ones. In Uganda, common at 700–2400 m from Bwamba and Kibale to Ankole and Kigezi, E to Kifu and Mabira; occurs in Agoro-Agu Forest Reserve in extreme N and on Mt Elgon in extreme E. In Rwanda confined to W third, including W part of Nyungwe Forest, and in Burundi known only from Musigati and Karahe Forest (at 1750–2300 m). In Kenya, locally fairly common from Mt Elgon and Kapenguria S to Kakamega, Mau and Trans-Mara, Lolgorien and Mara Game Reserve; in W Tanzania from Gombe Stream National Reserve S to Mahari Mts.

24. Braun's Bush-shrike

Laniarius brauni

French: Gonolek de Braun **German**: Angolawürger **Spanish**: Bubú de Braun
Other common names: Orange-breasted Bush-shrike(!)

Taxonomy. *Laniarius lühderi brauni* Bannerman, 1939, Quicolungo, Angola.
Forms a superspecies with *L. luehderi* and *L. amboimensis*, and all formerly regarded as conspecific. Recent molecular-genetic work indicates that this superspecies is sister to the superspecies formed by *L. aethiopicus* and *L. turatii*. Monotypic.

Distribution. NW Angola (S Uíge and NW Cuanza Norte).

Descriptive notes. 17·5 cm; one male 55 g, two females both 54 g. Male has forehead, crown, nape and hindneck chestnut, slightly paler in front and at side; feathers behind nostrils, lores, areas just above and below eye, ear-coverts, and band down side of neck to mantle and scapulars jet-black, slightly glossy; lower back and rump feathers (long, full and fluffy) greyish-black with large white subterminal spots, uppertail-coverts dull black; tail black; upperwing glossy brownish-black (flight-feathers becoming brown with buffy edges before being moulted), long white line in wing formed by white median coverts, large white tips on inner two or three greater coverts, and narrow outer edges and tips on innermost two secondaries; chin, throat and breast bright orange-red, rest of underparts pure white (lower flank feathers full, silky, fluffy); underwing-coverts and axillaries white; iris dark greyish-brown; bill black; legs slate-grey. Female differs from male only in that red area below appears less extensive. Juvenile apparently undescribed. Voice. Little known. Includes nasal twanging "tzaanana-tzaanana" and "tszowarrr" notes, likened to sound made by releasing a spring; very like contact calls and duetting songs of *L. luehderi* and *L. amboimensis*.

Habitat. Undergrowth of degraded secondary forest and gallery forest.

Food and Feeding. No information.

Breeding. Said to breed in Mar. No further information.

Movements. No information.

Status and Conservation. ENDANGERED. Restricted-range species: present in Western Angola EBA. Found only in small area of escarpment forests in NW Angola, where recorded at six localities: Bolongongo, Quicolungo, Canzele, Camabatela and 30 km S of Uíge (all within 25 km radius of each other) in altitudinal range 600–1265 m, and Quibaxe (74 km W of Bolongongo) at 935 m. Very few specimens or sightings on record, and most of these old, but recent relaxation of conflict that broke out in 1974 is allowing renewed observation; in Jan 2005, three duetting pairs were discovered in small patch of degraded forest 30 km S of Uíge. Almost nothing is known about present status of the Camabatela Forests Important Bird Area (IBA); coffee fazendas were commercially booming up to early 1970s, when logging of escarpment highlands had proceeded steadily for years, but coffee plantations have subsequently been neglected and coffee production has declined through the protracted period of civil war; the forest bird fauna may well have benefited somewhat.

Bibliography. Anon. (2008d), Bannerman (1939a, 1951, 1953), Butchart & Stattersfield (2004), Collar & Stuart (1985), Collar *et al.* (1994), Dean (2000b), Demey (2005), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fishpool & Evans (2001), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Franklin (2000), Mackworth-Praed & Grant (1963, 1973), Nguembock *et al.* (2008), da Rosa Pinto (1960), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Sinclair, Chamberlain *et al.* (2007), Sinclair, Spottiswoode *et al.* (2004), Stattersfield & Capper (2000), Traylor (1963), White (1962).

25. Gabela Bush-shrike

Laniarius amboimensis

French: Gonolek de l'Angola **German**: Amboimwürger **Spanish**: Bubú Angoleño
Other common names: Amboim Bush-shrike

Taxonomy. *Laniarius lühderi amboimensis* Moltoni, 1932, Amboim, Angola.
Forms a superspecies with *L. amboimensis* and *L. brauni*, and all formerly regarded as conspecific. Recent molecular-genetic work indicates that this superspecies is sister to the superspecies formed by *L. aethiopicus* and *L. turatii*. Monotypic.

Distribution. Small area around Gabela (in escarpment zone of W Cuanza Sul), in W Angola,

Descriptive notes. 17·5 cm. Forehead, crown, nape and hindneck are chestnut, slightly paler in front and at side; feathers behind nostrils, lores, areas just above and below eye, ear-coverts, side of neck, mantle and scapulars slightly glossy jet-black, lower back and rump (feathers long, full and fluffy) greyish-black, uppertail-coverts black; tail black; upperwing glossy brownish-black, long white line formed by white median coverts, large white tips on inner greater coverts, and narrow outer edges on innermost secondaries; chin, throat and entire underparts pure white; iris dark brown; bill black; legs slate-grey. Sexes alike. Juvenile apparently undescribed. Voice. Very like that of *L. luehderi*. Commonest call a deep, guttural, frog-like "worrrk" or disyllabic "wor-worrrk", repeated every 3–4 seconds; dry rattle "ker-r-r-r-r-r-r-r-r-r" which, when tape-recorded and played back, caused birds to switch to fast, deep "whioo whioo" whistle repeated every 1·5 seconds, and to harsh "tsik ksh-ksh-kshk" (the "tsik" and "ksh-ksh-kshk" possibly uttered by different individuals).

Habitat. Undergrowth in wet evergreen escarpment forests and degraded farmbush; on Mt Njelo, S of Gabela, lusher lower seaward slopes where forest merges with abandoned and regenerating shade coffee plantations; found in degraded secondary forest, old coffee plantations and primary forest at Kumbira Primero (Conda).

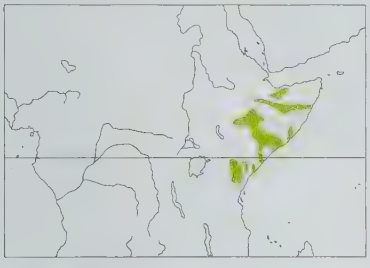
Food and Feeding. No information.

Breeding. No information.

Movements. Presumed resident.

Status and Conservation. ENDANGERED. Restricted-range species: present in Western Angola EBA. Known only from small area in escarpment zone near Gabela, in W Cuanza Sul; one old specimen (in Lubango Museum) from Egito, 125 km farther S, near Lobito. First discovered in 1930 and rediscovered in 1960 at Gabela (formerly Amboim); two pairs found in three days in 1992 at Conda and Assango; during short visits in 2001, 2002, 2003 and 2005, found to be fairly common in Kumbira Forest at 800–1000 m on W flank of Mt Njelo (7 km S of Conda), and also in degraded farmbush below 800 m with subsistence agriculture. Gabela, Conda, Assango and Kumbira are in radius of 15 km of each other, an area of 700 km²; Egito is 7·5 km to S (near Lobito). Scarp forests had been selectively logged before civil war broke out, in 1974; in that year a proposal was made to protect an area of 50 km² around Gabela, but it was not implemented; valley bottoms have now been cleared of undergrowth and 20–70% of canopy trees felled for banana, sweet potato, cassava and maize agriculture. Little more known about present status of Gabela forests themselves. The fact that this species has recently been found to inhabit farmbush, as well as intact forest, gives some grounds for optimism about its survival.

Bibliography. Anon. (2008d), Bannerman (1939a, 1951, 1953), Butchart & Stattersfield (2004), Cohen *et al.* (2004), Collar & Stuart (1985), Collar *et al.* (1994), Dean (2000b), Demey (2003), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fishpool & Evans (2001), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Franklin (2000), Hawkins (1993), Mackworth-Praed & Grant (1963, 1973), Mills & Dean (2007), Nguembock *et al.* (2008), Quantrill (2006), da Rosa Pinto (1960, 1962), Ryan *et al.* (2004), Sibley & Monroe (1990), Sinclair & Ryan (2003b), Sinclair *et al.* (2004), Stattersfield & Capper (2000), Traylor (1963), White (1962).



26. Red-naped Bush-shrike

Laniarius ruficeps

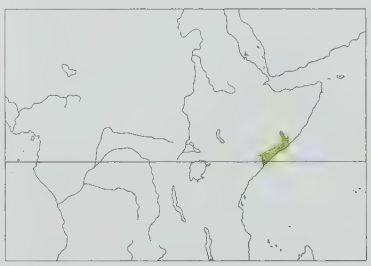
French: Gonolek à nuque rouge **German**: Rotnackenwürger **Spanish**: Bubú Nuquirrojo

Other common names: Red-naped Shrike, Red-crowned Shrike/Bush-shrike

Taxonomy. *Dryoscopus ruficeps* Shelley, 1885, Burao, Somalia.
Recent molecular-genetic studies indicate that this species is closest to *L. erlangeri*, the two composing a clade (lineage) that is deeper-branched than, or sister to, *L. aethiopicus*, *L. turatii*, *L. ferrugineus*, *L. sublacteus*, *L. bicolor*, *L. barbarus*, *L. erythrogaster*, *L. mufumbiri* and *L. atroflavus*. Three subspecies recognized.
Subspecies and Distribution.
L. r. ruficeps (Shelley, 1885) – NW Somalia.
L. r. rufinuchalis (Sharpe, 1895) – EC, S & SE Ethiopia and C & S Somalia (except SE coast).
L. r. kismayensis (Erlanger, 1901) – S Somalia coastal lowlands and NE & SE Kenya.

Descriptive notes. 18–19 cm; one male 35 g, female 29–33·4 g. Male nominate race has forehead black, crown, nape and hindneck bright orange-rufous or rufous-red, well-defined long white superciliary stripe from bill to side of neck (broadest above nostril); lores and area just above and below eye black, ear-coverts glossy black, narrow black stripe down side of neck joining ear-coverts and scapulars; mantle bluish-grey in mid-line, paling towards side of neck, upper back ash-grey, feathers of scapulars and lower back jet-black with bluish gloss and large white subterminal spots; rump feathers silky and fluffy, white with dark grey bases and narrow blackish tips, uppertail-coverts black; tail black, all except central two feather pairs with white terminal patch 10 mm deep, outermost rectrix also with white outer web; upperwing black, broad white longitudinal stripe formed by white median coverts, three inner greater coverts, and outer webs of three innermost secondaries; entirely creamy white below, side of breast and flanks washed with pale pink-buff; marginal and lesser underwing-coverts creamy white, greater under primary coverts dusky; iris hazel-brown; bill black; legs blue-grey or slate-grey, soles whitish. Female differs from male in having back olive-grey, not ash-grey. Juvenile lacks black facial mask, has ear-coverts dusky, indistinct pale supercilium, forehead to back uniformly olive-grey, scapulars brown with buffy tips (giving barred appearance), primary coverts and outer greater coverts brown with well-defined narrow buff edges and tips, tail greyish-olive, outer two rectrices broadly tipped and edged rufous-brown, underparts buffy brown-grey, throat and middle of belly whitish. Race *rufinuchalis* is similar to nominate, but black of forehead extends onto crown, so that only nape and hindneck are orange-rufous, breast and flanks buffy rufous; *kismayensis* is like previous, but mantle pale grey, extent of black on forehead and crown apparently variable. Voice. Not well known; varied, described as creaking (like sound of fishing reel), and harsh cawing very like main call of Pied Crow (*Corvus albus*). Song a short duet initiated apparently by either sex, a low-pitched "cheeo-oo" whistle or guttural snoring "gwaaar" or "grrrra" followed instantly by loud ticking or clicking in descending series, "grrrra-tktktktktktktk"; solo song or call a repeated low-pitched "kwoi" or longer "whooi"; alarm a loud burst of clicking and harsh scolds; clicks and explosive calls said to be like those of *L. barbarus*.
Habitat. Dense, impenetrable thornbush, in NW Somalia particularly *Acacia orphota*, and open thorn-scrub; sea-level to 1000 m.
Food and Feeding. Adult and larval insects. Forages on ground and lower branches in thickets, where it hunts silently, moving rapidly but furtively; secretive, skulking in shadiest interior of thorn thickets, but occasionally climbs to top of tree and stays there in full view for a few seconds. Foraging mates generally widely separated, and frequently give contact calls.
Breeding. Poorly known. Season May. Solitary breeder; possibly at times loosely colonial, with old (1920) record of 14 individuals found at Kyal, in Somalia, on one day in Jan and one day in May. Nest a thin structure made of twigs, rootlets and grass stems, placed 1·5 m above ground in bush or tree, often dense thorny acacia tree. Clutch 2–3 eggs. No other information.
Movements. Resident; may move locally.
Status and Conservation. Not globally threatened. Patchily distributed, and uncommon to locally common. In Somalia, present in NW in Burao region, common at Kyal, and patchily distributed from coast near Eyl S to hinterland of S Somalia, as far as Ethiopian and Kenyan borders. Uncommon in Ethiopia in S & SE, formerly common around Yavello; only 28 records, 18 old and ten recent. In Kenya, locally common below 1000 m from Garissa, Mwingi, Kitui and Mutomo Districts S to Mtito Andei, Ngulia, Maungu, Taru, Lali Hills and Galana Ranch; common around Kiunga (on coast near Somalia border), and extends S towards Boni Forest; recorded also in Mandera and Wajir Districts, in NE.

Bibliography. Archer & Godman (1961), Ash & Atkins (2009), Ash & Miskell (1983, 1998), Bennun & Njoroge (1999), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fishpool & Evans (2001), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Franklin (2000), Jackson & Sclater (1938), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1960), Nguembock *et al.* (2008), Redman *et al.* (2009), Serle (1943a), Short *et al.* (1990), Sibley & Monroe (1990), Sinclair & Ryan (2003a), van Someren (1932), Stevenson & Fanshawe (2002), Thorpe (1972), Tilahun *et al.* (1996), Urban & Brown (1971), White (1962), Zimmerman *et al.* (1996).



27. **Somali Boubou**

Laniarius erlangeri

French: Gonolek d'Erlanger **German**: Erlangerwürger **Spanish**: Bubú de Erlanger
Other common names: Erlanger's Boubou; Bulo Burti Bush-shrike ("*L. liberatus*")

Taxonomy. *Laniarius erlangeri* Reichenow, 1905, Umfudu, Jubba River, south Somalia.
Recent molecular-genetic studies indicate that this species is closest to *L. ruficeps*, the two composing a clade (lineage) that is deeper-branched than, or sister to, *L. aethiopicus*, *L. turatii*, *L. ferrugineus*, *L. sublacteus*, *L. bicolor*, *L. barbarus*, *L. erythrogaster*, *L. mufumbiri* and *L. atroflavus*. Was until recently regarded as a race of *L. aethiopicus*. A single bird caught in Somalia in 1989 was described as a distinct species, *L. liberatus*, but recent analyses of nuclear and mitochondrial DNA reveal that it is a variant of present species, and the possibility of its being a hybrid between this species and *L. ruficeps* rejected as highly improbable. Monotypic.
Distribution. Lower Shabeelle and Jubba valleys and coastal lowlands (between equator and 4° N), in SE Somalia.
Descriptive notes. 20 cm. Has forehead, crown, lores, cheek, ear-coverts, side of neck, hindneck and upperparts black with slight greenish gloss, lower back and rump (feathers long and fluffy)

with concealed white spots; tail black, outer feathers tipped white; upperwing black, median coverts distally white; white below, breast and flanks tinged pale pink; iris deep red; bill black; legs bluish-slate. Differs from very similar *L. aethiopicus* (of race *major*) in smaller size, greenish (not bluish) gloss, white in wing confined to median coverts, paler pink on underparts, slightly stouter bill. Black morph has plumage entirely black with bluish gloss, no concealed white spots in rump, tail without white tips on outer feathers. Both morphs occur in Jubba valley, only black morph in Shabeelle valley. Bulo Burti variant ("*liberatus*") has black parts of plumage unglossed, broad pale yellow superciliary stripe from bill to side of hindneck, pale yellow feather tips on hindcrown and nape, a few off-white tips on back feathers, partly concealed broad white subapical spots on most rump feathers, small white tips on all tail feathers except central pair; tertials and secondaries dull brown-black, outer webs of secondaries S4–S6 white-edged, inner greater wing-coverts with broad white tips on outer webs, median cov-

erts with small white tips on outer webs; mostly white below, side of throat, upper breast and side of lower breast pale yellow. Sexes alike. Juvenile is duller than adult, with pale feather tips above and some barring below. Voice. Poorly known, but said to differ markedly from voice of *L. aethiopicus*; may be rather silent. The single known Bulo Burti individual uttered ascending, disyllabic whistles, "poo-eeh" or "tuwe...tuwe", also low harsh churrs in flight, and single low "chack" calls when feeding.

Habitat. Thick bush and thorny thickets dominated by *Acacia nilotica* trees and with narrow riverbank woods and scattered *Cadaba mirabilis* bushes over very sparse herb layer; copses where umbrella-shaped canopy reaches ground, the low trees covered with climbing cucurbits, legumes and composites; also coastal scrub and dense, woody thickets.

Food and Feeding. Following details from observations on captive individual. Ate crickets (Orthoptera), cockroaches (Blattodea), and geckos (Gekkonidae) and other lizards; when it took a lizard in aviary, it carried this in its bill to a broken horizontal branch with spiky wood splinters and repeatedly beat the prey against the spikes until it was torn to pieces. On release, it foraged in or below dense tangled vegetation, taking prey on the ground or in very low branches deep inside acacia bushes, where it hopped around on ground rather in manner of a *Turdus* thrush, turning over branches and leaf litter; it followed same foraging route daily, spending 1–2 hours in one acacia bush before making a short low flight to another.

Breeding. No information.

Movements. Presumably resident.

Status and Conservation. Not assessed. Has very small overall range, but common and thought not to be of global conservation concern. Occurs along less than 450 km of coastal lowland between Mogadishu and Kismaayo (possibly no more than the 250 km where Webi Shabeelle runs parallel to coast, in province of Shabeellaha Hoose), and thence c. 250 km upstream in R Jubba valley and c. 230 km up Webi Shabeelle valley from Balcad Nature Reserve (near Mogadishu) to Buulobarde. Nothing known of the extent to which its habitat and population have been affected by civil unrest, agricultural development and urban growth. Balcad Nature Reserve is in one of the least disturbed patches of vegetation in R Shabeelle drainage system and is officially protected.

Bibliography. Anon. (2008d), Archer & Godman (1961), Ash & Atkins (2009), Ash & Miskell (1983, 1990), Butchart (2007), Butchart & Stattersfield (2004), Collar (1998, 1999), Collar *et al.* (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fishpool & Evans (2001), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Franklin (2000), Hustler (1996), LeCroy & Vuilleumier (1992), Mackworth-Praed & Grant (1960), Mearns & Mearns (1998), Nguembock *et al.* (2008), Prinzinger, Becker *et al.* (1997), Redman *et al.* (2009), Sibley & Ahlquist (1990), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Smith *et al.* (1991), Stattersfield & Capper (2000).

28. Tropical Boubou

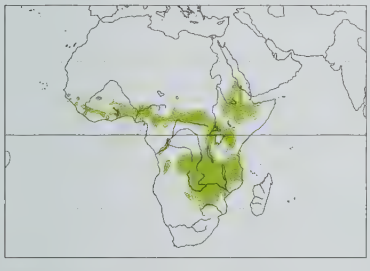
Laniarius aethiopicus

French: Gonolek d'Abyssinie **German**: Boubouwürger **Spanish**: Bubú Abisinio
Other common names: Tropical Bush-shrike, Ethiopian Boubou/Bush-shrike/Bellshrike, Bell Shrike, Boubou Shrike

Taxonomy. *Turdus aethiopicus* J. F. Gmelin, 1789, Ethiopia.

Forms a superspecies with *L. turatii* and closely allied also with *L. ferrugineus*, *L. sublacteus* and *L. bicolor*, the five previously treated as a superspecies and sometimes even as a single species. Until recently, *L. erlangeri* and *L. sublacteus* were included as races of present species. Where present species and *L. ferrugineus* meet, in R Limpopo valley (in N South Africa and Mozambique), their races are very similar and may hybridize and intergrade; but along R Runde, in Zimbabwe, race *limpopoensis* of present species overlaps with smaller race *savensis* of *L. ferrugineus* without interbreeding. Population on plateau of WC Angola, having especially white underparts, may represent an undescribed taxon. Race *major* intergrades with *mossambicus* in N Zambia and extreme N Malawi. Five subspecies currently recognized.

Subspecies and Distribution.



L. a. major (Hartlaub, 1848) – W Senegal (Casamance), N, SW & SE Guinea, NE Sierra Leone, NW Liberia, S Mali (Baoulé-Sud, Farako), C Ivory Coast, NE, C & S Ghana, Togo, Benin (S from Bétérou), C & S Nigeria, C & E Cameroon, S Chad and SW & C Central African Republic E to S Sudan, Uganda, Kenya (E to Rift Valley), Tanzania (E in N to Loliondo and Essimingor, in S to Njombe and Mahenge), N, E & SE DRCongo and R Congo (from Lukolela S to Kinshasa), C & E Angola, NW & N Zambia and extreme N Malawi.

L. a. aethiopicus (J. F. Gmelin, 1789) – E borders of Sudan, and Eritrea, Ethiopia, NW Somalia and N Kenya (Moyale area).

L. a. ambiguus Madarász, 1904 – highlands E of Rift Valley in Kenya (S from Mt Kulal and Mt Marsabit) and NE Tanzania (S to Mt Meru and Mt Kilimanjaro and Arusha and Moshi).

L. a. mossambicus (G. A. Fischer & Reichenow, 1880) – Zambia and Malawi, extreme NE Namibia (Caprivi Strip), N & E Botswana, Zimbabwe (except SE lowveld) and Mozambique.

L. a. limpopoensis Roberts, 1922 – SE Zimbabwe (area bordered by Sabi, Runde and Limpopo rivers) and extreme N South Africa (N Limpopo Province).

Descriptive notes. 19·5–25 cm; male 52–62 g and female 40–45 g (*major*), male 42–69 g and female 38–57 g (*mossambicus*), male 47·5–60 g and female 41–60 g (*ambiguus*). Nominate race is mostly glossy bluish-black above; feathers of lower back and rump long, full and fluffy, greyish or whitish with white subapical mark and black ends, overlying glossy bluish-black uppertail-coverts; tail black, slightly glossy, outer feathers sometimes white-tipped; upperwing mainly black, slightly glossy, median coverts white distally, innermost greater coverts with white outer web; throat and entire underparts white, breast and flanks tinged salmon pink; underwing-coverts white, axillaries white with pink tinge; iris deep red-brown; bill black; legs bluish-slate. Sexes alike. Juvenile has most feathers of upperparts tipped tawny-buff, underparts dull whitish, breast and flanks pale brown with some dusky barring, eyes sepia-brown, bill horn-coloured; immature like adult, but black areas duller and white areas buffy, upperwing-coverts and uppertail-coverts with buffish-white tips and edges, outer two pairs of rectrices with white tips. Races differ mainly in amount of white in wing and in tone of underpart colour: *major* is like nominate, but three innermost secondaries have white outer webs (combining with white of coverts to form long white wingstripe), breast and flanks only faintly tinged pink; *mossambicus* is like previous, but underparts strongly washed pinkish-buff, outer tail feathers never white-tipped; *limpopoensis* resembles last, but underparts buffy cream; *ambiguus* is like nominate, but black areas glossed greenish (rather than bluish), underparts much paler pinkish. Voice. Male and female sing in antiphonal duet, usually of 2–3 notes, sometimes of 5–8, occasionally up to 14, repertoire including repeated fluty whistles at variable pitch, resonant drawn-out whistles, and harsh tearing, croaking or snarling sounds. Some individual or pair variation, and geographical variation from mainly whistles in N of range to mainly croaks and snarls in S; fluty whistles vary from low-pitched single "hou" through double "boubou" to long series of rapid quavering or bubbling "bobobobobo..." noises; also long, loud and far-carrying whistles with resonant, bell-like quality, "hooooooooooo"; harsh notes (perhaps female's) include tearing "weeeer", "krzzzz", croaks, nasal snoring "haaw" and rattling "ke-ke-ke..."; common duet sounds like "ho-ho-u-ho", "hooooooo-ho-ho", "houho-weeer", "hoou-weeeer-hoou" or "weeer-weeer", the "ho" notes by male and "weer" notes by female; single individual can sing both its own and its mate's contributions. In experimental field study in Ivory Coast, twelve duet songs were identified, some initiated by male, others by female; important functions are joint territorial defence and mutual mate-guarding; after simulated territorial intrusions using tape playback, one particular duet was not used during encounters but always afterwards (that duet very loud and from high perch, male standing high on legs and raising bill skywards, appears to be a post-conflict display signalling victory). Male utters twanging "tchanananana", loud "schrang, schrang" and "kit-tuu-iii" notes in courtship and territorial threat; particularly vocal during nest-building period. Contact call a soft, low-pitched "bou"; alarm a chattering "ke-ke-ke..."; "tuk-tuk-tuk" calls given before settling to roost. Intense interactions accompanied by loud wing-fripping.

Habitat. Dense woody cover along riverbanks and watercourses, thickets and unkempt hedges in farmland and gardens, dense growth on termitaria and around bases of inselbergs and koppies; also thick elephant grass and tangles of creepers along edges of lowland forest and bushy hillside ravines; tall grass savanna, brachystegia (*Brachystegia*) woods, and dry *Acacia–Commiphora* bush; in highlands, found in *Hagenia* forest, *Arundinaria* bamboo, mixed evergreen scrub of olive (*Olea*), juniper (*Juniperus*) and *Podocarpus*, also bracken-briar and forest edges. Sea-level to mountains; to 3000 m in Kenya, 3030 m in Ethiopia.

Food and Feeding. Insects, including Orthoptera, mantises (Mantidae), termites (Isoptera), beetles (Coleoptera), caterpillars, other larvae and pupae; some small snails (Gastropoda) and small fruits; a few small vertebrates, including chameleons (Chamaeleonidae), skinks (Scincidae), geckos (Gekkonidae), amphibians, rodents, also bird eggs and nestlings; persistently raids nests of small birds, and often attacks waxbills (*Estrilda*). Young initially fed with quite large insects, later given several small vertebrates, most or all food obtained by parents within 20 m of nest. Shy and secretive, keeping inside cover, but inquisitive, even confiding, coming into the open on ground in large gardens and around game lodges. Forages mostly low down in woody vegetation and foliage, often dropping to ground, where it hops in leaf litter, turning a leaf or piece of bark when it sees an insect disappearing under it; gleans trunks, branches and foliage, but probably takes more food from ground than from vegetation; occasionally hawks for flying insects. Sometimes comes out from under bush and hunts in roadside drains or wet silt along path. Wedges larger prey items in a fork, and uses bill to tear them apart; not known to impale prey in the wild, but captive individual stuck pieces of meat on to branches in its aviary. Forages singly and in pairs, also in family groups; feeds alongside *L. bicolor* and *L. atrococcineus*, sometimes in same bush.

Breeding. Season May in Guinea, Feb–Mar and Jun in Nigeria, Jun–Sept in Sudan, Apr–Jun and Aug–Sept in Ethiopia and Eritrea, Apr–May in NW Somalia; in DRCongo, May in NE (Faradje), Dec–Jan in E (Baraka), Sept–Dec in SE (Katanga); in all months (mainly Mar–Jun) in Uganda and Kenya; Sept–Apr in Tanzania, Aug–Jun (mainly Sept–Feb) in Zambia, Sept and Jan in Malawi, Oct–Dec in Botswana, Jul–May (mainly Sept–Nov) in Zimbabwe, and Oct–Dec in Mozambique; double broods rare. Pair remains in territory all year, size c. 2 ha in breeding season, up to 8 ha at other times; territories well spaced, perhaps seldom contiguous, advertised and defended by calling, squabbles between neighbouring pairs rare; calling male often perches half-exposed on or near top of bush, bobs head and bows body with each note, in territorial interactions calling female often perches in bush below male. In courtship male chases female, the two hopping close together rapidly through foliage and branches and making short wing-fripping flights; male bobs head shallowly and, with neck extended, bows body, he gives snarling calls and flies or half-glides downwards with slow beats, whitish back and rump feathers fluffed out; courting male stands upright, raises head and calls, then depresses head and body while calling "kit-tuu-iii", he droops wings, fans tail, raises back and rump feathers and lets them droop fanwise while moving up and down, calling and fluttering in front of mate, then copulating. Nest built by both sexes, mainly female, several nests may be started, being successively plundered by pair, before female lays in definitive one; a shallow, open bowl made of loosely knitted rootlets and fine twiglets, lightly bound with spider web, sparsely lined with fine rootlets (usually eggs visible from below), well concealed in fork generally in thorn bush, or on horizontal branch among climbers and epiphytes, usually 1·5–3 m (sometimes up to 9 m) above ground, in tree such as *Terminalia prunioides*. Clutch 2–3 eggs; incubation mainly by female, less by male, sexes taking turns, at change-over singing in duet (initiated by sitting bird), period c. 15 days; chicks fed by both sexes, usually only one at nest at a time (if both parents away and male approaches nest, female gives call to warn chicks), nestling period c. 15 days; young can feed themselves by c. 7 weeks after leaving nest, remain with parents for c. 5 months, and have most of adult vocabulary by 5 months. Small number of nests (c. 2%) parasitized by Black Cuckoo (*Cuculus clamosus*); some pairs of present species appear to be repeatedly susceptible. From ringing studies, maximum recorded longevity at least 13 years 10 months.

Movements. Mostly resident; some adults strictly sedentary, but apparently a constant turnover of birds at a ringing station in Malawi. Local seasonal movements reported in Kenya; possibly some altitudinal movements in Ethiopia.

Status and Conservation. Not globally threatened. Uncommon to frequent over large part of sub-Saharan Africa; commoner in E & SE of range than in W & C. Sight record in Senegal (Casamance). In Guinea, common around Beyla and Macenta, in Haut Niger National Park, and recorded W to Gaoual and Conakry areas; frequent in E Sierra Leone, rare in Liberia (R Makona near Jalamai, and Monrovia), and common in C Ivory Coast; in Mali, small populations near Madina Diassa and at Farako; in Ghana, uncommon in coastal belt (from Axim to Accra Plains), frequent in N (at Mole and Tono Dam), otherwise known only from Wenchi, Ejura and Kete Kratchi; locally common in Togo S from Landa-Pozanda and Naboulgou, and frequent in Benin S at least from Bétérou; in Nigeria, not uncommon in S guinean savannas immediately N of forest zone, and occurs N to

On following pages: 29. Turati's Boubou (*Laniarius turatii*); 30. Southern Boubou (*Laniarius ferrugineus*); 31. East Coast Boubou (*Laniarius sublacteus*); 32. Swamp Boubou (*Laniarius bicolor*).

Kaduna, Jos Plateau and Yankari National Park, in suburbs of coastal towns and on Mambilla Plateau; in Cameroon, not uncommon N of forest zone (to c. 07° 30' N), in S penetrates forest zone in cleared areas and suburbs S to Gabon border; uncommon in Chad N to Sarh and Zakouma National Park; in Central African Republic, frequent in Dzanga Reserves, several records in middle latitudes, and rare in Bamingui-Bangoran National Park; in NE DRCongo, frequent and widespread in woodlands and grasslands N of Congo Basin rainforest (up to 1850 m) and penetrates S in cleared land to R Congo; common in SW Sudan, but uncommon near Ethiopian border in E & SE. Common to abundant in highlands in Ethiopia up to Sen'afe (at 3030 m), absent from hot lowlands in NE and from much of Ogaden, and uncommon or absent towards Kenya border; density of 34 birds/100 ha in Chilimo Forest (C Ethiopia). In Eritrea, frequent at up to 2725 m but absent from W and from dry coastal plain; common in NW Somalia. Common throughout Uganda; in Kenya, locally frequent in highlands in SW half of country; locally common to very common in Tanzania, in e.g. Serengeti National Park, occurs on Mt Kilimanjaro at 2050–2200 m, and absent from most of interior but locally frequent in Eastern Arc mountains, Mahenge and Njombe highlands and in SW. In Angola, frequent on WC plateau (area bounded by Lunda, Malanje and Huambo) and occurs also in E (Moxico), where status uncertain; in DRCongo (other than NE), occurs in W on lower R Congo, widespread in E & SE in woodlands S of rainforest block (in Kasai Occidental, S Kasai Oriental, throughout Katanga and in E Kivu); frequent to common and widespread in Zambia, but uncommon in W and absent from SW; in Botswana, fairly common to very common in Limpopo and Shashe drainages and at Kasane and Serondella, uncommon in Okavango and along R Botlete; common and widespread in Mozambique S to R Save, but in N absent from much of Zambezia and interior of Nampula. In South Africa, confined to riparian forest along R Limpopo and R Luvuvhu and tributaries in N lowveld, and Nyanda Bush in N Kruger National Park; density of 55 territorial pairs in 3·2 km² (i.e. 34 birds/100 ha) of linear transect along R Luvuvhu, and estimated population of 10,500 individuals in N Kruger National Park. Several records since 1998 in Lesotho.

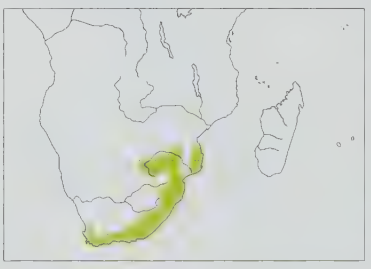
29. Turati's Boubou

Laniarius turatii

French: Gonolek de Turati **German**: Turatiwürger **Spanish**: Bubú de Turati
Other common names: Turati's Bush-shrike/Bellshrike

Taxonomy. *Dryoscopus turatii* J. Verreaux, 1858, "Senegal"; error = Guinea-Bissau.
Forms a superspecies with *L. aethiopicus* and closely allied also with *L. ferrugineus*, *L. sublacteus* and *L. bicolor*, the five previously treated as a superspecies and sometimes even as a single species. Has been treated as a race of *L. aethiopicus*, but the two overlap in range in a tiny area around Bafodia, in N Sierra Leone (formerly forested, and may have separated the two), where they do not react to each other, even though voices very similar. Monotypic.
Distribution. Guinea-Bissau S to Sierra Leone.



Descriptive notes. 20–22·5 cm. Forehead to hindneck and mantle, lores, upper cheek, ear-coverts and side of neck black, glossed with dark blue; scapulars and back feathers glossy black with concealed large white subterminal spots; rump feathers black, long, loose and fluffy, tips of overlying uppertail-coverts white; upperwing entirely glossy black; tail rather long, square-ended, black; chin, throat, breast and upper flanks buff-pink, merging to white on belly, rear flanks, thighs and undertail-coverts; inner underwing-coverts and axillaries black, greater under primary coverts black; iris dark brown; bill black; legs slate-grey or bluish-grey. Sexes alike. Juvenile undescribed. Voice. Male and female sing in synchronous duet, male uttering pure, soft, hollow whistle, "whawwhh", or drawn-out resonant, ringing, metallic "hoo, hoou-hoou" in slow series, and female a nasal, grating "dizhizhizhaaaanh" or "k-kchchnerr" and strident clicking notes; duet initiated by either sex. Also gives explosive "kek" notes, often in long series at variable speeds; in territorial threat and courtship uses slow nasal twanging calls, "wa-wa-zzzn-errrr". Bout of duetting may last several minutes. Voice very like that of *L. aethiopicus* in W Africa (but less variable, more stereotyped and more slowly delivered than that of *L. aethiopicus* in S Africa).
Habitat. Dense, creeper-festooned canopy of bushes and small trees in savanna woodland.
Food and Feeding. Little known. Forages singly and in pairs; shy. Foraging behaviour apparently like that of *L. aethiopicus*, but present species less inclined than latter to ascend high in tree. Where the two occur together (in N Sierra Leone), a pair of each species twice seen in same tree with no signs of aggression.
Breeding. Very little known. Breeds in May in Guinea-Bissau. Apparently monogamous and territorial. Nest a flimsy bowl made from grass stems and fine rootlets, may be lined with dry leaves, placed c. 2 m above ground in multiple horizontal fork in bush. Clutch 2 eggs. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Common in S of range. In Guinea-Bissau, old records from Farim and Gunnal; in Guinea, old record from Mamou and recent ones on coast and inland to Mambia, Foulayah, Koba and Kolenté, and frequent in N Fouta Djalon. Common and widespread in Sierra Leone E to Bafodia, Farangbaia and Shenge, with records farther SE at Bo and E of Bo and at Pujehun; common around Njala campus. May be in process of extending range E, at least in N Sierra Leone.
Bibliography. Bannerman (1939a, 1953), Borrow & Demey (2001), Collar & Stuart (1985), Demey (1995, 2007), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Field (1979), Fishpool & Evans (2001), Fry *et al.* (2000), Hall (1954), Hall & Moreau (1970), Harkrider (1993), Harris & Franklin (2000), Mackworth-Praed & Grant (1973), Nguembock *et al.* (2008), Serle & Morel (1977), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Thorpe (1972), White (1962).

30. Southern Boubou

Laniarius ferrugineus

French: Gonolek boubou **German**: Flötenwürger **Spanish**: Bubú Ferrugíneo
Other common names: Ferrugin(e)ous Bush-shrike/Boubou, African Bush-shrike/Boubou

Taxonomy. *Lanius ferrugineus* J. F. Gmelin, 1788, Cape of Good Hope, South Africa.
Has been treated as conspecific with *L. aethiopicus*, *L. turatii*, *L. sublacteus* and *L. bicolor*; genetically closest to *L. sublacteus* and perhaps forming a superspecies with it, but somewhat less closely allied with *L. bicolor* and a little farther removed from *L. aethiopicus* and *L. turatii*. Where present species and *L. aethiopicus* meet, in R Limpopo valley (in N South Africa and Mozambique), their races are very similar and may hybridize and intergrade; but along R Runde, in Zimbabwe, race *savensis* of present species overlaps with the larger race *limpopoensis* of *L. aethiopicus* without interbreeding. Six subspecies recognized.
Subspecies and Distribution.
L. f. savensis da Rosa Pinto, 1963 – SE Zimbabwe (lower R Runde) and S Mozambique (R Save valley).
L. f. transvaalensis Roberts, 1922 – SE Botswana (Gaborone and Lobatse areas) and lowlands of N South Africa (N North West Province and Limpopo Province, excluding Limpopo Valley, S to E Mpumalanga and N KwaZulu-Natal) and E Swaziland.
L. f. tongensis Roberts, 1931 – SE & extreme S Mozambique (E Sul do Save and Lebombo Range), and E South Africa (coastal KwaZulu-Natal, including L St Lucia).
L. f. natalensis Roberts, 1922 – E & S South Africa (W & S KwaZulu-Natal S to extreme SW Eastern Cape at Plettenburg Bay).
L. f. pondoensis Roberts, 1922 – coastal forests of E Transkei (Pondoland), in NE Eastern Cape.
L. f. ferrugineus (J. F. Gmelin, 1788) – S Western Cape (E to Plettenberg Bay).

Descriptive notes. 21–23 cm; male 53–69 g and female 54–62 g (nominate and *natalensis*), male 44–53 g and female 42–51 g (*tongensis*). Male nominate race has forehead, crown, hindneck, cheek, ear-coverts, side of neck, mantle and scapulars glossy jet black; lower back feathers long, full and loose, each with indistinct whitish subapical spot, rump feathers tipped buff-rufous, uppertail-coverts black; tail glossy black; upperwing mainly black, somewhat glossy, median coverts white distally, innermost two greater coverts with broad white outer edges, innermost two secondaries with white outer edges (long white wingstripe); chin, throat and breast buffy white, merging into ochraceous rufous on flanks, thighs and lower belly and into rich cinnamon-rufous on rear flanks and undertail-coverts; underwing-coverts and axillaries cream-buff, greater under primary coverts black; iris very dark brown, eye-rim black; bill robust, black; legs slate-grey. Female is like male but duller, forehead to mantle slaty or blackish-grey, has more extensive rufous on belly, dark brown eyes. Juvenile is similar to female but with variable degree of buff and dusky mottling above and rufous barring below, bill horn-coloured; immature like adult female but rather paler and duller, rump rufescent grey, entire underside from chin to undertail-coverts buffy, a little darker towards rear. Race *pondoensis* is like nominate, but male glossier black, upperparts of female tinged olivaceous; *natalensis* resembles previous, but male whiter (less buffy) on chin, throat and breast, and flanks less richly cinnamon, female upperparts darker; *transvaalensis* is like nominate, but both sexes have chin to breast buffy white grading into pale rufous lower belly, female with upperparts dark grey; *tongensis* is small, male mainly white below, with buffy flanks, thighs, belly and undertail-coverts, female like female *natalensis* but underparts paler; *savensis* is like last but still smaller, upperparts uniformly matt dark slate-grey, flanks tawny-buff. Voice. Highly vocal; duet-singing frequent throughout day and year, with much regional variation in duration, tonal quality and duet structure; a given pair has distinctive duet pattern. Repeated fluty whistles and harsh calls, mainly in duet initiated by either sex; bird that has lost its mate can sing whole duet by itself. In territorial interactions, male utters loud, ringing "houu" whistles and female responds with higher-pitched loud "huwee" or double "huwehuwe" (nest-relief signals similar, "houu" whistle by male and "huweyo" whistle by female); in aggression and courtship, loud "boubou" whistles and snarling, clashing, nasal "tchzanaa-tchananaa" or "bizzikizzkizz" calls; contact call a repeated, low-pitched "boubou", mainly by male; frips wings in flight; pair makes "tik-tik" calls when going to roost and when plundering a nest; alarm "tik-tik", "tschok", rattles, scolds and guttural "chaa-aa-aa"; another call, of unknown function, is high-pitched "squee-squee-squee-tik-tik-tik", which can evoke similar call by mate. Mimicry of Red-chested Cuckoo (*Cuculus solitarius*) once reported.
Habitat. Dense mesic woodland, favouring clumps of leafy bushes, tangles of creepers, coastal scrub, riverine thickets, edges of forest, stands of proteas (*Protea*), thickets around base of koppies and on termitaria, plantations, exotic acacias (*Acacia*) and mature gardens.
Food and Feeding. Beetles (Coleoptera), grasshoppers (Orthoptera), hairy caterpillars up to 90 mm long, bees (Hymenoptera), many snails (of species *Helix adspersa* and *Theba pisana*); occasionally eggs, nestlings and fledglings of small birds, house mice (*Mus musculus*), geckos (of species *Phyllodactylus porphyreus*) and their eggs; in gardens, also grain, porridge and fruit. Singly and in pairs. Keeps low down in dense, woody vegetation; secretive, seldom coming into open except around human habitation. Forages by leaping, hopping and creeping in rather horizontal posture through woody tangles and undergrowth, emerging briefly at edge and then disappearing from view again; often comes to ground littered with dead plant matter but with no herbs, in shade under bushes, hopping around in search of food; sometimes comes on to edges of lawns, and visits birdtables. Pulls bark off dead trees to find geckos. Occasionally probes flowers, and hawks after

flying insects; a captive regularly impaled prey. Hairy caterpillars vigorously rubbed against branch or in sand before being consumed; stings of bees rubbed off against perch before insect swallowed; to eat snail, breaks open shell by repeatedly beating it against branch, or wedges it into crevice and uses bill to tug flesh out. One individual took whole eggs one at a time from nest of Cape Robin-chat (*Cossypha caffra*), put each on ground and ate contents and shell.

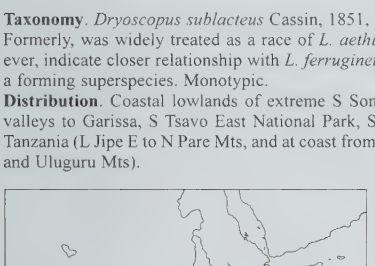
Breeding. In South Africa breeds Aug–May (mainly Oct–Dec) in N, Sept–Dec (mainly Oct–Nov) in KwaZulu-Natal, and Aug–Mar in Western Cape; Oct–Dec in Mozambique. Pair defends territory throughout year, but especially in breeding season, with repeated loud ringing whistles, mainly by male while in upright stance, bobbing head slightly and with half-open tail, half-exposed on elevated perch; in territorial interaction, rival males counter-sing, fanning tail and fluffing out white-spotted back feathers; male may fly or half-glide downwards with exaggerated, slow wingbeats, giving snarling calls with head up; pair becomes aggressive in breeding season, chasing other birds and plundering their nests. Courtship seem to be same as interactions of rival males; male and female sway, move close together through vegetation, hopping, creeping and winding through bush, fripping wings and duet-singing; in display-flight, male descends with slow, exaggerated beats, head held up and rump feathers fluffed. Nest, built by both sexes, in one case only by female (taking c. 6 days), a loosely knit bowl made of slender twigs, roots and grasses, sometimes bound with spider web and lined with finer grass and rootlets, or sometimes no twigs used (nest can be so flimsy that eggs visible from below); placed 1–8 m (usually c. 2 m) above ground in fork in dense bush, hedge or mass of creepers, or in dense foliage near end of branch, usually well concealed; occasionally in dead tree; pair destroys nest if much disturbed, and female once used the material to build another nest nearby; territory c. 3 ha. Clutch 2–3 eggs; incubation by both sexes, from first egg, period 16–17 days; eggshells eaten or (usually) carried away in bill by adult soon after eggs hatch; chicks fed by both parents, faecal sacs either swallowed immediately or carried away by adult, at one nest one or the other parent constantly brooded chicks for 11 days and both fed young thereafter, nestling period 16–17 days; at one nest, young respectively 16 days and 17 days old left nest on same morning within two hours of each other; fledglings stay in area of nest, begging from deep cover, and at 53–54 days forage for themselves but still also fed by parents; young still with parents at 80 days, by which time they have perfected adult vocal repertoire. A few nests (2%) parasitized by Black Cuckoo (*Cuculus clamosus*); parasitized rarely by Jacobin Cuckoo (*Clamator jacobinus*). One individual survived for at least 11 years.

Movements. Sedentary, pair apparently remaining in same territory for life; one individual moved 15 km.

Status and Conservation. Not globally threatened. Generally common to very common. Widespread but uncommon within small range in Botswana, where confined to Gaborone and Lobatse areas; in Zimbabwe, recorded only in small area in SE (25 km W of Marhumbini); common in S Mozambique. Widespread and locally common in N, E & S South Africa, and locally very common in Western Cape; also recorded from near Clocolan, in Free State. Adapts readily to well-wooded suburbs.

Bibliography. Aldiss & Hunter (1985), Ambrose (2000), Brewster & Tyler (2003), Clancey (1980, 1996), Cordeiro & Kiure (1995), Crane (2001), Cyrus & Robson (1980), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Earlé & Grobler (1987), Fishpool & Evans (2001), Frandsen (1982), Fry *et al.* (1988, 2000), Ginn *et al.* (1989), Hall (1954), Hall & Moreau (1970), Harcus (1977), Harris & Arnott (1988), Harris & Franklin (2000), Harrison *et al.* (1997), Hockey *et al.* (1989), Hunter (1988), Irwin (1977, 1987), Kaumanns (1975), Langley (1982, 1983), Lorber (1984), Mackworth-Praed & Grant (1963), Maclean (1993), Maclean & Vernon (1976), Markus (1972), McCarthy (2006), Monadjem (2002a, 2002b, 2003), Nguembock *et al.* (2008), North & Haagner (1966), Oatley (2003), Osborne & Tigar (1990), Oschadleus (2000), Parker (1999), Payne (1971), Priest (1948), Quickelberge (1966), Roberts (1932), Rowan (1983), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Sonnenschein & Reyer (1984), Symes *et al.* (2002), Tarboton (2001), Tarboton *et al.* (1987), Tyler *et al.* (2008), Vincent (1949), White (1962).

31. East Coast Boubou



Laniarius sublacteus

French: Gonolek de Cassin **German**: Sansibarwürger **Spanish**: Bubú de Cassin
Other common names: Dimorphic Boubou

Taxonomy. *Dryoscopus sublacteus* Cassin, 1851, Lamu, Kenya.

Formerly, was widely treated as a race of *L. aethiopicus*; recent molecular-genetic studies, however, indicate closer relationship with *L. ferrugineus*, to the extent that the two can be regarded as a forming superspecies. Monotypic.

Distribution. Coastal lowlands of extreme S Somalia (Boni Forest), Kenya (inland along river valleys to Garissa, S Tsavo East National Park, S Tsavo West National Park and L Jipe) and N Tanzania (L Jipe E to N Pare Mts, and at coast from Tanga S to Zanzibar, inland to E Usambara Mts and Uluguru Mts).

Descriptive notes. 22–25 cm; male 43–50 g, female 40–55 g. Commoner morph has forehead to hindneck, lores, cheek, ear-coverts, side of neck and upperparts slightly glossy bluish-black, feathers of lower back and rump long, full and fluffy, overlying glossy bluish-black uppertail-coverts; tail black, slightly glossy, outer feathers sometimes white-tipped; upperwing black, slightly glossy, sometimes 1–3 white or whitish median and greater coverts; white below, breast and flanks tinged salmon-pink; underwing-coverts white, axillaries white with pink tinge; iris deep red-brown; bill black; legs bluish-slate. Black morph has plumage entirely glossy black. Sexes alike. Juvenile is similar to adult, but has tawny or ochre feather tips above, dull whitish below (underparts sometimes with hint of barring). Voice. Wide repertoire of croaks, snarls, tearing sounds, short "bou" notes and long whistles, often delivered by two birds in duet; like voices of *L. ferrugineus* and *L. aethiopicus*.

Habitat. Dense vegetation in highland forest and forest edge and riverbank woods, in dense cover of thickets, woody tangles in cultivated areas, coastal scrub, unkempt hedges and gardens. Mainly lowlands; to 1800 m in Uluguru Mts (E Tanzania).

Food and Feeding. Mainly insects, also small fruits and small vertebrates. Shy and retiring, foraging mainly in deep shade and dense cover low down, or often on ground. Obtains food by gleaning branches, foliage, stems and ground litter. Not known to differ markedly from *L. ferrugineus* and *L. aethiopicus*.

Breeding. Season Dec–Mar. Seemingly monogamous. Strongly territorial, defending territory vocally and by chasing. Nest a shallow, loosely knit open bowl of wispy vegetation, fine grasses and thin twigs with some spider silk, built a few metres from ground in fork of thin branch deep in twiggy bush. No further information.

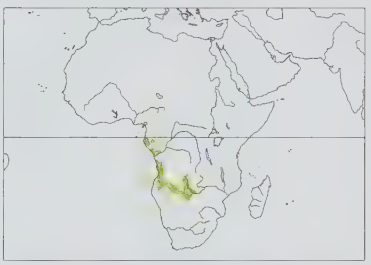
Movements. Sedentary.

Status and Conservation. Not assessed. Probably not globally threatened. Only recently regarded as a distinct species, separate from the common and widespread *L. aethiopicus*. Black morph occurs mainly in NE of range, from S Somalia S to coastal E Kenya (to Lamu I, Manda I and mouth of R Tana mouth). Frequent in much of its somewhat restricted range, in some areas apparently uncommon but in others common. Inland populations probably secure, although there is increasing concern about impact of eucalypt (*Eucalyptus*) plantations and forest fragmentation on bird communities in E Usambara Mts and elsewhere; coastal populations and black-morph birds, in particular, could be at risk from tourist and residential development of beach frontage and the concomitant loss of insect-rich dense woody cover.

Bibliography. Borghesio *et al.* (2008), Britton (1980), Burgess *et al.* (2007), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Franklin (2000), John & Kabigumila (2007), Lack (1985), Lewis & Pomeroy (1989), Newmark (1991), Nguembock *et al.* (2008), Pakenham (1979), Redman *et al.* (2009), Sibley & Monroe (1990), Stevenson & Fanshawe (2002), Tyler *et al.* (2008), White (1962), Zimmerman *et al.* (1996).

32. Swamp Boubou

Laniarius bicolor



French: Gonolek à ventre blanc **German**: Sumpfwürger **Spanish**: Bubú Bicolor
Other common names: Gabon/Gaboon Boubou, Ngami Bush-shrike/Boubou

Taxonomy. *Dryoscopus bicolor* Hartlaub, 1857, Gabon.

Recent molecular-genetic analyses indicate that this species is closest to *L. ferrugineus* and *L. sublacteus*, the three composing a sister lineage to *L. aethiopicus* and *L. turatii*. Has in the past been treated as a race of *L. ferrugineus*, and sometimes considered to form a superspecies with latter and *L. aethiopicus*; but overlaps in range with *L. aethiopicus* around Chobe–Zambezi confuence, where the two occupy different habitats, and differs from *L. ferrugineus* in morphology (larger size but lighter weight, less robust bill) and in voice and habitat. Races intergrade. Three subspecies recognized.

Subspecies and Distribution.

L. b. bicolor (Hartlaub, 1857) – W Cameroon S to Gabon and extreme NW Angola (coastal Cabinda).
L. b. guttatus (Hartlaub, 1865) – PRCongo S to W Angola (S to near Lubango).
L. b. sticturus Hartlaub & Finsch, 1870 – interior of S Angola E W Zambia, NE Namibia and N Botswana.

Descriptive notes. 23–25 cm; male 52–65 g and female 45–57 g (*guttatus*), male 48–57 g and female 43–58 g (*sticturus*). Nominate race is glossy bluish-black above, including upperwing and tail, median coverts tipped white, innermost greater covert with white outer web, next two completely white; throat and underparts pure white, greater under primary coverts black, other underwing-coverts and axillaries white; iris dark brown; bill black; legs slate-blue. Sexes alike. Immature is like adult but spotted with buff above and faintly barred below, outer tail feathers buff-tipped, white wing-coverts blotched with greyish-brown. Race *guttatus* is very like nominate, but has white on outer web of one or two inner secondaries; *sticturus* is largest race, has white (3 mm wide) on outer edges of innermost three secondaries forming long white wingstripe, sometimes white tips on tail. Voice. In S of range song a synchronous or overlapping duet, male uttering soft but ringing, fluty "whhawww" or "houuu" whistle and female a grating, descending cackle, "kikikakakrrrrrr", or harsh ratchet-like rattle, "kakakakakkkk"; sometimes male's whistle higher-pitched, "whheeeeww", answered by female with "tatatrrrr". Male's whistle usually preceded by short, soft but guttural "grr" or "werk" sounds, often double. In PRCongo voice somewhat different; includes ringing, upslurred "woi-woi-woi", soft "hop-hop", repeated ringing "paw-paw-paw", and short duets "haw-kaka" with "hooee-kaka". Duetting tends to be in lengthy sequence, initiated by either sex; frequency increases as breeding season progresses. Number of strophes in ratchet call varies individually, and is greater in high-intensity interactions. Threat a harsh, loud, rapidly repeated "kawkaw..." and nasal, twanging "tchzenenene" during flight display; alarm a slowly repeated "tuk" or scolding "jik-jik-tzhaaaa" or longer "tizzh-zhizhi-zhaaaa"; discordant "tik-tik-tik" calls before settling to roost. Sometimes makes wing-fripping sounds in flight.

Habitat. In Cameroon, found in stunted mangroves with small areas of drier ground surrounded by tidal shallows and soft mud; dry coastal thickets and low secondary growth in PRCongo; in Angola, inhabits reedbeds, edges of papyrus (*Cyperus papyrus*) swamps and thickets in patches of riverine forest; in Zambia and Botswana, restricted to major river floodplains with tall reeds, dense papyrus beds, water figs (*Ficus verruculosa*), thick riverine bush, acacia (*Acacia*) thickets, riverside gardens, swamps and choked streams. Generally in densest part of vegetation.

Food and Feeding. Invertebrates, including moths and caterpillars (Lepidoptera), beetles (Coleoptera), bugs (Hemiptera) including cicadas (Cicadidae), also millipedes (Diplopoda), small worms (Annelida); a few small fruits; once a frog. Forages singly and in pairs in dense woody vegetation, low down in papyrus or in canopy of larger riverine trees. Advances in inclined posture, leaping and slipping through small branches, twisting head in search of prey. Gleans trunks, branches, foliage, and reed and papyrus stems; tends to work its way upwards in shrub or thicket, then glides down to base of adjacent clump. Often comes to ground in dry, bare and shaded areas below woody growth; on ground moves with short, bouncing hops, flicking aside bits of debris with bill. Occasionally catches insects in flight. Forages alongside *L. aethiopicus* without aggression.

Breeding. Immature in Jun in Cameroon; pairs duetting Oct–Jan and May in Gabon; eggs in Aug–Nov and Jan–Apr (mainly Nov, once Jun) in Botswana. Pair keeps all year in territory of c. 2 ha, defending it by calling; utters threat call accompanied by bowing, wing-flicking and tail-flicking. Courting male and female chase each other, keeping in tandem as they hop and bounce through vegetation (often in upper canopy of large trees), male gives drawn-out whistles and glides behind female; in territorial or courtship behaviour, two duetting birds sit upright, close together on exposed perch, each with head up and tail slightly fanned, male bobs head as he gives "grr" call and bows body when giving "houuu" whistle, female vibrates tail when she answers with ratchet call; one utters twanging calls while flying steeply down with exaggerated, slow wingbeats, head held up, rump plumage fluffed, tail fanned. Nest a neat cup or flimsy saucer made of loosely woven fine twigs and tendrils, sometimes with grass, placed 1·5–4 m above ground in *Bougainvillea* or tangled palm frond, on horizontal fork in bush or axil of palm frond. Clutch 2 eggs; incubation by both

sexes, somewhat negligently, period 21 days; nestling period 13 days. One nest parasitized by Black Cuckoo (*Cuculus clamosus*).
Movements. Resident.
Status and Conservation. Not globally threatened. Locally common. In Cameroon, small population on coast near Tiko, and pair sighted near Bibundi, on Mt Cameroon; occurs on Gabon coast in R Ogooué mouth, Ogooué Maritime, Fernan Vaz, Port Gentil and Nyanga Districts, and quite common around Mouila and in Moukalaba-Doudou National Park; in PRCongo, common along coast of Kouilou Basin and up to 22 km inland. Common in Angola in coastal Cabinda and from coast to varying distances away from it in Zaire S to Namibe, inland to W Cuanza Norte, Huambo, N Bié and C Huila, and in Cunene valley in Cunene and probably Cuando Cubango; occurs in Cuchi and Cubango valleys downstream to Caprivi Strip (Namibia) and probably present and perhaps widespread in E Cuando Cubango and SE Moxico. Locally common in Zambia throughout Zambezi Valley above Kapanda Bridge and Mambova and W to Angola border; in SW occurs along Mashi valley, but absent between Mashi and Zambezi (in W Sesheke). In Namibia occurs in part of Cunene valley, and in Cubango/Kavango and Cuando floodplains (in Caprivi Strip). In Botswana, common in Okavango, Linyanti and Chobe river systems, and sparse at L Ngami; average density of 1–2 birds/10 ha in fringing gallery woodland at Okavango Swamps and R Linyanti. No confirmed records from Zimbabwe, although almost certainly present above Katombora Rapids.

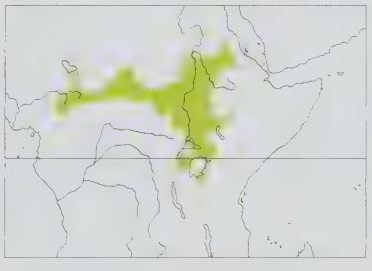
33. Yellow-crowned Gonolek

Laniarius barbarus

French: Gonolek de Barbarie **German**: Goldscheitelwürger **Spanish**: Bubú Coronigualdo
Other common names: Common Gonolek/Boubou/Shrike, Barbary Shrike; Sierra Leone Gonolek (*helenae*)

Taxonomy. *Lanius barbarus* Linnaeus, 1766, Senegal.
Was formerly held to compose a superspecies with *L. atrococcineus*, *L. erythrogaster* and *L. mufumbiri*, some authors including *L. atroflavus* in this group. Recent molecular-genetic studies indicate that this species is sufficiently closely related to *L. erythrogaster* for the two to be regarded as a superspecies, that *L. mufumbiri* and *L. atroflavus* are a sister-group in same lineage, and that the four are only distantly related to *L. atrococcineus*. Two subspecies recognized.
Subspecies and Distribution.
L. b. barbarus (Linnaeus, 1766) – S Mauritania (mainly in Senegal valley, but N to Tagant area), Senegambia and NW Guinea E to C Mali and S Niger, and S Chad, S to Liberia (Monrovia and Congo Town lagoon), N & S Ivory Coast, Togo and Benin, N, C & extreme SW Nigeria and N Cameroon.
L. b. helenae Kelsall, 1913 – Sierra Leone coast from near Guinea border S to Bonthe.



Descriptive notes. 23 cm; 44–52·5 g. Nominate race has forehead to hindneck olive-yellow, front and side of crown clearer yellow; lores, narrow line over eye, upper cheek, ear-coverts, side of neck, and upperparts, including upperwing and long tail black with dark blue gloss, some scapular feathers with concealed white mark in centre, and lower back and rump feathers with mainly concealed large white subterminal spots; uppertail-coverts glossy black; chin to belly bright vermilion-red, vent, thighs and undertail-coverts buff, with blackish wedge down from rump, separating rear flanks from undertail-coverts; underwing-coverts and axillaries black; one mated 7-year-old individual had underparts all yellow; iris dark brown; bill black; legs slate-grey or bluish-grey. Sexes alike. Juvenile has top of head mustard-yellow, upperparts uniformly dark brown, upperwing-coverts with yellowish tips, underparts ochre-yellow, side of breast, flanks and belly narrowly barred greyish-black, eyes dark brown; later, yellow feathers replaced with scattering of red ones, starting mainly on throat and lower belly. Race *helenae* differs from nominate in having forehead, crown and hindneck rufous or orange-brown, not olive-yellow. Voice. Pair utters precisely synchronized calls in duet. Commonest duet a loud, pure, resonant, liquid double "whee-u" or "kweeho" or "tyaw" whistle by one individual, partner giving dry rasping rattle or short trill of 2–4 clicks, "kikiki" or "ch-chacha", duet lasts 0·3–0·4 seconds; male and female motifs each 0·2–0·3 seconds and overlap, with auditory response time of 0·08–0·1 seconds. Male usually initiates duet with "whee-u" but female can do so with "kikiki"; apparently each sex can both whistle and rattle; some duets tripartite, "huweeu-kkkk-huweeu". Single bird commonly utters repeated rhythmic "twoo-woo" whistle. Eight pairs used eight different duet patterns, and any one pair uses several different forms of "whee-u" call. One type of duet is repeated 10–40 times, with very regular intervals of 1·16–1·70 seconds between duets, then, after pause of several seconds, pair sings series of another duet type. Contact calls in deep cover are series of up to ten rapid clicks (lasting 0·9 seconds) by one bird followed after 0·2 seconds by clicks at different pitch (lasting 0·5 seconds). In courtship flight, emits calls like sound made by winding in a fishing reel, and makes wing-fripping noise.
Habitat. Dense undergrowth in mesic and dry wooded savannas; thickets on large, old termite (Isoptera) mounds surrounded by bare soil or light grassland with only few scattered low shrubs; riverine bush, gallery-forest understorey, dense acacia (*Acacia*) woods with *Zizyphus* and other small thorn trees along watercourses, especially if plenty of woody litter on ground in shade of trees; farmland hedges, small groves of coppiced tamarinds (*Tamarindus*). Also large, mature gardens in main towns in Ghana, dense coastal scrub in Nigeria. Race *helenae* in W Sierra Leone lives in mangroves, rarely visiting adjacent coastal thickets.
Food and Feeding. Eats insects, including beetles (Coleoptera), caterpillars and large numbers of grasshoppers and locusts (Acrididae); occasionally takes small birds and nestlings. Forages singly and in pairs low down in woody growth, moving through branches and on ground in long hops or sometimes creeping; partners usually within a few metres of each other, frequently calling (whether in sight of each other or not). Often forages in canopy up to 5 m high; can spend long periods in a single large fig (*Ficus*) or *Parkia* tree with shrubby growth and vegetation litter on ground below. If undisturbed spends much time on ground, where it assumes a rather upright posture, with tail held more or less horizontally. Will also move in full sun across lawns, flicking tail with every hop. Flicks aside dry leaves and woody litter; makes short runs after insects. Flies reluctantly, and never far; moves low over open patch, with very short glide into foot of bush.
Breeding. Breeds primarily in wet season: Aug–Sept in Mauritania, Jan–Sept (mainly Jun–Aug) in Gambia; in Mali, Apr–Sept N of 13° N and Nov–Dec S of it; Apr–May in Ghana, and Jun–Aug (and once nestlings in Feb) in Nigeria. Apparently monogamous and territorial. In apparent courtship flight, gives calls with bill wide open and makes wing-fripping noise; flight display also described as involving deep, slow, stalling beats, with audible wing-snaps, accompanied by churring call like sound of squeaky bed-springs. Nest an open cup built from loosely intertwined coarse plant stems, unlined, or lined with fine tendrils and roots, placed 1·5–4·5 m up in thicket or in small soft-leaved tree in shrubby copse. Clutch 2 eggs. No other information.
Movements. Sedentary, often highly so, pair keeping to same dense thicket all year.
Status and Conservation. Not globally threatened. Common or fairly common in much of range. Frequent to common throughout Senegal and Gambia, and frequent in N Guinea-Bissau; quite common in C & S Mali, where frequent in Haut Niger National Park and common in Boucle du Baoulé National Park, and common in parts of Burkina Faso; in Niger, common in W National Park and in R Niger valley (S from Tillabéry), infrequent away from river (S from Tahoua), and in SE frequent in Komadugu-Yobé area (near L Chad). Poorly known in Guinea but likely to be widespread in N. Race *helenae* locally common in coastal Sierra Leone. Only two records in Liberia (Monrovia and Congo Town lagoon); in Ivory Coast, common N of Bouaké, scarce in S guinean woodlands, and common along dry coast from Azagny National Park E to Assinie; widespread in riverine thickets in N & C Ghana, and on coast confined to thickets from Elmina E to Accra and Keta Plains; common and widespread in N Togo, uncommon or absent in S guinean zone, and common along coast. In Nigeria, frequent and widespread in N (Sokoto and Kano Provinces and lower Komadugu Gana valley S to Ilorin and Benue valley) and present also on SW coast (Badagri E to Lagos); locally common in N Cameroon, including Waza National Park, and uncommon in Mbam-Djerem National Park; uncommon but widespread in soudanian zone in Chad, where E limits unclear. This species is too adaptable to be of conservation concern; nevertheless, long-term threats to its abundance in Hwimo area of NW Nigeria (and probably applicable also to vast swathes of its W African range) include timber-felling and shrub clearance for building and farming, the regular cutting of small trees for firewood, hunting (with guns and catapults), brushwood fires, and increasing ecological imbalance resulting from various human activities.
Bibliography. Balança & de Visscher (1997), Bannerman (1939a, 1953), Barlow *et al.* (1997), Bates (1930), Bobo *et al.* (2006), de Bont (2002), Borrow & Demey (2001), Claffey (1995), Crick & Marshall (1981), Crisler *et al.* (2003), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire & Dowsett (2005), Elgood *et al.* (1994), Fishpool & Evans (2001), Fry (1970), Fry *et al.* (2000), Fuchs *et al.* (2005), Gee (1984), Gore (1990), Greig-Smith & Davidson (1977), Grimes (1965, 1966, 1978, 1987), Hall & Moreau (1970), Harris & Franklin (2000), Hooker & Hooker (1969), Jensen, F.P. *et al.* (2008), Jensen, J.V. & Kirkeby (1980), Leisler & Winkler (2001), Louette (1981), Mackworth-Praed & Grant (1973), Morel & Morel (1982, 1988), Mundy & Cook (1972), Ndao (1989, 1999b), Nguembock *et al.* (2008), Nikolaus (2000), Payne (1970, 1971), Rodwell (1996), Salewski (2000), Scholte *et al.* (1999), Serle (1943b), Serle & Morel (1977), Shelley (1912), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Thiollay (1985), Thorpe (1972), White (1962).

34. Black-headed Gonolek

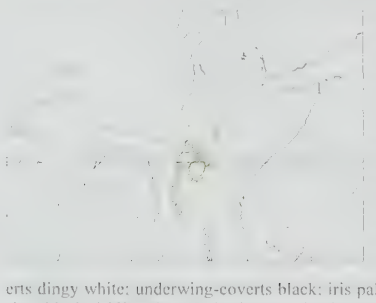
Laniarius erythrogaster

French: Gonolek à ventre rouge **German**: Scharlachwürger **Spanish**: Bubú Cabecinegro
Other common names: Abyssinian/Red-bellied Gonolek, Black-headed Bush-shrike, Barbary Shrike

Taxonomy. *Lanius erythrogaster* Cretzschmar, 1829, Kordofan, Sudan.
Was formerly held to compose a superspecies with *L. atrococcineus*, *L. barbarus* and *L. mufumbiri*, some authors including *L. atroflavus* in this group. Recent molecular-genetic studies indicate that this species is sufficiently closely related to *L. barbarus* for the two to be regarded as a superspecies, that *L. mufumbiri* and *L. atroflavus* are a sister-group in same lineage, and that the four are only distantly related to *L. atrococcineus*. Monotypic.
Distribution. NE Nigeria, S Chad, N & C Cameroon (S to Adamawa Plateau) and N Central African Republic E to E Sudan, W Eritrea and W Ethiopia, S to E DRCongo, N Tanzania and W Kenya; also in SE DRCongo (Lualaba valley from about Kabalo S to L Kisale and Bukama).

Descriptive notes. 20·5–21·5 cm; male 42–53 g, female 46–55 g. Top of head to below eye, ear-coverts, side of neck and upperparts, including upperwing and tail, are black with dark blue gloss (some individuals, especially in Lualaba valley, in SE DRCongo, have scattered yellow feathers on crown); long feathers of lower back, rump and some uppertail-coverts with large white subterminal spots (mainly concealed), rump feathers (c. 45 mm long) proximally dark grey, tip with dark grey band (7 mm deep) ending proximally in black arc (1 mm deep) and with silky white patch (6–7 mm long) at shaft; throat and underparts bright vermilion-red, vent and undertail-coverts buff, thighs variably black, red or buffish, rear flanks, vent and undertail-coverts separated by blackish area; underwing-coverts and axillaries black; iris pale straw-yellow; bill black; legs black or dark lead-grey, toes sometimes bluish-black. Sexes alike. Juvenile is blackish above, with buff feather tips on mantle to rump and upperwing coverts, dull yellowish-buff below, with narrow blackish bars from chin to vent, chin tinged pink at side, breast tinged pink, a few vermilion feathers on flanks, eyes dark brown; immature duller black above than adult, with buff tips on forehead, crown and wing-coverts, like juvenile below but patchy and mottled, with crimson banding posteriorly (beginning on lower belly). Voice. Pair sings in duet, a loud, resonant, bell-like, disyllabic "wheeyou", "hweeu", "yoick" or "tyotyo" whistle by male answered instantly by female with hiss or short, harsh, rasping "jaar", "zeeer", "tzzz" or "kssrrrrr", the combined "hweeuzeeer" sounding like song of single bird (another song involving both sexes is reported as "chuyo-chuyo-chyochochocho"); "yoick" is 0·1–0·25 seconds in duration (and quite variable in sonagram shape), hiss 0·2–0·35 seconds (but constant in shape); in eight consecutive duets by one pair, interval between initiator's calls were 2·5–5·6 seconds and second bird responded after 0·125–0·160 seconds. A three-month-old juvenile joined in with adults' duet, synchronizing precisely with female and uttering female part of duet, but at six months had developed male part of duet. Alarm a rapid, continuous chatter, "chk-chk-chk...".
Habitat. Thornbush, wooded and bushy grasslands, thick belts of woody growth along streams and lakesides, grassy river plains subject to flooding, and dense riparian scrub, especially with doum palms (*Hyphaene thebaica*); papyrus (*Cyperus papyrus*) swamps in W of range; also acacia (*Acacia*) woods, dense thickets and shrubby copses. In Uganda, dense cover in forest patches and riverine forest in sparsely wooded country, and in N also acacia thickets; leafy urban gardens in Entebbe and elsewhere in S. Mostly lowlands; to 1500 m in E of range.
Food and Feeding. Insects, including Orthoptera and caterpillars, also some small fruits; some small lizards and bird eggs taken. Forages singly and in pairs. Skulks in dense, shady vegetation, but often inquisitive and responsive; can become bold and conspicuous around Entebbe (Uganda).
Breeding. Poorly known. Season Mar and Jun–Jul in Sudan; in Uganda, Mar–Apr in N & E and Sept–Jan and Mar–Jun (mainly Apr–Jun) in W & S. Monogamous and territorial, pair keeping in territory throughout year. Nest a loosely constructed open cup made from rootlets, grass or bark fibres, lined with fine rootlets (eggs sometimes plainly visible from side and below), placed 4–8 m

On following pages: 35. Papyrus Gonolek (*Laniarius mufumbiri*); 36. Yellow-breasted Boubou (*Laniarius atroflavus*); 37. Mount Kupe Bush-shrike (*Chlorophoneus kupeensis*); 38. Bocage's Bush-shrike (*Chlorophoneus bocagei*); 39. Many-coloured Bush-shrike (*Chlorophoneus multicolor*); 40. Black-fronted Bush-shrike (*Chlorophoneus nigrifrons*); 41. Olive Bush-shrike (*Chlorophoneus olivaceus*); 42. Orange-breasted Bush-shrike (*Chlorophoneus sulfureopectus*).



above ground in fork in middle of thick bush or in outer branch of tree, often a fig (*Ficus*). Clutch 2 eggs. No other information.
Movements. Resident; in Chad thought to move N in wet season.
Status and Conservation. Not globally threatened. In Nigeria common on shores of L Chad S to R Logone inundation zone, Waza National Park and Logomani, and common in N Cameroon S to Adamawa Plateau; in Chad common in soudanian zone and local in sahelian zone, and in Central African Republic common in Manovo-Gounda-Saint Floris National Park and uncommon in Vakaga prefecture. Common and widespread in Sudan S from W Darfur and Khartoum, and recorded near Atbara; absent from S Bahr al Ghazal and most of Western Equatoria. In Ethiopia frequent to common in NW, W & SW, and in Eritrea common along all W river valleys up to c. 900 m. In DRCongo, common in lowlands around L Albert and L Edward and in Rutshuru area; also in Lualaba valley from about Kabalo S to Bukama. Common throughout Uganda (except perhaps extreme NW) at 600–1500 m. In Kenya confined to W parts, around Lokichokio and N end of L Turkana, in Suam valley at Kongelai, and in Marich, Nasolot Nature Reserve and S Kerio valley, and recorded at Marigat and L Baringo; common in L Victoria basin E to Muhoruni and Migori, and one of commonest bird species in Ndere Island National Park (just off N shore of L Victoria). Recorded in E Rwanda and E Burundi. In Tanzania, occurs in Mara, W Serengeti National Park (where very common in Grumeti forest), and N Shinyanga and Mwanza districts, and common in extreme NW.

35. Papyrus Gonolek

Laniarius mufumbiri

French: Gonolek des papyrus **German**: Papyruswürger **Spanish**: Bubú de los Papiros
Other common names: Papyrus Bush-shrike, Mufumbiri Gonolek/Shrike/Bush-shrike, Yellow-crowned Gonolek(!)

Taxonomy. *Laniarius mufumbiri* Ogilvie-Grant, 1911, Mufumbiro Volcanoes = Vichumbi, Lake Edward, DRCongo.
Closely related to *L. atroflavus*, but the two are better treated as independent species, rather than as a superspecies; their closest allies are *L. barbarus* and *L. erythrogaster*, the four constituting a lineage that is sister to the cluster comprising *L. aethiopicus*, *L. turatii*, *L. ferrugineus*, *L. bicolor* and *L. luehderi*. Monotypic.
Distribution. W & S Uganda, Rwanda, Burundi, extreme E DRCongo (Vichumbi, Rutshuru), NW Tanzania, and SW Kenya (shores of L Victoria SE to Kisumu, Yala Swamp and Kendu Bay).

Descriptive notes. 17–19 cm; male 45–46 g, unsexed 34–46 g. Has forehead, crown, nape and central hindneck dull golden-yellow; lores, areas just above and below eye, ear-coverts, side of neck, and upperparts, including tail and most of upperwing black, slightly glossy; rump feathers full, soft and fluffy, with whitish tips and concealed white subterminal spots; median upperwing-coverts white with black bases, greater coverts black, innermost ones with white margin along outer web; chin and throat red with orange tinge; breast, belly and most of flanks bright pinkish-red, rear flanks black, thighs, vent and undertail-coverts dingy white; underwing-coverts black; iris pale lemon-yellow; bill black, mouth black; legs slate-black. Differs from *L. barbarus* in having white in wing, much less deep-based and robust bill, much more slender tarsus and toes, and longer and less strongly decurved claws. Sexes alike. Immature differs from adult in having forehead and crown blackish-olive, becoming black on hindneck, white spots in upperwing-coverts may include greater primary coverts, chin and throat yellowish-buff, merging to buffy pale rufous-vermilion on breast and flanks, rear flanks dusky blackish, eyes greyish-brown. Voice. Calls or sings in duet, a double, hollow, gong-like "pyo-pyop" given alone or answered with grating "zeetu" or buzzy "tzrrrr"; duet commonly of two or three high-pitched whistles, "weyo-weyo, u-u, yo-yo yoo-yo" or "yoo yong-yong", followed instantly by presumed female's single or double, harsh "u-tzeu, u-tzeu"; sometimes four-syllable "pyo-pyo-pyo-pyo" answered by similar but faster call, and "peetoo-peetoo" answered by identical call; also "tyo-wzzz" and rhythmic series of "wi-onk" or "chonk" notes with female's antiphonal harsh "chh-t-chh" notes.
Habitat. Confined to papyrus (*Cyperus papyrus*) swamps and beds, mainly the interior of large ones, beside meandering rivers and along lakeshores; inhabits pure stands of papyrus, papyrus-grass (*Miscanthus*), papyrus mixed with woody shrubs, and mosaics of floating prairie–papyrus. Mainly in lowlands and to 1600 m, but up to 2050 m.
Food and Feeding. Mainly small insects, such as myrmecine ants, beetles (including families Curculionidae, Carabidae, Elateridae and Staphylinidae), flies (Diptera), bees and wasps (Hymenoptera), caterpillars; also small snails (Gastropoda) and fruits. Singly and in pairs. Skulks in dense vegetation, occasionally making short flights over open water. Forages at all levels in papyrus, and sometimes in emergent woody shrubs; seen also at edges and along raised swamp roads.
Breeding. Very few data. Eggs in Jun, Sept–Dec (mainly Sept) and Feb in Kenya; sings Feb–Mar. Doubtless territorial; once seen to chase *L. erythrogaster* at edge of papyrus swamp. Nests found but not described. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Recent population estimate of c. 2,000,000 adults. Thought to be potentially at risk owing to its specialized, restricted habitat. Locally common in Uganda at 1100–1600 m; widespread in S & W Lango and L Kyogo to Ankole and Kigezi, shores of L Victoria from Masaka to Kenya border. Widespread and locally abundant in E Rwanda and E Burundi; in NW Tanzania, occurs in middle Akagera basin and along R Ruvubu and in Malagarazi basin (on Burundi border) to c. 4° S. Locally common in Kenya, where seven individuals mist-netted (two singing) in 15 months in 1-ha plot at Kadenge. Estimated density of 6–10 birds/ha at site in Kenya; in Uganda, 13 birds/ha in centre of undisturbed swamp but less than 1 bird/ha in polluted and degraded swamps. Abundance directly related with height and density of papyrus, with numbers larger in taller and denser stands. Even though not immediately at risk, this species requires monitoring. Many papyrus marshes on shores of L Victoria are suffering from adverse effects of increasing human population, intensification of fishing and agriculture, burning, papyrus-harvesting, cattle grazing, goat browsing, pollution and falling water levels (level in L Victoria has fallen by c. 1 m in last decade); to what extent such changes are being monitored and management policies implemented is uncertain.
Bibliography. Anon. (2008d), Britton (1970, 1978), Butchart & Stattersfield (2004), Carswell *et al.* (2005), Collar & Stuart (1985), Collar *et al.* (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fishpool & Evans (2001), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Franklin (2000), Jackson & Sclater (1938), Leisler & Winkler (2001), Lewis & Pomeroy (1989), Lippens & Wille (1996), Mackworth-Praed & Grant (1960), Maclean *et al.* (2003), Marks *et al.* (2003), Nguembock *et al.* (2008), Owino (2005), Owino & Oyugi (2008), Schouteden (1969), Short *et al.* (1990), Sibley & Monroe (1990), Sinclair & Ryan (2003a), van Someren (1922), Stattersfield & Capper (2000), Stevenson & Fanshawe (2002), Thorpe (1972), Vande weghe (1981a, 1981b, 1992), White (1962), Zimmerman *et al.* (1996).

36. Yellow-breasted Boubou

Laniarius atroflavus

French: Gonolek à ventre jaune **German**: Gelbbauchwürger **Spanish**: Bubú Pechigualdo
Other common names: Mountain Gonolek, Yellow-breasted Shrike

Taxonomy. *Laniarius atroflavus* Shelley, 1887, Mount Cameroon, Cameroon.
Closely related to *L. mufumbiri*, but the two are better treated as independent species, rather than as a superspecies; their closest allies are *L. barbarus* and *L. erythrogaster*, the four constituting a lineage that is sister to the cluster comprising *L. aethiopicus*, *L. turatii*, *L. ferrugineus*, *L. bicolor* and *L. luehderi*. Birds from Mt Oku (Cameroon) described as a geographical race, *craterum*, on account of slightly greater size, but size variation of species is clinal. Monotypic.
Distribution. SE Nigeria (Obudu Plateau, Mambilla Plateau, Chappal Hendu) and W Cameroon (Bamenda Highlands, Mt Manenguba, Mt Cameroon).

Descriptive notes. 18–20 cm; 40–47 g. Top of head down to lores, below eye and ear-coverts, and upperparts, including upperwing and tail, are black with very dark blue or oily green gloss; upper rump feathers black with concealed large white subterminal spots, lower rump feathers broadly buff-tipped and long (overlying uppertail-coverts); chin and throat lemon-yellow, grading to brilliant orange-yellow on breast, flanks and side of belly, middle of belly white with buff-pink tinge, thighs and undertail-coverts buffy white; marginal wing-coverts oily black, lesser and greater under primary coverts blackish, greater underwing-coverts buff, axillaries lemon-yellow; iris dark brown; bill black; legs slate-black. Sexes alike in plumage, female perhaps slightly larger than male. Juvenile undescribed; immature like adult but upperparts with dark brown wash, wings dark brown, greater primary coverts have buff tips and outer two pairs of tail feathers long buff tips. Voice. Very noisy, with wide repertoire of loud whistling, swishing, rattling, harsh grating, explosive stuttering notes and duetting. Pair duets loudly with "whee-oo-chook" or "hweeu-kzzr-hweeu", the "whee-oo" thought to be given by male and clicking "chook" or tearing "kzzr" by female, interval between the two can be as little as 0·145 seconds; initiated by either sex; sings sometimes in canopy, birds often in sight of each other, invariably approaching tape recorder on hearing playback and continuing to duet. Male also has ringing "quik-quik-quik", prolonged series of "hweeu" calls, and "quelch" instantly answered by female's "ich". Many calls similar to, and some inseparable from, those of *L. poensis*. Makes bill-clashing sounds like those of *Chlorophoneus* bush-shrikes.
Habitat. Dense undergrowth of clearings and secondary scrub in and near montane forest, and low undergrowth in small remnant forest patches and bamboos in ravines and on ridges; also in topmost branches of figs (*Ficus*), wind-shaped bushes on highest peaks, in bramble, heath, bracken and tiny remnant copses and thickets around villages, including those on bleakest hilltops. Forages in slightly more open situations; retreats into deep shade in dense vegetation if disturbed. At 700–2900 m.
Food and Feeding. Insects. Forages actively in pairs, restless and skulking; never flies far. Forages in gloomy woodland with old trees covered with moss and lichen, and in small flowering shrubs (e.g. *Agauria salicifolia* and *Hypericum*). Gleans foliage and branches in undershrubs and trees, searching up to 7 m above ground.
Breeding. Season Nov–Mar, breeding completed by late Mar. Territory advertised by duetting song and whistle calls; bird bows forward when whistling. Nest described both as neatly woven and as badly constructed, a rather flimsy, shallow cup made of coarse dry tendrils, lined with fine hair-like fibres and roots; sited 0·6–4 m (once 10 m) above ground, deep in undergrowth such as bushes, bracken and brambles. Clutch 2 eggs. No further information.
Movements. Sedentary; pair regularly duets and stays in same spot year after year.
Status and Conservation. Not globally threatened. Restricted-range species: present in Cameroon Mountains EBA. In Nigeria not uncommon on Obudu Plateau; single record in Mambilla, but common on Chappal Hendu in adjoining Gashaka-Gumti National Park. Abundant on SE flanks of Mt Cameroon at 1500–2100 m and on S flanks at 1300–2300 m, frequent to common down to lower range at 700–1300 m; common on Mt Manenguba at 1950–2250 m; widespread in Bamenda Highlands; in Kilum-Ijim area, density in seven vegetation types 2·23–2·68 birds/ha; very abundant on Mt Oku at 2000–2900 m, where the seventh commonest bird species, and so abundant in Big Babanki (27 km SW of Mt Oku) that it can be seen or heard constantly; frequent to common around L Bambulue, in Bafut-Ngemba Forest Reserve, Bali-Ngemba Forest Reserve, Santa, Sabga Pass, Mbengwi-Tinachong at 1800 m, Bamboutos Mts at 2000–2600 m, Wum, Mt Lefo and Banso Mts; occurs also on Tchabal Waddi, Tchabal Mbaba (Genderu) and between there and Banyo. Deforestation and forest degradation continues to take place in submontane parts of this species' range; whether it is consequently any less numerous than it formerly was is not known, but seems probable.

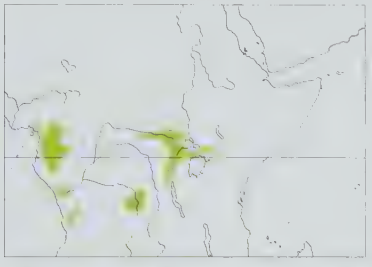
Genus *CHLOROPHONEUS* Cabanis, 1851

37. Mount Kupe Bush-shrike

Chlorophoneus kupeensis

French: Gonolek du Kupé **German**: Halsbandwürger **Spanish**: Bubú del Kupé
Other common names: Kupé (Mountain)/Serle's Bush-shrike

Taxonomy. *Chlorophoneus kupeensis* Serle, 1951, Kupé Mountain, Kumba Division, Cameroon.
Genus sometimes subsumed in *Malaconotus* or in *Telophorus*. Affinities of this species obscure; appears intermediate between latter genus and present one in size and bill size (but underwing pattern like *Malaconotus*), has palate orange, not black (as other bush-shrikes), and voice more like that of a babbler (Timaliidae) than that of a bush-shrike. Perhaps best allocated its own monotypic genus, pending study and clarification of its characters. Monotypic.
Distribution. Extreme SE Nigeria (NE Cross River National Park) and uplands of SW Cameroon.



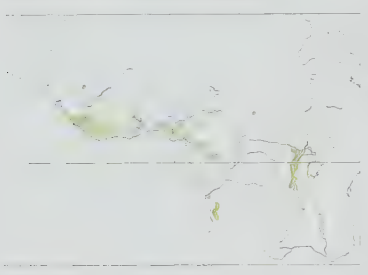
Descriptive notes. 17·5–21·5 cm. Occurs in two plumage morphs, possibly sex-related but this unlikely. "Necklace morph" (previously thought to be male) has black forehead, lores and ear-coverts, grey crown with paler side, grey nape, hindneck and mantle, bright olive-green back, rump, uppertail-coverts and tail; upperwing mostly bright olive-green, inner webs of remiges blackish, outer primaries fringed yellowish-olive at base, outer primary all black; chin and throat white, blackish-maroon line or row of three or four spots on lowermost throat (line thicker in middle); breast, upper flanks and upper belly grey, rear flanks olive-green, thighs olive, bright yellow patch on rear belly, bright yellow vent and undertail-coverts; iris violet; bill black, four long rictal bristles on each side, palate orange or yellow; legs grey. "Spot morph" (previously thought to be female) is like necklace morph, but has only one dark maroon or metallic purplish-black rounded spot (6 mm in diameter) on centre of throat, with thin line of white between it and breast; lower belly and undertail-coverts pale greenish-yellow. Sexes probably similar. Juvenile is poorly known; single museum specimen, a female, is like adult necklace morph, but forehead, side of neck and side of throat tinged green, grey of upperparts flecked with olive-green, chin and middle of throat flecked with pale yellow, narrow line of yellowish-brown spots below throat, breast patchily greenish, larger area of olive on flanks. Voice. In Cameroon, two presumed territorial males by L Edib, each accompanied by a presumed female (silent), sang loud, short chatter, "thec-thec-kh-kh-kh", followed by 3–4 "tchraaa-tchraaa-tchraaa" notes at rate of 2 per second; up to 29 "tchrraa" notes in a faster series (3 notes per second) by bird flying overhead in response to tape playback; rarely, a distinctive song of three ascending, detached whistles (sounding discordant), repeated up to six times. Song uttered regularly in response to tape playback. Other vocalizations include loud, rapidly fluctuating nasal whistle, also a clear liquid "crooa" whistle, rising and falling in pitch, singly or in series of up to four; also a series of harsh, accelerating "tic" notes ending with richer but husky, scalding notes, "tic tic tic tic tic tic tic cheeow cheeow cheeow"; quiet, continuous insect-like grating ascribed to this species seems to be rare. Angry male makes noisy snapping of wings in flight, 4–6 snaps in a series, again responding to playback; wing-snaps like those of *Dryoscopus* and differ from courtship wing-fripping of several congeners and of *Malaconotus* species.
Habitat. Primary forest with relatively open understorey, sometimes on steep hillsides; at 930–1550 m.
Food and Feeding. Insects, including beetles (Coleoptera), grasshoppers (Orthoptera) and caterpillars. Forages usually 3–4 m above ground, sometimes down to 0·5 m and up to 18 m; on Mt Kupé mostly at heights of 1–6 m, but occurs almost to top of canopy; mainly above 10 m in Bakossi Mts; occasionally comes to ground (where one killed in a snare at Kodmin, in Bakossi Mts). Moves slowly and deliberately through dense leafy growth, diligently searching foliage; has been seen to hang sideways on vertical stems and then launch itself vertically upwards to seize prey in bill, before falling back to perch. Sometimes hawks flying insects. Large prey items held in the bill and beaten against branch. Forages singly and in pairs; readily joins mixed-species flocks, which may take it into smaller trees.
Breeding. No information. Pairs seem to be territorial.
Movements. Resident.
Status and Conservation. ENDANGERED. Restricted-range species: present in Cameroon Mountains EBA. In Cameroon, occurs on Mt Kupé, in Bakossi Mts and in S Banyang Mbo Wildlife Sanctuary; possibly also on Mt Cameroon. Uncommon on Mt Kupé, where forest only c. 21 km² in extent in late 1950s; discovered there in 1951, not located during extensive searches in 1984, but was found again in 1989 at 1220–1310 m, and 39 sightings in 1990–1994; in Mar–May 1997 up to four birds seen six times, and perhaps no more than seven pairs present near Max's Trail and Shrike Trail (together c. 8 km long). Found in Bakossi Mts in 1992, and often encountered at 1150–1200 m near Kodmin, L Edib and Messaka; population possibly only c. 50 pairs; suitable forests in Bakossi are eight times greater in extent than those on Mt Kupé, and this species could possibly occur also on Mt Mwenzekong and Mt Ekomane and on lower S slopes of Mt Manenguba and Mt Nlonako, although searches on lower slopes of Mt Nlonako in 1999 and Mt Manenguba in 2000 both unsuccessful. Discovered in Banyang Mbo Wildlife Sanctuary, extending from Bakossi Mts, in 1999. Concern for this species' survival in the face of continuing forest destruction led to the setting-up in 1991 of Mount Kupé Forest Project (by BirdLife International), which involves local communities in education, forest conservation and development of ecotourism; nevertheless, some forest was lost at 1250 m on Max's Trail in 1998. In 2004–2005, this species found to be present in NE Cross River National Park, in SE Nigeria, but status there not known.
Bibliography. Anon. (2008d), Bannerman (1939a, 1953), Borrow & Demey (2001), Bowden (2001), Bowden & Andrews (1994), Butchart & Stattersfield (2004), Cohen & Mills (2002a, 2002b), Collar & Stuart (1985), Collar *et al.* (1994), Demey (1997, 1998, 1999, 2003, 2005), Demey & Kirwan (2000), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire (1999, 2004), Dowsett-Lemaire & Dowsett (1989, 1998b), Fishpool & Evans (2001), Fry *et al.* (2000), Gibbons (1995), Hall & Moreau (1970), Harris & Franklin (2000), Louette (1981), Mills & Cohen (2004), Serle (1951), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stuart & Jensen (1986), White (1962), Williams (1998).

38. Bocage's Bush-shrike

Chlorophoneus bocagei

French: Gonolek à front blanc **German**: Bocagewürger **Spanish**: Bubú de Bocage
Other common names: Grey/Grey-green Bush-shrike

Taxonomy. *Laniarius bocagei* Reichenow, 1894, Yaoundé, Cameroon.
Genus sometimes subsumed in *Malaconotus* or in *Telophorus*; also, present species has been placed in *Dryoscopus* and *Laniarius*. May be closely allied with *C. olivaceus*. A specimen from Entebbe (Uganda), named as *C. andaryae*, was probably a hybrid between present species and *C. sulfureopectus*. Proposed race *ansorgei* (described from N'dalatando, in NW Angola), supposedly with slightly paler back, treated as synonym of nominate. Two subspecies recognized.
Subspecies and Distribution.
C. b. bocagei (Reichenow, 1894) – SE Nigeria (Obudu Plateau) and S Cameroon S to NW Angola.
C. b. jacksoni (Sharpe, 1901) – NE & SC DRCongo, Uganda and W Kenya.



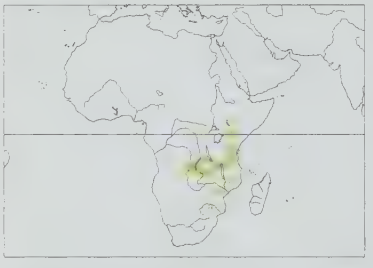
Descriptive notes. 23–25·5 cm; male 27–28 g, female 22–28 g. A small bush-shrike, dark above, with small bill and graduated or strongly rounded tail. Male nominate race has white forehead, lores, superciliary stripe, chin and throat; jet-black crown, ear-coverts and hindneck; dark slaty-grey upperparts and upperwing; tail black, small white tips on all except central two feather pairs; underparts white with ochre-buff tinge, breast sometimes buffy; underwing-coverts and axillaries white; iris dark red-brown; bill black; legs slate-grey. Female is like male, but tail greyish, eyes dark brown (not reddish). Juvenile has grey upperparts finely barred dull blackish, pale lores and supercilium, blackish mask, grey wings and tail, upperwing-coverts tipped pale yellow, each with subterminal black bar, secondaries tipped buff, underparts dirty white or yellowish-white with fine, faint dark grey vermiculations, mouth orange; subadult less boldly pied than adult, crown, nape and ear-coverts dull blackish, tail brownish-black, underparts greyish white, upperwing-coverts and secondaries with small white tips, flight-feathers edged olive. Race *jacksoni* differs from nominate only in that female has a black (not dark grey) tail. Voice. Male song variable, a sharp, ringing, upslurred "tp-tooi-tweeee", a clipped "tewp-tewp-tewp", often a repeated series of four syllables, "wewewewit", or of two syllables, "po-hee" or "peee-u", and faster clipped "tyo-tyo-tyo-tyo-tyo-tyo-tyop" (6 or 7 notes); main advertising song of clear rapid whistles, quite high-pitched and sometimes repeatedly monotonously, pitch, number of notes and rate of delivery varying; one song, "kuli-kuli-kuli-kuli-kuli-kuli-kuli", very like that of African Yellow Warbler (*Chloropeta natalensis*). Male and female perform duets: male gives up to seven (usually four) clear loud "doi" notes like those of *Telophorus viridis*, female immediately replies with harsh, tearing "zreeekk, tzrrrerr" or shorter "zzerr-wik" notes like those of Chin-spot Batis (*Batis molitor*); or male utters liquid trill followed by female's nasal "nyaaaa"; or one bird gives liquid "tiplee, tiplee", a second answers with "nyaaaa" and a third with "wizzzz".
Habitat. Fairly open wooded country with large-crowned trees (e.g. *Albizia* and *Pentaclethra*) scattered irregularly among bushes and shrubs; tall secondary forest with dominant swathes of mimosaceous plants; cocoa and coffee plantations with closed canopy, again with plenty of Mimosaceae; old second growth bordering clearings, and gallery forest e.g. in brachystegia (*Brachystegia*) woodland; also park-like gardens around large houses, leafy suburbs, and thickets with parasol trees at borders of cultivation. Rarely in primary forest. Mainly in lowlands; to 2200 m in E Africa.
Food and Feeding. Eats insects, especially caterpillars, also beetles (Coleoptera), termites (Isoptera) and grasshoppers (Orthoptera), mantids (Mantidae), cicadas (Cicadidae); also some berries. Butterflies and moths (Lepidoptera) and larvae fed to nestlings. Generally in pairs. Forages in foliage in middle and upper levels of trees, 8–20 m above ground, and sometimes in tops of very tall trees; moves slowly and deliberately through thick foliage. Elusive and skulking, except when exploiting emerging termites.
Breeding. Few details. Season Sept in Cameroon, and sings all year (especially Nov–Feb) in Gabon; breeds Aug–Sept in DRCongo and Feb, Jul and Aug in Uganda. Pair lives in territory of c. 2 ha, advertised with singing by male and duetting by pair. Nest a shallow but strong open cup made entirely from interwoven dry vine tendrils, placed in fork high in tree. Clutch 2 eggs; incubation apparently by both sexes. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Rare or uncommon to locally common. Recent record from Nigeria at Belekiti, on Obudu Plateau. Widespread in S Cameroon W to Mbulu Forest (near Nigerian border) and N to Mbam-Djerem National Park; one or two encountered on one-third of 70 2·5-km circuits of N suburbs of Yaoundé in 21 months in 1993–1995. One record in Rio Muni; in Gabon, quite common around Makokou but absent from Lopé National Park; in PRCongo, frequent in parts of Mayombe and scarce in Odzala National Park. In Angola, not uncommon in Cuanza Norte and Malanje (S to Canhoca and N'dalatando), frequent around Camabatela, and scarce in Cabinda. In DRCongo, scattered records in S Kasai Oriental, but widespread in E from upper R Lulu and Garamba National Park S to Itombwe Highlands at 1100–1670 m. Locally common in W & S Uganda at 1100–2200 m, but scarce S of Mabira Forest; uncommon in Nandi and Kakamega Forests, in W Kenya. E African range possibly contracting, since formerly occurred in Kenya SE to Kericho and Nyarondo; appears to be extinct in Rwanda, where recorded in the past. Although this species is doubtless eliminated locally as a result of woodland clearance, it is probably not adversely affected by replacement of primary forest and woodland with tree plantations and woody secondary growth.
Bibliography. Bannerman (1938, 1939a, 1939b, 1953), Bates (1911, 1930), Bobo *et al.* (2006), Borrow & Demey (2001), Bowden (2001), Brosset & Érard (1986), Brown & Britton (1980), Carswell *et al.* (2005), Chapin (1947, 1954), Dean (1974a, 2000b), Demey (2005, 2006, 2007), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire (1997b), Dowsett-Lemaire & Dowsett (1998a, 1999), Fishpool & Evans (2001), Friedmann (1937), Friedmann & Williams (1970), Fry *et al.* (2000), Grant & Mackworth-Praed (1946), Hall & Moreau (1970), Harris & Franklin (2000), Jackson & Sclater (1938), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1973), McCarthy (2006), Nguembock *et al.* (2008), Prigogine (1971), Quantrill & Quantrill (1998), Rand *et al.* (1959), Redewald *et al.* (1994), Sargeant (1993), Schouteden (1969), Serle (1950, 1952a), Short *et al.* (1990), Sibley & Monroe (1990), Sinclair & Ryan (2003a), van Someren (1916), Traylor (1963), White (1962), Zimmerman *et al.* (1996).

39. **Many-coloured Bush-shrike**

Chlorophoneus multicolor

French: Gonolek multicolore **German**: Vielfarbenwürger **Spanish**: Bubú Multicolor
Other common names: Four-coloured Bush-shrike

Taxonomy. *Laniarius multicolor* G. R. Gray, 1845, no locality = Accra, Ghana.
Genus sometimes subsumed in *Malaconotus* or in *Telophorus*. Forms a superspecies with *C. nigrifrons* and possibly conspecific with it. Occurs in five basic colour morphs with additional six variants, present in varying proportions throughout range and interbreeding freely. Although geographical variation partly obscured by polymorphism, several characters enable differentiation of races. Three subspecies recognized.
Subspecies and Distribution.
C. m. multicolor (G. R. Gray, 1845) – SW Mali, Sierra Leone, SE Guinea and Liberia E, discontinuously, to W Cameroon.
C. m. batesi Sharpe, 1908 – patchily S Cameroon, NE Gabon, NW & SW PRCongo, NW Angola, Central African Republic, NE DRCongo (Ituri) and W Uganda (Kibale).
C. m. graueri (E. J. O. Hartert, 1908) – montane forests of E DRCongo (Kivu S to Itombwe), SW Uganda and W Rwanda (Nyungwe).



Descriptive notes. 18–20 cm; male 43–61 g and female 46–54 g (nominate), male 38–41 g and female 36–39 g (*batesi*), male all 41 g and female 36–39 g (*graueri*). Polymorphic; five principal colour morphs and a further six quantifiable variants or intermediates occurring in varying proportions throughout range; in most regions two or three morphs occur together and interbreed, but seemingly only one morph in Angola; a pair often composed of different morphs. Male nominate race yellow morph has well-defined broad black mask from forehead to side of neck; hindcrown to upper mantle grey, paling to white on forecrown and supercilium (amount and brightness of white variable, forecrown and supercilium sometimes grey); rest of upperparts green; tail feathers green, grading to blackish distally, with broad yellow tips (c. 10 mm deep on central rectrix, increasing to c. 15 deep on outermost), tail darker in W Cameroon (all morphs) than farther W; flight-feathers dark brown with green outer webs, secondaries and inner primaries tipped yellow, borders of inner webs bright yellow, tertials green with yellow tips, alula and upperwing-coverts green; cheek to chin, throat and upper breast bright orange-yellow, rest of underparts bright yellow, underside of tail blackish, underwing-coverts and axillaries bright yellow; iris blue-green, bright violet or purple; bill black; legs bluish to brownish-grey. Scarlet morph differs in having chin to lower breast scarlet, rest of underparts yellow, often with orange tinge, tips of tail feathers orange-yellow. Black-and-yellow morph has chin to upper breast black (continuous with black face mask), sharply demarcated from bright yellow on rest of underparts. Black-and-red morph is like preceding morph, but has belly, flanks and undertail-coverts red. Female of all morphs differs from male in having forehead and lores to ear-coverts grey (not black), fainter greyish-white supercilium behind eye, tail greenish both above and below and with yellow tips; yellow morph bright yellow below, but lacks orange tinge on throat and breast; scarlet morph more orange-red below than male, the colour restricted more to throat and upper breast. Juvenile has forehead to lores and ear-coverts grey; indistinct paler supercilium, top of head to upper mantle grey with dark grey barring, rest of upperparts green with yellowish barring, tail like adult female, wing like adult but alula fringed yellow and all upperwing-coverts tipped yellow, chin to upper breast, flanks and thighs barred yellowish and dark grey, lower breast to undertail-coverts yellow; juvenile plumage replaced probably rapidly by unbarred immature plumage, both sexes then like adult female but retain yellow-tipped juvenile wing-coverts. Races differ mainly in amount of white on forecrown, depth of green on tail, extent of yellow at tail tip, also in weight, bill size and degree of sexual disparity: *batesi* male yellow morph has forecrown and side of crown always white, and more distinctly so than in whitest individuals of nominate, tail black (not green) above with yellow tips, occurs also in scarlet morph with entire underparts scarlet and tail feathers tipped reddish-yellow, female differs from nominate female in having whiter forecrown and supercilium; *graueri* male has white on head as in nominate, tail black like previous, differs further from others in having buff morph, with whole underparts pale cinnamon-buff (occurs also in yellow and scarlet morphs). Voice. Male song a short, hollow whistle, "hoh" or "whoup", sometimes disyllabic, "huwo", "hooui" or "hohoh", repeated on same pitch every 3–4 seconds, duration of note and repetition rate vary, and disyllabic note may have low and high parts ("whoo-op" or "fu-fee"), some with terminal inflection ("huolo"); female responds in duet with low-pitched coughing "hoh-gah" or drawn-out rasping "kzzrrr", and duet thus sounds like "hooi-kzrrr". In Rwanda, male's short "woh" is repeated at intervals of 2–3 seconds, and a fast "fufufufufufufu" uttered usually only once.
Habitat. Primary lowland and submontane rainforest, to 1100 m in W Africa (Mt Nimba, Mt Cameroon) and to 2500 m in E (Itombwe, in E DRCongo); inhabits matted tangles of creepers and lianas festooning canopy and undercanopy of forest. Found also in forest with dense bushy growth in abandoned slash-and-burn patches, dense vegetation near villages, thick secondary growth in clearings, old secondary forest, forest–grassland mosaic, gallery forest and swamp-forest.
Food and Feeding. Insects, often large ones, including grasshoppers (Orthoptera), mantises (Mantidae), stick-insects (Phasmida), bugs (Hemiptera), beetles (Coleoptera), ants, bees and small and large wasps (Hymenoptera), moths and caterpillars (Lepidoptera). Forages among dense tangles of lianas, in epiphytes and on mossy limbs of large trees, in Liberia at 8–30 m above ground but in Gabon at 2–10 m. Hops and creeps about in crouching posture, gleaning from trunks, branches, matted creepers and thick foliage, gradually working upwards in tree. Occasionally hawks insects in air. Singly and in pairs, and in Itombwe (DRCongo) parties of up to eight individuals recorded; often joins mixed foraging flocks of drongos (Dicruridae), Old World orioles (Oriolidae), cuckoo-shrikes (Campephagidae), bulbuls (Pycnonotidae), batises (*Batis*), weavers (Ploceidae) and squirrels (Sciuridae).
Breeding. Assorted evidence of breeding in Jul–Jan and Mar–Apr in Liberia, roughly Oct–Apr in Gabon and Angola, about Dec in Uganda, and in Jan, Mar–Jun and Sept in E DRCongo (Itombwe). No other information.
Movements. Generally sedentary; in Mali a visitor in May–Jun wet-season.
Status and Conservation. Not globally threatened. Locally common. Very patchily distributed, but shy, skulking and unobtrusive; may have more continuous range than is currently realized. In Mali, frequent breeding visitor in S (N to Baoulé). In Sierra Leone, frequent in S and probably throughout; frequent on Ziama Massif, in S Guinea. Fairly widespread in Liberia, where frequent to common in at least 60 localities; density (estimated from calls at Zwedru) 3–9 pairs/km², and total population estimated at c. 200,000 pairs. Uncommon in Ivory Coast, where recorded from Taï to Lamto, Yapo, Maraoué and Comoé. In Ghana, formerly not uncommon at Accra, Cape Coast and Mampong (Ashanti), Kumasi, Makessim, in interior of "Fantee" and at Agomé Tongwe, but recent records only from Akropong (Akwapim) and Amedzofe. Uncommon in Togo, but several recent records around Misahöhe; not known to occur in Benin, although 19 corpses found in Cotonou's largest traditional-medicine market on one day in 2002 (origin uncertain). In Nigeria, found mainly in SW, also at Kagoro and in Gashaga-Gumti National Park. Not uncommon in S & extreme W Cameroon; in Central African Republic known from Lobaye Prefecture, and Manovo-Gounda-Saint Floris and Bamingui-Bangoran National Parks. Scarce in Mbini; frequent in Gabon between Makokou and Mékambo, but not yet found in Lopé National Park; in PRCongo, found only in Odzala National Park, where very local, and in SW, where frequent in Kouilou Basin; fewer than ten records in Angola. Apparently absent from DRCongo except E, where frequent W of L Albert from R Nepoko and Medje S to Ituri and Itombwe; in Uganda, known only from Kibale, Budongo and Bwindi Impenetrable Forest at 1500–1600 m; in Rwanda, recorded only in W Nyungwe Forest, where common to 2000 m and uncommon at 2000–2500 m. Comparative prevalences of morphs vary regionally: from Sierra Leone E to Togo scarlet morph most frequent (80%), followed by yellow (10%), black-and-yellow (6%) and black-and-red (4%); in Nigeria and W Cameroon, scarlet 44%, yellow 46%, black-and-yellow 8·5%, black-and-red 1·5%; in Kumba and Ekona areas of W Cameroon, scarlet 46%, yellow 27%, black-and-yellow 27%; in rest of Cameroon and Gabon, scarlet 67%, yellow 33%; in NW Angola, yellow 100%; in DRCongo, scarlet 73% and yellow 27% (Ituri), scarlet 23%, yellow 64% and buff 13% (W of L Edward), and scarlet 6%, yellow 74% and buff 20% (NW of L Tanganyika).
Bibliography. 40. **Black-fronted Bush-shrike**

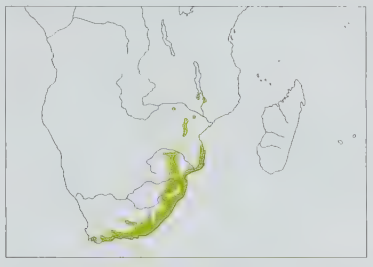
Chlorophoneus nigrifrons

French: Gonolek à front noir **German**: Graustirnwürger **Spanish**: Bubú Frentinegro

Taxonomy. *Laniarius nigrifrons* Reichenow, 1896, Marangu, Kilimanjaro, Tanzania.
Genus sometimes subsumed in *Malaconotus* or in *Telophorus*; present species has been placed also in genus *Laniarius*. Forms a superspecies with *C. multicolor* and possibly conspecific with it. Occurs in five main colour morphs. Three subspecies recognized.
Subspecies and Distribution.
C. n. nigrifrons (Reichenow, 1896) – mountains of E Uganda (Mt Elgon), Kenya, Tanzania and N Malawi.
C. n. manningi (Shelley, 1899) – E Angola, SE DRCongo (Katanga) and N Zambia.
C. n. sandgroundi Bangs, 1931 – S Malawi, Mozambique, E Zimbabwe and N South Africa (Limpopo Province).

Descriptive notes. 18–19 cm; male 28–40 g, female 25–42·5 g. Polymorphic; males occur in four colour morphs and females in three. Male nominate race yellow morph has black forehead, lores, upper cheek and ear-coverts, dark grey crown to upper mantle and side of neck, and dark green remaining upperparts, including upperwing and tail, outer four pairs of rectrices with yellow tips c. 4 mm deep; lower cheek, chin, throat and underparts yellow, tinged golden on breast, tinged greenish on belly and undertail-coverts, flanks greenish with faint darker barring, underwing-coverts and axillaries bright yellow; in Songea (S Tanzania) underparts duller yellow, washed coppery, on Ufipa Plateau (SW Tanzania) breast golden-brown; iris red-brown or crimson; bill black; legs bluish-grey. Red morph has chin to breast orange-red. Buff morph is pale cinnamon-buff below, whiter on chin and throat, tinged greenish-grey on flanks and undertail-coverts. Black-and-green morph (restricted to Usambara Mts, in Tanzania) has chin to breast black, continuous with black of face mask, and merging into green on rest of underparts. Female is like male, but face mask duller, greyer behind eye, eyes paler crimson, and underparts duller; yellow morph with underparts greenish; red morph with red below less extensive and less intense than on male; buff morph with underparts duller and browner than male. Juvenile has upperparts and tail like adult's, but tips of secondaries, tertials, alula and upperwing-coverts with narrow whitish fringes; yellow morph yellow below, with close greenish barring on breast, flanks and undertail-coverts, buff morph greyish-white below with dark grey barring, tinged greenish on flanks; juvenile plumage seems to be replaced directly by adult plumage, with no intermediate immature stage. Race *manningi* is smaller and more lightweight than nominate, two morphs, male scarlet morph has chin to upper breast brilliant scarlet, red morph generally duller red than equivalent morph of nominate and yellow tail tips larger, some males very like red-morph nominate female, some females like copper-tinged yellow-morph male of Songea population of nominate; *sandgroundi* also is smaller and lighter than nominate, two morphs, red morph like equivalent morph of nominate but duller, more orange-brown below, black-and-green morph (restricted to Mt Namuli, in Mozambique) like that of nominate. Voice. Varied. Main song of male a low-pitched, hollow series of "hou" or "hoi" or "quoh" whistles, repeated up to 20 times in 4 seconds; also short, rapid trisyllabic "hohoho", like that of Hoopoe (*Upupa epops*), repeated three times in 8 seconds; and commonly a melodious, soft, liquid "woo-hah" (the "hah" grating, downslurred or upslurred), in S of range repeated 8–12 times at intervals of 3–5 seconds; male may sing alone, or accompanied by female with dry, rasping snarl that increases in volume, "kzeeerrr, screeee, shnyaaaaa", or clicking notes, and single "hoh" followed by long "tick-zzzhaaaa"; also male's high-pitched disyllabic "wop, wop" answered by female's nasal "gaaanh"; male may give both parts of duet, "who-nyaaanh". Other calls a single long snore, both grating and ringing; loud click like sound made by shutting of well-oiled lock, sometimes followed by scolding "klitik-waaa"; high-pitched "zreee" and deeper "gruk-gruk"; in alarm a raucous "rraa-kaaa-kaaa" and bill-snapping followed by growl. When excited, makes wing-fripping sounds in flight.



Habitat. Inhabits canopy of montane forest above 2300 m and, at lower elevations, escarpment, lowland and riverine evergreen forests; *Cryptosepalum* forest in Zambia, also thickets bordering marshes. In W of range (race *manningi*) also on dry wooded plateaux, in brachystegia (*Brachystegia*) woods, and in thickets near termite (Isoptera) mounds.
Food and Feeding. Insects, including beetles (Coleoptera), wasps (Hymenoptera), grasshoppers (Orthoptera) and caterpillars. Forages in middle and upper levels of tall forest, keeping to thick tangles of creepers and mossy branches with epiphytes. Searches small branches, twigs, dense foliage, matted creepers, mossy limbs and trunks; works its way up tree and then glides down into next tree. Sometimes hawks insects in air. Solitary and in pairs; often joins mixed-species foraging flocks. Appears to respond to some calls of *C. olivaceus* and to be aggressive towards it.
Breeding. Season Feb in Tanzania, Jul–Aug and Oct in SE DRCongo (Katanga), Oct–Mar in Zambia, Oct–Nov in Malawi, Oct–Jan in Mozambique, and Nov–Feb in Zimbabwe. Territory maintained all year, defended by pair by calling, when bird adopts inclined-upright posture and bows slightly with each call, two males often counter-sing (using same call), probably at territorial boundary; territory size 3–10 ha. Courtship barely known; seems to involve male and female in bowing, swaying, calling, wing-flicking and tail-flicking, and short-flight wing-fripping. Nest, built probably by both sexes, a flimsy shallow saucer or flat platform made from dry twigs and tendrils, lined with *Usnea* lichen, well concealed in creepers or dense foliage 20–30 m above ground in forest tree. Clutch 2 eggs; young thought to be tended by both parents. No other information.
Movements. Resident and partial vertical migrant. In Tanzania, mainly at 1200–2200 m but in Jun–Jul sometimes down to 300–400 m in Uluguru Mts, and seasonally down to 300 m in E Usambaras; possibly an altitudinal migrant also in Zimbabwe and seasonal non-breeding visitor in NE South Africa (Kruger National Park). In Malawi, regular dispersal of 60–100 km possible.
Status and Conservation. Not globally threatened. Range somewhat fragmented, and several montane populations small and isolated. Widespread but local, and uncommon to frequent. In Kenya, occurs on Mt Elgon, Saiwa National Park, Cheranganis, Elgeyu-Maraquet, Tugen Hills, Kericho, Mau, Trans-Mara, Lolgorien, Meru, Embu and Aberdares, but apparently no longer found in Nairobi nor in Taita Hills. In NE Tanzania recorded from Marang Forest (L Manyara) to Arusha National Park and Kilimanjaro, Pare Mts and Usambaras, mainly at 900–2200 m, also S to Ulugurus, Ufipa Plateau, Mbeya, Tatanda, Njombe, Matengo Highlands and Rondo Plateau; very common in forests in E Usambaras. In SE DRCongo (Katanga) apparently uncommon and local; in Zambia frequent and widespread in N, common in *Cryptosepalum* forest, in Northern and Luapula Provinces E to Nyika, and in Western and North Western Provinces. In Malawi, occurs in N in Misuku Hills and on Nyika Plateau, and in SE (E of Rift Valley) in Mangochi, Blantyre, Chiradzulu, Mulanje and Thyolo Districts; on Nyika Plateau, occupies all forest patches of 7·5 ha or more at 2000 m, pairs occupied six out of ten forests of 6·5–8·5 ha at 2200 m, and above 2200 m one pair in 10-ha patch, one pair in 10·5-ha patch and two pairs in 12-ha patch. In Mozambique, found on Mt Namuli and locally in Chimanimani Mts along Zimbabwe frontier and on Mt Gorongoza. In Zimbabwe, present on E slopes of Inyanga Highlands (to 2000 m), Pungwe Falls, the Vumba, Chimanimani Mts (at c. 1800 m), Honde Valley (at 750 m), Lusitu–Haroni confluence, and on Mt Selinda (Chirinda Forest); believed to be locally threatened by continuing destruction of lowland forest. In N South Africa, occurs in escarpment region from Soutpansberg (Hangklip to Entabeni) S to Woodbush, Duiwelskloof, Serala and Mariepskop; accorded conservation status of "Indeterminate" in South Africa. Comparative prevalences of morphs vary regionally: in DRCongo (Upemba), scarlet morph 39% and red morph 61%; in Malawi and South Africa, only red except for a few buff-morph birds on Nyika Plateau (Malawi); in Kenya (Mt Kenya) and Tanzania (Kilimanjaro), red 43%, yellow 53% and buff 4%; in E Kenya Highlands (other than Mt Kenya and Taita Hills) yellow 100%, in W Kenya Highlands red 19% and yellow 81%, in SE Kenya (Taita Hills) and E Tanzania (Pare and Usambara Mts) yellow 53%, buff 43% and black-and-green 4%; in E Tanzania (Ulugurus) yellow 72% and buff 28%, and in S Tanzania (including Songea) yellow 47% and buff 53%.

41. **Olive Bush-shrike**

Chlorophoneus olivaceus

French: Gonolek olive **German**: Olivwürger **Spanish**: Bubú Oliváceo
Other common names: Rufous-breasted Bush-shrike

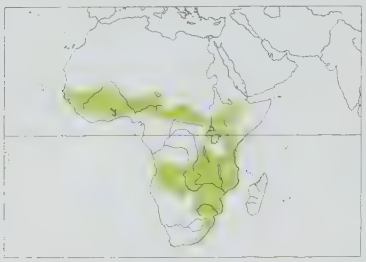
Taxonomy. *Lanius olivaceus* Shaw, 1809, Algoa Bay, South Africa.
Genus sometimes subsumed in *Malaconotus* or in *Telophorus*. Closely related to the superspecies formed by *C. multicolor* and *C. nigrifrons*, but not a member of it since parapatric with latter from S Malawi to N South Africa. May be closely allied with *C. bocagei*. Nominate race occurs in two colour morphs, which may possibly be two formerly allopatric races beginning to intergrade; further study required. Proposed race *taylori* (described from E Mpumalanga, in NE South Africa) is synonymized with nominate. Five subspecies currently recognized.
Subspecies and Distribution.
C. o. bertrandi (Shelley, 1894) – S Malawi E of Shire Valley.
C. o. makawa Benson, 1945 – S Malawi (W of Shire Valley), E Zimbabwe, and extreme N South Africa (N Limpopo Province).
C. o. interfluvius (Clancey, 1969) – W Mozambique.
C. o. vitorum (Clancey, 1967) – SE Mozambique coast S from R Save.
C. o. olivaceus (Shaw, 1809) – E & S South Africa (from NE Limpopo S to S Western Cape), Swaziland and extreme S Mozambique.
Descriptive notes. 18–23 cm; male 31–39 g, female 24·5–43·5 g. Male nominate race buff morph has lores white, narrow whitish postocular superciliary stripe, broad black patch across ear-coverts extending to side of neck and narrowly around upper front of eye; forehead to upper mantle bluish-grey, rest of upperparts olive-green; central three pairs of tail feathers blackish with olive-green outer edges, next pair blackish with distal part of outer web dark green and tip yellow (c. 7 mm long), outer two pairs with outer web green, inner web black at base and yellow at tip; upperwing dark green, most larger feathers broadly fringed olive-green; cheek and chin to breast light creamy buff, breast more cinnamon-buff, belly white, undertail-coverts greyish-white, flanks pale grey or olive (sometimes with about five faint dark bars), thighs olive; underwing-coverts and axillaries

pale yellow (coverts along leading edge of wing grey), large yellow area on underside of flight-feathers formed by broad borders of inner webs; iris dark brown to chestnut-red or purple-brown; bill black, sometimes greyish base of lower mandible; legs bluish-grey. Olive morph differs in having whole of upperside, including crown, bright olive-green, lores and supercilium greenish-yellow, cheek and chin to breast light orange, belly and undertail-coverts greenish-yellow, and flanks bright green. Female of buff morph is like buff-morph male, but ear-coverts to side of neck grey (like crown), often darker grey on ear-coverts, supercilium vestigial or absent, breast duller, slightly more barring on flanks, all tail feathers green, outer two pairs with narrow yellow fringe on tip and inner web; female olive morph is like male of corresponding morph, but ear-coverts grey, supercilium inconspicuous, flanks with more extensive dark green barring, tail feathers as for buff-morph. Juvenile buff morph is dull olive-green above, greyer on head, whitish below, chin to upper breast barred dusky, lower breast and flanks barred dark green, tail as female, wing as adult but tips of secondaries, tertials and upperwing-coverts fringed buffish-white; olive-morph juvenile similar, but brighter olive-green above, greenish-yellow with dark green barring below, primary coverts barred, bill horn-brown. Races differ mainly in details of coloration and in bill size, all except nominate being monomorphic (buff): *makawa* resembles buff-morph nominate, but brighter green above, bill larger; *bertrandi* is like previous, but male has indistinct supercilium, and has greener tail with blackish confined to basal part of inner feathers and yellow to narrow fringes on outer two feather pairs; *interfluvius* is like nominate, but breast paler and less yellow-tinged, flanks pale olivaceous grey and faintly barred, and bill less heavy than in preceding two races; *vitorum* resembles last, but white supercilium more prominent, and facial mask dark grey (rather than black). Voice. Vocal; calls all year, mainly in austral spring. Male song varied, 5–10 ringing whistles, first two usually short and higher-pitched; can be slow and measured "hi-hhh-hay-kway-kway-kway-kway-kway-kway" or faster "pikwik-koi-koi-koi-koi-koi-koi" or almost trilled "wikokokokokoko"; either ascending "ki-ki-ki-ki-heeee" (very like song of *C. sulfureopectus*) or descending, slowing "hi-hi-tew-tew-tiew-tiew-teyouw"; males often counter-sing with each other, using same calls. Female occasionally joins in with a few tearing scolds, "zzrrreee-zzrrreee".
Habitat. Coastal, lowland and montane evergreen forests up to mistforest; matted evergreen dune forest, thickly wooded valleys and riverbanks, dense patches of thornveld, *Philippia* heath, wattle (*Acacia*) plantations; isolated forest patches at up to 2300 m.
Food and Feeding. Hymenoptera, including bees, hornets and ants; also beetles (Coleoptera), grasshoppers (Orthoptera), mantises (Mantidae), larvae, spiders (Araneae); some fruit, including figs (*Ficus*). Forages mostly in canopy and middle stratum; sometimes descends to low tangles at forest edge. Gleans from leaves and wood, hopping and bounding among twigs and small branches; agile, moving through vegetation rapidly and silently, peering, darting at prey, often making short "fripping" flights, and gliding quite fast between trees. Singly and in pairs, secretive, even when singing, but inquisitive; frequently joins mixed-species flocks. Seems to respond to calls of *C. nigrifrons*.
Breeding. Season Oct–Nov in Malawi, Oct–Jan (mainly Nov) in Zimbabwe and Nov–Dec in Mozambique; in South Africa, Nov–Feb in N (former Transvaal), Sept–Dec in KwaZulu-Natal and Dec–Jan in S; single-brooded. In territorial interactions, male threatens with horizontal stance, bowing, swaying from side to side, flicking tail, and making discordant notes and piping whistles, snapping or clicking bill and making short wing-fripping flights; males often counter-sing with each other, in upright stance, tail slightly fanned. Nest, built by both sexes, a flimsy shallow saucer made from long, wiry twigs, thin pieces of grass, fine *Asparagus* stems, roots, aerial roots and tendrils (tendrils and roots becoming finer towards centre of nest structure), lined fairly thickly with rootlets and other fine material, eggs often visible from below; placed up to 6 m above ground in fork or across main branch, well concealed among foliage, often in acacia, creeper, *Philippia* or *Woodwardia* tree. Clutch 1–2 eggs; incubation by both sexes, period 18 days; chicks fed by both parents, at first by regurgitation, some evidence that only male broods them, nestling period 16–17 days. Sometimes breeds for first time while still in barred juvenile plumage. Adult can survive for more than 7 years.
Movements. Mainly resident; evidence of altitudinal migration in Malawi and E Zimbabwe, where occurs down to 350 m in Lusitu–Haroni confluence in non-breeding season. Some individuals of this species in SW Mozambique possibly non-breeding visitors from adjacent South Africa (escarpment forests in Limpopo Province).
Status and Conservation. Not globally threatened. Patchily distributed in N of range; more continuous in S. In Malawi, found W of Rift Valley from Chongoni and Mt Dedza to boundary between Ntcheu and Mwanza Districts, and E of Rift from Malosa (Zomba) to Mulanje District; recorded at Fort Lister. In Zimbabwe, a single record in N, and in E highlands frequent at 1300–2300 m and uncommon at lower levels. In Mozambique, frequent near Zimbabwe frontier and on Mt Gorongoza at 900–1200 m, also in upper R Búzi drainage and the Vumba; uncommon along Sul do Save littoral and in S. Uncommon to frequent in South Africa and Swaziland; estimated density of 1 pair/1·5 ha in forests of former E Transvaal. Probably threatened locally to some degree by deforestation.
Bibliography. Arnott (1982), Benson (1945), Benson & Benson (1977), Chapin (1947), Clancey (1964a, 1967, 1971a, 1974, 1975, 1980a), Cyrus & Robson (1980), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire (1989), Fishpool & Evans (2001), Frandsen (1982), Friedmann & Loveridge (1937), Fry *et al.* (2000), Ginn *et al.* (1989), Hall & Moreau (1970), Hall *et al.* (1966), Hanmer (2001b), Harris & Arnott (1988), Harris & Franklin (2000), Harrison *et al.* (1997), Hockey *et al.* (1989), Irwin (1981), Mackworth-Praed & Grant (1963), Maclean (1993), Maclean & Vernon (1976), Parker (1999), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Sonnenschein & Reyer (1984), Steyn (1996), Swynnerton (1908), Tarboton (2001), Tarboton *et al.* (1987), Vincent, A.W. (1949), Vincent, J. (1935), White (1962).

42. **Orange-breasted Bush-shrike**

Chlorophoneus sulfureopectus

French: Gonolek soufré **German**: Orangebrustwürger **Spanish**: Bubú Azufrado
Other common names: Sulphur-breasted Bush-shrike



Taxonomy. *Lanius* (*Tchagra*) *sulfureopectus* Lesson, 1831, no locality = Senegal.
Genus sometimes subsumed in *Malaconotus* or in *Telophorus*. Probably closely allied with *C. multicolor*, but also closely resembles the much larger, heavy-billed, savanna-dwelling *Malaconotus blanchoti*. Birds in E coastal lowlands described as additional races *suahelicus* (S Somalia S to C Mozambique) and *terminus* (SE Tanzania S to SE South Africa), but differ only in slightly smaller

size from *similis*; both are synonymized with latter. A specimen from Entebbe (Uganda), named as *C. andaryae*, was probably a hybrid between present species and *C. bocagei*. Two subspecies currently recognized.

Subspecies and Distribution.

C. s. sulfureopectus (Lesson, 1831) – S Senegal and N Sierra Leone E to Central African Republic, W Sudan, N DRCongo and W Uganda.

C. s. similis (A. Smith, 1836) – S Sudan, Ethiopia, S Somalia, SW & E DRCongo, E Uganda and Kenya S to Angola, N Namibia, N & E Botswana, Zimbabwe, Mozambique and E South Africa.

Descriptive notes. 17–19 cm; male 24–34 g, female 24–32 g. Male nominate race has forehead, forecrown and long superciliary stripe bright yellow, lores black, ear-coverts black, grading to dark grey on side of neck; hindcrown to mantle light bluish-grey, rest of upperparts to uppertail-coverts and tail green, all tail feathers except central pair with yellow tips (c. 3 mm wide on T2, increasing to c. 8 mm on T6) and, on outer three pairs, extending as fringe along inner web; flight-feathers dark brown, primaries with green base of outer web and yellow margin near tip, secondaries with green outer webs, tertials green, tips of secondaries and tertials with narrow yellow fringe, alula and upperwing-coverts green, greater coverts tipped yellow; cheek and chin to throat bright yellow, upper breast orange, rest of underparts bright yellow; underwing-coverts and axillaries yellow, underside of flight-feathers extensively yellow (broad yellow borders of inner webs); iris dark brown; bill black; legs dark grey or blue-grey. Female is very like male, but orange on breast less intense. Juvenile has crown to side of neck, mantle and back barred grey and whitish, supercilium pale buff, back and wing feathers tipped whitish or pale yellow with dusky subterminal mark, uppertail-coverts barred with pale yellow, throat and underparts pale yellowish-buff, breast, upper belly, flanks and thighs barred whitish and dark grey, eyes light brown; immature like adult, but forehead olive (not yellow), supercilium whitish, lores and ear-coverts pale grey, upperwing-coverts spotted with yellowish, underparts pale yellow; rump and upper breast with vestigial dusky bars. Race *similis* closely resembles nominate, but has ear-coverts grey, blackish only near eye. Voice. Song of presumed male, from within upper canopy of prominent tree or from near top of thick bush, variable, ventriloquial, of pure ringing whistles, 3 or 4 short notes and one long one, "wi-hi-hi-hi-wheeee", first note sometimes lower ("woo-hi-hi-heeee"), the whole sometimes descending, as "hi-hi-hu-hu-hu-yooo"; a second common song is faster, with 4–9 (up to 15) notes on one pitch, 5 notes per second, "wi-wi-wi-wi-wi-wi-wi", and even faster versions higher-pitched. Some geographical variation: in Senegal typically a 4-note "put-wit-too-weee" and 2-note "hoop, heeee", each repeated in series; in Ivory Coast mainly a 3-note "hooey-hooey-hooey", also repeated in series. Presumed female sometimes responds with quiet, husky "skizzz" or "tzzrrik-tzzrrik". Threat call a harsh, drawn-out "tzzrrrrr" immediately followed by bursts of bill-clicking; in alarm and aggression the "tzzrrrr" longer, higher-pitched, and interrupted by short, jerky flights with wing-fripping; also, a snoring "chizzzzip" scold, and in anxiety or alarm a soft, low "chrrr" and "tu-tu-tu-tu-tu". Begging call of nestlings a high-pitched "seeeep-seeeep" with ventriloquial quality.

Habitat. Wide variety of woody vegetation, mainly rather low and with dense foliage, including acacia (*Acacia*) woods, especially along streams, *Cryptosepalum* forest, brachystegia (*Brachystegia*) woodland, *Erythrina* bushland, scrub, gallery forest and mixed riparian groves, also forest edge, bushveld, clumps of bushes and shrubby pasture, thornveld, coastal savanna bush, thickets growing on termitaria, and woods around foot of inselbergs. Mainly below 1500 m; uncommonly to 3000 m.

Food and Feeding. Small insects, including bees, wasps and other Hymenoptera, caterpillars and other larvae, mantises (Mantidae), beetles (Coleoptera); caterpillars and, after them, Hymenoptera seem to be important foods. Possibly takes chicks of small birds. Forages at various levels, e.g. in canopy of acacia woods and in canopy and middle stratum of *Cryptosepalum* forest. Hops strongly and rapidly among branches and leafy twigs, making short flights within tree, pausing and peering about, and darting quickly at an insect; works its way up tree to top, and then glides down to base of canopy of nearby tree. One individual, when taking honeybees (*Apis*) at a flowering shrub, perched very still and snatched each one as it passed; it flew into adjacent tree, carrying each bee in bill, and beat it against branch. May prey on chicks of Red-billed Quelea (*Quelea quelea*) in colonies. Forages singly and in pairs; often joins mixed-species flocks.

Breeding. Breeds in Mar–Jun in Mali, May–Jul in Ghana and Nigeria, Aug–Sept in Sudan, Apr–May in Ethiopia, Feb–Jun in Uganda, Dec–Jan in Tanzania, mid-Sept to mid-Oct in DRCongo (Lubumbashi); birds with enlarged gonads in Nov and Jan in Angola; season Oct–Feb in Zambia, Aug–Feb in Malawi, Oct–Jan in Botswana, Sept–Apr (mainly Oct–Dec) and some records in Jun and Jul in Zimbabwe; Sept–Mar (mainly Oct–Nov) in N South Africa (former Transvaal); probably generally single-brooded, but some records of second brood. Nest, built by both sexes, a flimsy, openly constructed platform made from grass, petioles and fine dry twigs, sometimes with cobweb, depression in centre lined with fine rootlets and creeper tendrils (eggs visible from below), placed generally more than 4 m and can be up to 10 m above ground in multiple fork in lateral branches of thorn tree or among thick foliage or creeper tangles (although sometimes built before tree in leaf), usually near site of previous season's nest; once a second nest built for rearing of second brood. Clutch 1–3 eggs; incubation by both sexes, period 13–14 days; chicks fed by both parents, nestling period 12–14 days. Adult can survive for at least 6 years.

Movements. Generally resident, but evidence of seasonal movements in Uganda and S Malawi, and a partial migrant in W Africa. Apparent influx on Ghana coast in dry season, Nov–Feb, and in Nigeria records farthest N tend to be in wet season, May–Jul; seasonal changes in abundance at Bamako, in S Mali; around Ouagadougou, in Burkina Faso, appears only between late Mar and mid-Sept; widespread resident in Togo, but may also be partial migrant there.

Status and Conservation. Not globally threatened. Has wide distribution across nearly all sub-Saharan Africa except for Congo Basin, the Horn, and SW Africa. Generally not uncommon in W Africa; locally common in E & S of range. Uncommon in Senegal, and frequent in Gambia (commonest near coast); in Niger occurs only in W National Park, where rare; uncommon to frequent in N & C Nigeria, absent from Liberia, SW Ghana, Gabon and PRCongo; frequent in Cameroon and S Chad; in Central African Republic, uncommon to locally frequent N to Bamingui-Bangoran National Park but uncommon in NE (Vakaga). In Sudan, fairly common in better woodlands in SW & SE, and occurs N to Jebel Marra and En Nahud area; frequent to common in S Ethiopia (mainly below 1800 m), with records N to L Tana; in Somalia restricted to extreme S (Boni Forest), Jubba–Webi Shabeelle triangle, and Shabeelle valley N of Mogadishu. In DRCongo, frequent in Uele, scarce in Kasai, and frequent in Manyema, Katanga and Marungu; common throughout W & S Uganda; present in N Rwanda and S Burundi (Bururi Forest), but status in both (also in adjacent parts of DRCongo) unclear. Widespread in S Kenya, but absent from arid regions in most of N & E (except coast and some localities with dense riverine acacias); common in E in Tanzania but sparse in W (not found recently in C areas). Locally common throughout interior Angola (except in highlands) and along coast from Cabinda and mouth of R Congo S to about Benguela, and frequent in Cunene Valley; present almost throughout Zambia. Uncommon to locally frequent in N & NE Namibia, N & E Botswana, Zimbabwe, Swaziland and E & SE South Africa.

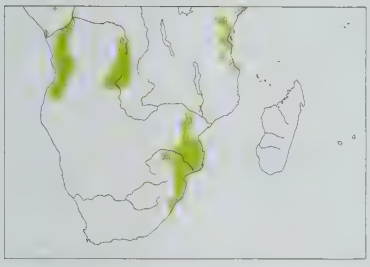
PLATE 6 ➤

Genus *TELOPHORUS* Swainson, 1832



43. Gorgeous Bush-shrike
Telophorus viridis

French: Gonolek vert **German**: Perrinwürger **Spanish**: Bubú Verde
Other common names: Four-coloured Bush-shrike; Perrin's/Perkins's Bush-shrike (*viridis*)

Taxonomy. *Laniarius viridis* Vieillot, 1817, Malimbe (= Malembo), Cabinda, Angola.
Molecular-genetic studies suggest that genus is more closely allied to *Chlorophoneus* and *Laniarius* than to the clade formed by *Malaconotus*, *Dryoscopus* and *Tchagra*, although has been thought to link arboreal *Chlorophoneus* and semi-terrestrial *Tchagra*. Present species forms a superspecies with *T. dohertyi*; the two have conventionally been grouped in *Chlorophoneus*, but studies of nuclear and mitochondrial DNA support their placement in present genus. Green-bellied nominate race in W of range formerly treated as a separate species, distinct from the three yellow-bellied races in E, but all are vocally very similar. Four subspecies recognized.

Subspecies and Distribution.
T. v. viridis (Vieillot, 1817) – SE Gabon, SW PRCongo, W & E Angola (including Cabinda), SW & S DRCongo and NW Zambia.
T. v. nigricauda (S. R. Clarke, 1913) – extreme S Somalia, SE Kenya and E Tanzania.
T. v. quartus (Clancey, 1960) – S Malawi, E Zimbabwe and W & S Mozambique.
T. v. quadricolor (Cassin, 1851) – NE South Africa (N & E Limpopo S to NE Eastern Cape) and Swaziland

Descriptive notes. 18–19 cm; male 30–40·5 g, female 31–39·5 g. Male nominate race has saffron-yellow line across forehead extending back to eye; crown, hindneck and upperparts, including upperwing, dark olive-green, tail blackish; cheek to chin and throat scarlet, enclosed by black band through lores, below eye and narrowly along side of throat, joining broad black gorget across

upper breast, gorget bordered below by transverse band of red; belly and flanks bright green, with scarlet-maroon lower edge of red subgorget band and irregular scarlet-maroon stripe, often broad, down mid-line to undertail-coverts, which are brownish-maroon; underwing-coverts and axillaries green; iris dark brown; bill black; legs bluish-grey or slaty brown. Female is duller than male, differs in having lores dusky, little black around side of throat, tail tinged green at base, narrower black gorget (often broken), chin and throat more orange than scarlet (often mottled yellow, sometimes all yellow), middle of belly brown, undertail-coverts orange-brown. Immature is duller green above, most wing feathers having blackish subterminal line, no black or red in plumage, has ill-defined yellowish stripe from bill to eye, yellowish chin and upper throat, yellowish-green breast finely barred, rest of underparts greenish-yellow, greener on flanks, yellower on undertail-coverts. Races differ mainly in coloration: *quadricolor* is slightly less dark above than nominate, central tail feathers green and grading to blackish distally, broad supercilium yellow, gold or orange and longer (extending a little behind eye), chin and upper throat sometimes more orange-red (less scarlet), red below gorget less deeply toned and often paler (more of a reddish wash), lower breast and belly greenish-yellow (no reddish mid-line), undertail-coverts orange-red; *quartus* is similar to previous, but brighter above, yellow in underparts tinged brownish; *nigricauda* also is similar, but central tail feathers blacker, greater area of red in centre of breast below gorget. Voice. Male song loud, far-carrying liquid whistles, 1–3 short "ko", "kok" or "kong" notes followed immediately by 1 or 2 upslurred "kowick" or "kowee" notes; also a slow "ko-ko-whoeee", a more emphatic "ko-koweet-koweet", a less emphatic "ko-koway-koway" and a rapid "kokoweekowee"; song lasts c. 1 second and repeated after 2–5 seconds, may sing c. 20 times per minute for several minutes on end; song often preceded by soft "ti" or "klink" note (audible only at very close range). Female of race *quadricolor* (but apparently not of nominate) sometimes duets with single or double harsh "zzrrrer-zzrrrer" notes. Contact call a low, guttural "grr-grr-grr"; alarm a louder frog-like or corvid-like rasp; when excited, makes fripping noises with wings.

Habitat. Undergrowth in patches of montane high forest, to 2000 m. In Angola coffee forest and dry forest; in Zambia only *Cryptosepalum* forest; in Kenya found in *Afzelia*, brachystegia (*Brachystegia*) and *Cynometra* in gallery forest, woodland and thickets. In S Africa occurs in semi-evergreen thickets at edges of lowland and middle-altitude forests, riparian forest, *Ficus sycamorus* on R Limpopo, tangles of forest creepers, secondary forest with thorny lianas and brambles on drainage lines and hillsides, dune forest and thick undergrowth.

Food and Feeding. Small arthropods, including hawkmoths (Sphingidae) and other moths (Lepidoptera), caterpillars, beetles (Coleoptera), parasitic wasps (Apocrita), and spiders (Araneae). Forages in low forest undergrowth, tangles, shrubs and rank grass; tends to work its way upwards in trees, gleaning trunks, branches and foliage; hops on ground, turning over leaf litter. Agile, moving silently and quickly in crouched, horizontal posture; peers about and darts at prey. Sometimes hawks insects in air. Usually in pairs; sometimes singly.

Breeding. Season Mar–May in Angola, Apr in Malawi, Oct–Feb in Zimbabwe, Nov–Feb in Mozambique, and Oct–Dec in South Africa. Male advertises territory, of less than 2 ha, by singing from canopy, in upright posture with head held up, scarlet throat feathers expanded to show yellow bases; one individual occupied same territory for 6·5 years; males often counter-sing in unison or antiphonally, perching sometimes less than 1 m apart; singer bows excitedly, jerks body from side to side and flicks wings and tail, and threatens with rapid bill-snapping. In courtship, male bows, sings and bill-snaps in front of female. Nest a rather thin platform or saucer of twigs, roots, stalks and grasses, lined with dry leaf petioles and tendrils (eggs visible from beneath nest), hidden 60–160 cm above ground on woody fork or among twigs or creepers. Clutch 2–3 eggs; incubation mainly by female, sometimes assisted by male; chicks brooded by female, fed by both parents; no information on duration of incubation and nestling periods; fledglings remain with parents for at least four months.

Movements. Mainly resident; race *quadricolor* moves locally from drier parts of range for non-breeding season.

Status and Conservation. Not globally threatened. Three main populations. Nominate race uncommon to locally common, probably widely under-reported, being secretive in dense thickets, and likely to thrive in those parts of S DRCongo and C & NE Angola where presently unknown. In Gabon recorded only at Leconi, and in PRCongo only at Pointe-Indienne, Diosso and Diosso–Mpinde road; locally common in Angola in Cabinda, Uíge, Malanje and Cuanza Norte S to Huíla; in DRCongo, occurs in W (E to Kwamouth) and recorded in SE in Kasai and Katanga (where doubtless under-reported), also once at Baraka, on L Tanganyika, but absent from Itombwe. Race *nigricauda* local and uncommon, mainly below 600 m in extreme S Somalia and in coastal Kenya S from Boni Forest and Lamu, inland on lower R Tana, Mt Endau (at 1200 m), Mt Kasigau and Shimba Hills National Park; Kenyan range apparently contracting, as no recent records from former sites in Chyulu, Taita, Sagala Hills and on R Voi, in Tsavo East National Park; in coastal Tanzania S to Mikindani and inland to N Pare Mts (at 1100–2000 m), foothills of Uluguru Mts, Liwale and Rondo Plateau (no recent records from E Usambara foothills). Races *quartus* uncommon in undeveloped parts of lower Shire valley (S from Lengwe), in Malawi, where rediscovered at Lengwe in 2002 after 18-year lack of records, and 20–30 pairs occupying 9–10 km² of suitable habitat; local and uncommon in E highlands of Zimbabwe (to 1500 m), and apparently frequent in W Mozambique, and widespread and not uncommon S of R Save (especially near coast); *quadricolor* locally common in NE South Africa in Soutpansberg–Blouberg foothills and N lowveld, and locally common in E KwaZulu-Natal from coast up to 600 m; some evidence that this species was once more widespread in E South Africa, but also may have benefited from bush encroachment resulting from overgrazing there and in Swaziland.

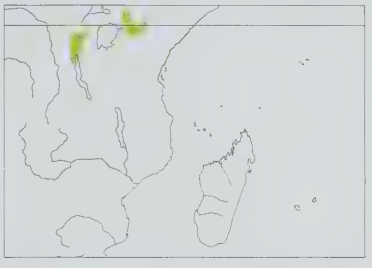
44. Doherty's Bush-shrike



Telophorus dohertyi

French: Gonolek de Doherty **German**: Rotstirnwürger **Spanish**: Bubú de Doherty

Taxonomy. *Laniarius dohertyi* Rothschild, 1901, Kikuyu Escarpment, Kenya.

Molecular-genetic studies suggest that genus is more closely allied to *Chlorophoneus* and *Laniarius* than to the clade formed by *Malaconotus*, *Dryoscopus* and *Tchagra*, although has been thought to link arboreal *Chlorophoneus* and semi-terrestrial *Tchagra*. Present species forms a superspecies with *T. viridis*; the two have conventionally been grouped in *Chlorophoneus*, but studies of nuclear and mitochondrial DNA support their placement in present genus. Monotypic.

Distribution. E DRCongo, SW Uganda, W Rwanda, W Burundi and W Kenya.

Descriptive notes. 19 cm; 36–40 g. A relatively small-billed bush-shrike. Male of crimson morph has forehead and forecrown, lower cheek, chin and throat bright crimson, sharply demarcated from black lores, band under eye, down side of neck and as a broad gorget across breast; hindcrown to uppertail-coverts and upperwing olive-green, tail black; below black gorget, centre of breast and belly bright yellow, side of breast, flanks and thighs yellowish-green, undertail-coverts crimson; underwing-coverts and axillaries olive-green; iris dark brown; bill black; legs grey or bluish-grey. Yellow morph (rare) has crimson areas of plumage replaced by bright yellow. Female (crimson morph) differs from male in having faint, narrow olive-green outer edges of tail feathers. Juvenile is tawny olive-green above, with fine blackish barring from hindcrown to uppertail-coverts, wings brownish-green, upperwing-coverts and tertials tipped buff and with blackish subterminal line, tail greenish-grey, chin to belly yellowish-green, pale on throat, brighter on belly, with breast and flanks finely barred, undertail-coverts pinkish-red. Voice. Song, presumably of male, variable, of loud piercing fluty whistles or liquid notes in brief phrases, "wok-wok-week-week", upslurred "koo-wee, koo-wee, koo-wee", liquid "koi-kwer" or "koi-kwodi", "chop-o-chop-o-chop", "quit-quit-quit-work" or slow trilled "kikoikoikoikoikoi"; repeats one phrase several times and then switches to different one; song resembles that of *T. viridis*, but lacks latter's repeated low-pitched notes. Also, a sharp "quip" and, in alarm, "tchrak, tchrak" and low rasps. No information on voice of female.

Habitat. Low, dense, moist thickets and tangles of scrub and bracken in clearings and at edges of montane and submontane forest (both primary and secondary forest); also thick bushes among bamboo. At 1500–2700 m in DRCongo; 1360–2100 m in Uganda; 1600–3350 m in Kenya.

Food and Feeding. Beetles (Coleoptera) and other arthropods. Forages on ground among shrubbery, probably also in shrub foliage. Generally in pairs.

Breeding. Various indications of breeding in May–Jul in DRCongo, Aug in Rwanda, Dec in Uganda and May–Jun in Kenya. No further information.

Movements. Resident.

Status and Conservation. Not globally threatened. Readily overlooked, but reportedly fairly common in Kivu (DRCongo). Although absent from Lendu Plateau and Ruwenzori Mts, fairly common in extreme SW Uganda (1360 m to at least 2100 m); common in W Rwanda. Locally common in highlands of W & C Kenya on Mt Elgon, Cherangani Hills, Mau, Nyandarua (Aberdare) Mts and Mt Kenya; old records from Sotik, Kericho, Limuru and Kiambu. Uncommon, or perhaps overlooked, in other parts of range.

Bibliography. Bennun & Njoroge (1999), Britton (1980), Brown & Britton (1980), Carswell *et al.* (2005), Chapin (1954), Cheke (1978), Dowsett (1990), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire (1990), Fishpool & Evans (2001), Fry *et al.* (2000), Fuchs *et al.* (2005), Gaugris (1976), Gronvik (1934), Hall & Moreau (1970), Harris & Franklin (2000), Lewis & Pomeroy (1989), Lippens & Wille (1976), Mackworth-Praed & Grant (1960, 1973), Nguembock *et al.* (2008), Prigogine (1971), Schouteden (1938, 1960, 1966, 1969), Sessions (1966), Short *et al.* (1990), Sibley & Monroe (1990), Sinclair & Ryan (2003a), Stevenson & Fanshawe (2002), White (1962), Zimmerman *et al.* (1996).

45. Bokmakierie

Telophorus zeylonus

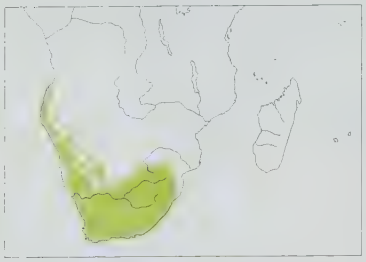
French: Gonolek bacbakiri **German**: Bokmakiriwürger **Spanish**: Bubú Silbón
Other common names: Bokmakierie Shrike/Bush-shrike

Taxonomy. *Turdus zeylonus* Linnaeus, 1766, Cape of Good Hope, South Africa.

Molecular-genetic studies suggest that genus is more closely allied to *Chlorophoneus* and *Laniarius* than to the clade formed by *Malaconotus*, *Dryoscopus* and *Tchagra*, although has been thought to link arboreal *Chlorophoneus* and semi-terrestrial *Tchagra*. Present species sometimes placed in *Chlorophoneus*, but differs in lack of mouth spots and in nest structure, egg coloration, semi-terrestrial habit and communication behaviour. Thought to be most closely related to *T. cruentus*, which it resembles in plumage pattern, tail shape and pattern, behaviour and voice. Four subspecies recognized.

Subspecies and Distribution.

T. z. phanus (E. J. O. Hartert, 1920) – SW Angola (arid coastal plain) and NW Namibia (Kaokoveld).



T. z. thermophilus Clancey, 1960 – Namibia (S from c. 21° S), SW & SE Botswana and W & N South Africa (E to Limpopo and W Free State).

T. z. zeylonus (Linnaeus, 1766) – E & S South Africa (C & E Free State and KwaZulu-Natal S to SE Western Cape), Swaziland and Lesotho.

T. z. restrictus Irwin, 1968 – Chimanimani Mts, on Zimbabwe–Mozambique border.

Descriptive notes. 22–24 cm; male 57–71 g, female 48–76 g. Nominate race has grey forehead to hindneck, well-demarcated bright yellow superciliary stripe from bill to above or just behind eye,

On following pages: 46. Rosy-patched Shrike (*Telophorus cruentus*); 47. Brubru (*Nilaus afer*); 48. White-tailed Shrike (*Lanioturdus torquatus*).

bright olive-green upperparts, including upperwing; central pair of tail feathers dark olive-green, remainder black with bright yellow tips, yellow area progressively larger from rectrix T2 to T6; lores black, chin and throat bright yellow, bordered by black band 3–5 mm wide at side of throat and 12–17 mm wide in mid-line; lower breast and belly yellow to rich olive-yellow becoming olive-green or grey on sides of breast and, broadly, on flanks, thighs olive-green sometimes with variable amounts of grey or yellow, undertail-coverts yellow; underwing-coverts greyish-yellow; iris mauve-brown; bill black; legs blue-grey. Sexes alike, female's gorget perhaps on average narrower than male's. Immature has forehead to hindneck dark greyish olive-green, upperparts like adult but dark area of tail feathers brownish-slate (not black), lores and ear-coverts dark grey, chin and throat pale grey, merging into yellowish-olive on breast and greyish-olive on rest of underparts, breast and flanks finely and inconspicuously barred or vermiculated with blackish, eyes greyish-brown, bill horn-coloured with paler base; juvenile at fledging like immature, but with large patch of bare grey skin around eye, visible skin between other feather tracts pale yellow and bright pink, gape yellowish-white, mouth bright yellow, yellow throat patch begins to show at 70 days of age. Race *thermophilus* is paler than nominate, particularly on crown and nape, mantle greyer, no greenish tinge on side of breast and flanks; *phanus* is like previous but paler still, flanks chalky white, bill slightly heavier; *restrictus* is darker than nominate, particularly on crown and nape, and with heavy grey wash on flanks, also somewhat shorter-winged and longer-tailed. Voice. Song loud, liquid, far-carrying, generally by two paired individuals in antiphonal duet; twelve or more different songs identified; male and female seem to have different repertoires but share some notes, and may utter sounds simultaneously or in rapid succession antiphonally. Male sings loud ringing whistles, varying from slow "houuuu" or double "hu-hu" or "hwe-hwe" to a rapidly delivered phrase including both slow "huu-huhuhu" and rapid, higher-pitched "hehehe"; female responds with lengthy, rapidly repeated whistles, which include "wikwikwikwikwikwik..." and high-pitched "hwehwehwehwehwe" or "teuteuteuteu...". Duetting initated usually by male, sometimes by female, and mate responds whether nearby or distant; if mate has disappeared, partner can sing complete duet sequence by itself. Songs have marked individual and regional variation, and different pairs can be identified by their duets; species' vernacular name is onomatopoeic, from duet of "bok-bok..." or "wok-wok..." followed by trilling "trrrreee". Immature starts to sing, imperfectly, at 55–70 days, joining parents to make trio songs. Other sounds are variety of stuttering, croaking, tearing and slashing notes, bill-clicking and wing-fripping; in territorial threat, pair duets with rising trills "trrrrrrrrree...", tearing "tzzrrreeo...", buzzing noises and sharp bill-clicking; when one individual changes notes, mate also does so; frips wings when excited; alarm at predator on ground slow "tok" notes, at aerial predator harsh scolding and "krrr..." sounds.

Habitat. Bushes and thickets with plenty of quite open ground around. Thickets in open grassland, bushy and rocky hillsides, scrub in hillside ravines, broken thornveld on stony ground with aloes (*Aloe*) and euphorbias (*Euphorbia*), also plantations, farmyards, gardens, tamarisk (*Tamarix*) growth along dry watercourses, dense protea (*Protea*) scrub, coastal fynbos and red dunes. In Mozambique, steep boulder screes with *Philippia* heath or *Hymenodyction* scrub and borders of forested ravines where rugged quartzite and schist massifs fold; in Namibia, occurs on arid boulder-strewn mountainsides with scattered bushes, and dunes with sparse scrub. To 2550 m.

Food and Feeding. Mainly invertebrates, including longhorn and shorthorn grasshoppers (Orthoptera), stick-insects (Phasmida), heteropteran bugs, mantises (Mantidae), moths and both hairless and hairy caterpillars (Lepidoptera), adult and larval beetles (of families Tenebrionidae, Scarabaeidae, Curculionidae, Lampyridae), flies (Diptera), termites (Isoptera), spiders (Araneae), sun-spiders (Solifugida), centipedes (Chilopoda); less commonly geckos (Gekkonidae), young chameleons (Chamaeleonidae), small snakes, and frogs; rarely, takes small birds up to size of prinias (*Prinia*) and white-eyes (Zosteropidae); occasionally a few seeds and small fruits. Hunts in grass tufts and in clumps of bushes and small trees, moving on ground, searching bases of vegetation, sometimes jumping up to seize prey; hops about in shrub, searching stems and leaves, gradually working its way upwards, and then flies down to base of another clump nearby. Most prey caught on ground, the bird often chasing it by hopping and running in zigzags with long, swift strides, with head drawn in and tail depressed; may fly up from bush to seize insect in flight. Large prey generally beaten and chewed on ground, then carried in bill to concealed perch in foliage; caterpillar usually wiped on ground or wedged in grass fork and scraped with the bill before before being consumed. When flushed from ground, flight rather laboured, close to ground, with fast shallow wingbeats and tail generally fanned; dives straight into cover. Usually in pairs.

Breeding. Season lengthy in South Africa, mainly Aug–Nov (but clutches in all months except Apr) in Limpopo, Sept–Mar in KwaZulu-Natal, Jul–Mar in Eastern Cape and Jul–Oct in Western Cape; female with oviduct egg in Apr in Namibia, and birds in breeding condition Aug–Sept in Zimbabwe. Territory or home range c. 5 ha in suburban habitats, larger in open bushy country and arid areas (after young have left, adults move into larger territory which may be extension of breeding one), defended vigorously by pair and advertised throughout year, bird perching on top of low eminence, body inclined, neck stretched, bill open and pointing upwards so that yellow throat displayed, and sings solo or duets; in territorial threat, tenses body and bows jerkily, flicks wings and fans tail, while making bill-clicking, croaking and ripping sounds; in one encounter, adult pursued another at distance of 1–1·5 m, each often turned to face opponent and displayed by raising and spreading ■ wing (usually the right one) and pointing bill skywards (revealing yellow throat and gorget), then bowing forwards with tail cocked and spread (showing black-and-yellow pattern), pursuer uttered low "kok-kok, wit", and the two fought briefly until, after 20 m of quite slow pursuit, the intruder crossed back into its own territory. Courtship not known to differ from territorial threat display. Nest built by both sexes, sometimes constructing several before settling on one, a shallow bowl, quite neat and compact, made from dry grass, wet stems (e.g. of *Helichrysum*), herbs, fine twigs, roots and rootlets, sometimes with woolly plant down, leaves and man-made materials, sometimes decorated externally with asparagus fern (*Asparagus*), lined with fine grass and rootlets; placed on ground or, on average, 60 cm above it on fork of branch in dense foliage in bush, hedge or tree. Clutch 2–6 eggs, usually 3; incubation by both sexes, usually only female at night, period 14–19 days, usually 16 days; chicks brooded and fed by both parents, which carry more than one food item in bill at a time, parents take shifts in feeding and guarding, both remove faecal sacs (dropping them good distance away), nestling period 14–21 days, average 18 days. Nest occasionally parasitized by Jacobin Cuckoo (*Clamator jacobinus*).

Movements. Resident. Longest distance covered by ringed individual 5 km.

Status and Conservation. Not globally threatened. Locally common within its large range. Not uncommon in Angola from Lobito Bay S to R Cunene; occasional in Iona National Park. Widespread in W & S Namibia; in Botswana, uncommon in SW (from Nossob Camp to Bokspits and Khuis) and sparse in extreme SE. Isolated population in Chimanimani Mts, on Zimbabwe–Mozambique border, estimated in 1981 at 400 birds, mainly in Mozambique (at 1350–2100 m), with only a few pairs in Zimbabwe. Common and widespread in South Africa and Swaziland; in N South Africa restricted to highveld and escarpment region (N to about Ohrigstad) and bushveld (N to about Rust der Winter). Common throughout Lesotho at 1970–2550 m, where population estimated at 10,000–100,000 individuals.

46. **Rosy-patched Shrike**

Telophorus cruentus

French: Gonolek à croupion rose **German**: Rosenwürger **Spanish**: Bubú Pechirrosado
Other common names: Rosy-patched Bush-shrike; Tsavo Bush-shrike (*cathemagmenus*)

Taxonomy. *Lanius cruentus* Hemprich and Ehrenberg, 1828, Arkiko, near Massawa, Eritrea.
Molecular-genetic studies suggest that genus is more closely allied to *Chlorophoneus* and *Laniarius* than to the clade formed by *Malaconotus*, *Dryoscopus* and *Tchagra*, although has been thought to link arboreal *Chlorophoneus* and semi-terrestrial *Tchagra*. Present species was previously placed in latter genus by several authorities or in its own genus *Rhodophoneus* by several others. Thought to be most closely related to *T. zeylonus*, which it resembles in plumage pattern, tail shape and pattern, behaviour and voice. Four subspecies recognized.

Subspecies and Distribution.
T. c. kordofanicus (W. L. Sclater & Mackworth-Praed, 1918) – W Kordofan, in WC Sudan.
T. c. cruentus (Hemprich & Ehrenberg, 1828) – NE Sudan, Eritrea and extreme N Ethiopia.
T. c. hilgerti (Neumann, 1903) – extreme SE Sudan, C, E & S Ethiopia, Djibouti, Somalia and N & E Kenya.
T. c. cathemagmenus (Reichenow, 1887) – S Kenya and NE Tanzania.

Descriptive notes. 22–23·5 cm; male 40–62 g, one female 50 g (*hilgerti*). Distinctive, with long, graduated tail, quite heavy and strong bill hooked and notched. Male nominate race has forehead and crown light grey-brown, tinged pink, lores and narrow short superciliary stripe creamy white, nape to mantle and scapulars pale grey-brown, long fluffy back feathers pink-carmine, rump, uppertail-coverts and central tail feathers like mantle; central pair of tail feathers pale grey-brown with c. 18 structural bars, remaining feathers brownish-black, outer four pairs with white ends (c. 13 mm long on T3, 23 mm on T4, 31 mm on T5, 28 mm on T6), white areas often stained buff or pale rufous by soil in habitat; upperwing light brown, feathers narrowly edged pale buff, leading edge from carpal to below alula conspicuously pale buff; ear-coverts light pink-tinged grey, grading to whitish towards cheek and throat; chin whitish, large patch of pink-carmine in centre of throat and upper breast surrounded by creamy white or very pale buff, the patch separated from (or just confluent with) oblong or irregularly diamond-shaped patch of same colour on lower breast; large grey-brown patch at side of breast extending to side of neck; belly silky white in mid-line, buff at side, flanks and thighs buff, vent buffy, undertail-coverts pale buff; underside of tail black and white, underside of flight-feathers pale silvery brown, underwing-coverts and axillaries buff; iris dark brown or russet; bill grey-black, slate or black; legs lead-grey or greyish-horn. Female is like male, but pink-carmine on throat and upper breast replaced by wide black gorget which extends as malar stripe up to corner of bill, enclosing large white area on chin and upper throat; below gorget a ragged pink-carmine patch, like that of male but narrower and shorter. Immature is like adult above, male has chin to breast white, a scattering of carmine feathers on lower breast, large grey-brown patch at side of breast, middle of belly white, feathers silkily fluffy, female like young male but gradually acquires black gorget, at first indistinctly as broad black malar stripes and a black dot in centre of breast, these soon joined together. Race *kordofanicus* is like nominate, but brown areas much paler and rather greyer, ear-coverts white with brown tinge, grading to white on cheek and throat; *hilgerti* also is like nominate but darker above, forehead to mantle and scapulars strongly tinged carmine, lores pale, supercilium and grey ear-coverts contrasting with pink-grey forehead, crown and hindneck, rump tinged carmine, male with chin carmine (not white) and carmine patch or patches from chin to upper belly stronger in tone and better demarcated; *cathemagmenus* is like previous, but male has black malar stripe and black gorget (like female), chin and throat carmine, sometimes a small buff or white tip on rectrix adjacent to central pair, female has comparatively small pink-carmine patch on lower breast. Voice. Various thin, piercing or chirping, quavering whistles, somewhat slurred and ventriloquial. Apparent territorial song a whistled duet between two males or a male and female, initiated with male's high-pitched "tzee" or "twee-u" or "tzwee-wee" notes, immediately answered by female with slightly lower "ter-ee" or "tzee-ur" notes, the two then alternating indefinitely; calling birds duet monotonously for long periods from top of bush, perching out in open or with only head visible; two pairs may duet together, males only a few centimetres apart. Alarm a harsh, grating "krrrr" and scolding "zwerrrrk-zwerrrrk" notes.

Habitat. Wadis with extensive acacia (*Acacia*) groves, hot coastal plains with acacia and dry, open, low thorn-scrub, lava fields, and arid bush and semi-desert with scattered shrubs; to 1970 m, mainly below 1300 m.

Food and Feeding. Insects, including beetles (Coleoptera) and grasshoppers (Orthoptera); some small fruits. Terrestrial, spending much time on open or almost bare ground not far from cover. Forages in surface litter, progressing in hops and bounds; runs fast over ground, and flies very low over it. Singly and in pairs, sometimes in small groups. Likes to keep out of sight, but restless; can be conspicuous and confiding.

Breeding. Breeds probably in response to rain, duetting common in spring and early summer; about Mar–Jun on Egypt–Sudan border (Jebel Elba), Oct–Nov in Sudan (Red Sea Hills), Nov–Mar and May in Eritrea, Sept–Apr in Ethiopia, Jan–Jul (mainly Jun) in N Somalia, and Apr–Jun and

Nov in Kenya. Probably territorial, but poorly known; two males often counter-sing, perched on bushtop or ground within 1 m of each other, one stretches legs, body and neck upwards and whistles, other performs similarly, the two alternating until a female arrives, then following her (on foot or on wing); individuals in small party chase each other around large stone, wings outstretched and tail fanned, and perch on dead bough, bobbing up and down and giving nasal 2-note call, seeming almost oblivious of observer. Nest an untidy shallow cup or platform, made from vegetable fibres, twigs and dry grass stalks or grass leaves, unlined, well concealed low down in thorn bush or small shrub, one covered with creeper (*Cissus rotundifolia*), sometimes in topmost foliage (e.g. of *Suaeda fruticosa* bush). Clutch 2–3 eggs; no information on incubation and nestling periods.
Movements. Resident. Possible movement in Red Sea Hills, in Sudan, where said to be common only seasonally. Race *hilgerti* recorded in or very near range of *cathemagmenus* in S Kenya (Tsavo), suggesting that some non-breeding individuals may wander.
Status and Conservation. Not globally threatened. Race *kordofanicus*, known only from three specimens collected in 1902 in Ogayeh Wells (near El Obeid), in Kordofan, and one individual seen near Wadi el Melik; may be close to extinction. Species locally common around Jebel Elba and in Red Sea Hills, in E Sudan; uncommon in extreme SE Sudan and Eritrea (coastal plains and Danakil and on R Baraka S to Karkabat); frequent in lowland C & S Ethiopia (to 1800 m). Common to abundant on coastal plain in Djibouti (more than twelve seen in a day in 20 km between Doralé and Loyada); in Somalia, very common in NW (to 1970 m) and common and probably widespread S to c. 2° N. In Kenya, possibly more widespread in E than currently realized; uncommon or locally frequent from coast and lower R Tana up to 1600 m (scarce above 1300 m). Locally fairly common in Tanzania from L Natron to lowlands N of Arusha, Ardai Plains, Tarangire National Park, Mkomazi Game Reserve and Masai Steppe S to Kondoa and Kilosa.

Genus *NILAUS* Swainson, 1827

47. **Brubru**

Nilaus afer

French: Brubru africain **German**: Brubruwürger **Spanish**: Brubrú
Other common names: Brubru Shrike; Southern Brubru (*brubru*); Northern Brubru (*afer*); Black-browed Brubru (*nigritemporalis*); Angola Brubru (*affinis*)

Taxonomy. *Lanius afer* Latham, 1801, Senegal.
An enigmatic, monotypic genus which has been placed variously in families Laniidae, Prionopidae and Muscicapidae; nest and tarsal scutellation like those of prionopids, and bill shape and juvenile plumage similar to those of laniids. Nest also very like those of *Batis* species (family Platysteiridae), as are white nape and back, fluffy rump and white wingstripe, in which respects this genus links present family and Platysteiridae; duet-singing and some aspects of breeding behaviour (destruction of own nest, parental sharing of nest duties), however, are typical of present family, and not of platysteirids. Race *massaicus* intergrades with nominate in NE Uganda (Karamoja); *nigritemporalis* intergrades with *affinis* and *brubru* in SE DRCongo (Katanga), and with *solivagus* in Zambia (middle Zambezi valley). Proposed race *hilgerti* (described from R Kassam, in E Ethiopia) synonymized with *minor*. Nine subspecies recognized.
Subspecies and Distribution.
N. a. afer (Latham, 1801) – S Mauritania and Senegal E to Eritrea and NW Ethiopia, S to NW & C Cameroon, W & NW Central African Republic and NW Uganda; dry-season visitor in coastal Liberia and Ghana.
N. a. camerunensis Neumann, 1907 – Cameroon highlands, S Central African Republic, and N & NE DRCongo (E to N end of L Albert).
N. a. minor Sharpe, 1895 – SE Sudan, SE Ethiopia, Somalia (except NE), plateau country in N & E Kenya (S to Kerio valley, Baringo, Isiolo, Tsavo and Taru), and NE Tanzania.
N. a. massaicus Neumann, 1907 – NE DRCongo, Uganda, Kenya (except N & E) and N Tanzania (Serengeti S to Shinyanga).
N. a. affinis Bocage, 1878 – N Angola and S DRCongo (Kasai, and Katanga E to Mt Kabobo).
N. a. nigritemporalis Reichenow, 1892 – E Angola, S & SE DRCongo and Tanzania (except far NW & NE) S to Zambia (except extreme SW), Zimbabwe (in middle Zambezi valley), Malawi and Mozambique (except extreme S).
N. a. brubru (Latham, 1801) – SW & W Angola, extreme SW Zambia, Namibia, Botswana, W Zimbabwe, N South Africa (W Limpopo S to extreme N Northern Cape and W Free State) and W Swaziland.
N. a. solivagus Clancey, 1958 – C plateau of Zimbabwe, SW Mozambique (W Sul do Save), N South Africa (N & E Limpopo, KwaZulu-Natal) and E Swaziland.
N. a. miombensis Clancey, 1971 – extreme SE Zimbabwe (around Marhumbini), SE Mozambique lowlands and NE South Africa (coastal KwaZulu-Natal).

Descriptive notes. 12·5–15 cm; male 17–32 g and female 18–30 g (*solivagus*); male 21–27 g and female 21–25 g (*nigritemporalis*), sexes combined 13–20 g (*minor*). Male nominate race has central forehead, crown, nape, and stripe from behind eye to side of neck black, side of forehead, lores and long broad superciliary stripe white, hindneck whitish; side of mantle black, scapulars black, rest of mantle and back rufous-buff with black spots; rump plumage very full, soft and fluffy, black and white (each feather with blackish tip, large white subterminal patch, dark grey base), uppertail-coverts black; tail black, outermost feather with white tip and white outer web, next two pairs with small white triangle at tip and white streak along outer edge, next pair with or without small white tip; upperwing black, primaries with narrow rufous-buff edges, tertials with broad warm rufous-buff outer edges, median and inner greater upperwing-coverts warm rufous-buff; cheek, chin, throat and underparts white, comparatively narrow dark chestnut line on side and flanks; underwing-coverts and axillaries white, blackish carpal patch; iris dark crimson-brown; bill black; legs grey. Female is like male, but black areas above duller and warm brown, rich rufous-buff tinge in white areas, narrow dark chestnut line from below eye running down sides of throat and breast to flanks, chestnut on flanks somewhat paler and less extensive, slight dark streaking from chin to breast. Juvenile plumage (of short duration) whitish with dark brown bars on forehead and crown, hindcollar buffy, mantle whitish with dark brown bars, back mainly white, tail dark brown and warm buff, wings warm dark buff, dull white below with widely spaced narrow dark vermiculations; immature crown dark brown with white speckles, white supercilium mottled dark brown, hindneck and sides of mantle and back dark brown with broken white bars and white speckles, centre of mantle and back with large white blotches, rump and uppertail-coverts dark brown and whitish, wings dark brown and pale buff, ear-coverts whitish with dusky speckles, dark line behind eye to hindneck, underparts white with irregular short dark brown bars and few rufous feathers at side. Races differ mainly in plumage coloration and pattern: *camerunensis* is like nominate but white areas on head and underparts more greyish, female chin to breast greyish-white and slightly dark-speckled; *minor* is similar to *brubru*, but smaller; *massaicus* resembles nominate but pale areas in upperparts white, cream or pale rufous, and chestnut line on side much wider and slightly paler, female dark brown and white above, dark line from eye down to side of breast; *nigritemporalis* has white forehead, black lores, short white anterior supercilium, pale areas above are white (not buffy), underparts like nominate but stripe on side rufous (not chestnut), female like nominate but light areas in upperparts pale buff, rufous line along side narrow and fragmentary; *affinis* short white anterior supercilium, pure white below without any rufous, female dark brown and creamy above, greyish-white with slight buffy wash below, chin to breast quite heavily streaked and speckled with black; *brubru* has lores white with black spots, pale areas above are white (not buffy or rufous), chestnut line on flanks paler, and broader, female dark brown and white above, lacks dark line from eye down to side of breast, line on side pale rufous and smaller than male's, chin to upper breast with blackish streaks and speckles; *solivagus* has blacker upperparts than previous, white on back tinged yellowish, underparts creamy (not white), chestnut stripe narrower and darker than in previous; *miombensis* male is like male *nigritemporalis*, female pure white below, unmarked on throat and breast, stripe along side reduced to small chestnut streaks. Voice. Male song, commonly heard, a repeated far-carrying, high-pitched trill lasting 0·5–0·8 seconds, varying regionally from fast buzz with individual notes barely discernible, "prrrrriiiii", to slower, telephone-like trill, "b-r-r-r-r-r-u-u-u-u-u", trill sometimes (especially in S Africa) preceded by up to 6 soft clicking notes, "tch-tch-wrrrrreeeee" or "wop-prrrrreeeee", song repeated up to c. 40 times; female responds erratically with few short, squeaky notes, usually synchronously with male's trill. Two males often counter-sing, using trills at different pitches, females joining in with repeated "eeeu-eeeu" and "tu-tu" calls; duets used for maintaining long-range contact, soft "pe-with" or "chip-chip" notes or harsh rasps for short-range contact. At least ten distinct calls known, including repeated short trills and wing-fripping in territorial encounters, a repeated penetrating "piep-piep-piep..." by both sexes; nasal "naaa-naaa" notes; rapidly-repeated "chk-chk-chk..." and rasping "tzzrr" in alarm; in E Africa a long rapid chatter, "chatatatatatata...". Often frips wings loudly and excitedly.
Habitat. Varies regionally, from canopy of mature *Brachystegia*, *Colophospermum*, *Combretum* with *Terminalia* and other broadleaf woodlands in mesic areas to flat-topped acacia (*Acacia*) woods and scrub in arid environments; occurs in 11 out of 17 woodland types in Botswana; often in open park-like country. In desert areas occurs in small, isolated clumps of thorn trees. At 1000–1500 m in Uganda, 530–2120 m in Ethiopia, and to 1360 m in Eritrea.
Food and Feeding. Invertebrates, including moths and caterpillars (Lepidoptera), ants (Formicidae), beetles (Coleoptera), grasshoppers (Orthoptera), flies (Diptera) and spiders (Araneae). Unobtrusive, never gregarious; spends nearly all of its time in foliage, often near tops of emergent broadleaf or microphyllous savanna trees. Flight fast and undulating, at or above treetop level. Pair-members often forage far apart; silent for long periods when foraging. Active, gleaning foliage and branches in canopy; quite acrobatic, feeding in manner of a tit (Paridae), with body at all angles, sometimes head down or completely upside down as it investigates leaf sprays, inflorescences or pods at tips of branches. Occasionally hawks insects in air. Holds large prey item under one foot in order to deal with it. Often joins mixed-species foraging flocks.
Breeding. Season about Jun–Nov in Gambia and Mali, about Jan–Feb in Ghana and Nigeria, May in Niger, Feb in Chad, Apr–May and Nov in Sudan, Apr in Ethiopia, Apr–May in Somalia, about Jan–Feb in DRCongo, May–Jul in Uganda; Mar, May, Jul, Sept–Oct in Kenya (E of Rift Valley) and NE Tanzania, Oct–Dec in rest of Tanzania; Sept–Jan (mainly Sept) in Zambia, Aug–Sept and Mar in Malawi, Oct–Nov in Namibia, Oct–Feb in Botswana, Sept–Jan (mainly Sept–Oct) in Zimbabwe; in South Africa, Aug–Jan in former Transvaal and Sept–Dec in KwaZulu-Natal. Pair defends permanent territory of 33–42 ha, advertises it by singing all year; disputes between neighbouring pairs common, with chasing and supplanting, intense territorial interactions involving counter-singing and zigzag display-flights with wing-fripping and deep, rather slow wingbeats, also (when perched) bowing and rapid side-to-side movements of body; male sings from exposed treetop perch, with body inclined, head raised, neck outstretched, crown and throat feathers raised, tail slightly fanned. Courtship incorporates elements of territorial behaviour; in sexual display, male perched with food in bill and gave series of high-pitched "tuet-tuet-tuet" calls interspersed with "prrreeee" trills, then flew to female, sidled up to her and the two copulated. Nest-building shared by sexes (see page 76), building takes two days, shaping a further four days (eggs laid up to four days later); a small, neat, not very deep, open cup made from bits of fine pliant leaf petioles, twigs, tendrils and pieces of bark, felted together with spider web, generally covered profusely on outside with bits of foliaceous lichen (two nests each made entirely of three materials: spider web, c. 95 pieces of lichen, and up to 550 petioles); placed usually on two-pronged or three-pronged fork on gently sloping branch (c. 7 cm in diameter) 2·5–9 m up in tree, often *Terminalia sericea* or *Burkea africana* (at Nylsvlei, Transvaal), nest often highly cryptic on lichenous substrate; strong tendency to abandon early nests without laying in them (one pair built and destroyed three nests in four weeks, starting fourth nest near end of that time and laying in it). Clutch 2–4 eggs, generally 2, second laid 26–27 hours after first; incubation from first egg, by both sexes, for 98% of daytime, by female rather more than by male, only female at night; stints last 17–178 minutes (average 42 minutes), when female sitting male initiates change-over by calling as he approaches, she responding in duet; when male incubating he initiates change-over by calling on nest, female arriving immediately and taking over; incubation period c. 19 days; chicks brooded by either parent, continuously for first 6–7 days, sporadically for next 3–4 days, thereafter only at night, fed by both, faecal sacs removed and eaten by either parent, nestling period 21–22 days; young stay with parents for c. 55 days after leaving nest, remain in parental territory but not accompanied by parents. Of ten nests in one study, only three were successful. Longevity at least 8 years.
Movements. Mostly resident. Partial migrant in W Africa, dry-season visitor late Oct to mid-Mar in coastal Liberia and on Accra Plains, in Ghana; thought to be migratory in Ouaddaï region of

Chad, where occurs Jul–Sept; common resident in Ennedi hills, in Sahara, but perhaps also partial migrant there.

Status and Conservation. Not globally threatened. Common in many parts of its vast sub-Saharan range. Uncommon in Togo. Global population perhaps in low millions; probably more than 100,000 individuals in S Mozambique. In S uncommon to locally very common; densities of 1 pair/30–50 ha in former Transvaal (South Africa), 1 bird/9 ha in eleven woodland types in N Botswana and 1 bird/4 ha in tall acacia woods in Okavango; four localities in acacia savanna in Swaziland held, respectively, 3, 11, 24 and 30 birds/100 ha.

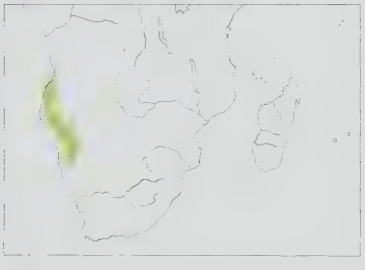
Genus *LANIOTURDUS* Waterhouse, 1838

48. White-tailed Shrike



Lanioturdus torquatus

French: Lanielle à queue blanche **German**: Drosselwürger **Spanish**: Laniotordo
Other common names: Chatshrike, Flycatcher Shrike

Taxonomy. *Lanioturdus torquatus* Waterhouse, 1838, Bull's Mouth Pass, Naukluft Mountains, Damaraland, Namibia.

Affinities uncertain. Originally thought to be an aberrant member of present family, with which it shares several cranial and limb-bone characters and is similar in various aspects of behaviour; has sometimes been placed with Old World flycatchers (Muscicapidae), and eggs resemble those of helmet-shrikes (Prionopidae). Plumage pattern and nest, however, strongly reminiscent of batises (*Batis*), and some structural characters, e.g. jaw musculature, shared with those and wattle-eyes (*Platysteira*), both in family Platysteiridae; recent molecular-genetic studies corroborate close relationship with *Batis*, and the species is possibly better assigned to Platysteiridae (see HBW 11, page 164). Monotypic.

Distribution. SW Angola and NW & C Namibia.

Descriptive notes. 14–15 cm; 23·5–45 g. A small, large-headed and short-tailed bush-shrike with long legs, somewhat crested appearance. Forehead is white, lores and crown to nape, hindneck and ear-coverts black, slightly glossy, hindneck with long narrow white horizontal patch in mid-line; mantle to uppertail-coverts blue-grey, dappled with white, rump feathers and uppertail-coverts long and fluffy; tail white, feathers rather stiff, central pair with long teardrop-shaped black mark on distal half; upperwing black, with white bases of primaries and small white tips on all flight-feathers, white greater and median secondary coverts and greater primary coverts, but outermost greater covert black, generally small white tips on alula feathers, and small white patch on leading edge near bend of wing; chin, throat and side of neck white, sharply demarcated; slightly glossy black band (c. 7 mm deep in middle, narrowing to point at side) across upper breast, lower breast blue-grey at side and paling to off-white in middle; upper flanks blue-grey, rest of lower underparts white; iris yellow or greenish-yellow; bill and legs black. Sexes alike, male perhaps fractionally larger than female. Juvenile is like adult, but hindneck mottled, breastband narrower, eyes brown. Voice. Male song a mix of two notes, a penetrating high-pitched, querulous crescendo whistle, "eeee", "oo-eee" or "hooou", lasting 0·5 seconds, repeated up to five times, and an abrupt liquid "tewp" or "tiu" (lower than the "eeee") sounding like that of a *Lamprotornis* starling; one 25-second song consisted of three, one and six whistles alternating with one and ten "tewp" notes, separated by variable-length pauses; some whistles double, the second note following without pause but lower-pitched and quieter. Female song a number of low-pitched discords "tchzrr" or "kichurrr" at irregular intervals, synchronously with male's song; in aforementioned 25-second song, female uttered five "tchzrr" notes interpolated only with male's "tewp" calls (not with his whistles). Contact call a hollow metallic "chink", by either sex. In high-intensity territorial interaction male has ratchet-like "ch-ch-kkkk-kkkkkk..." rattle (duration more than 2 seconds); another territorial note is nasal "kzzzzp, kzzzp" by male and "ktchzrrr" by female; also discordant "chuk" notes when going to roost, slow "chuk'chuk" in apprehension, and counter-sung whistles and nasal and ratchet notes in threat; nasal "chk-chk-chk-chk..." stutter in alarm, explosive "skzeer, skzeer" in high-intensity alarm, and "heee-u" whistle on approaching and while guarding nest. Male makes fripping sounds with wings in display-flights.

Habitat. Climax and degraded brachystegia (*Brachystegia*) woodland, *Terminalia sericea* and teak woods on sandy soils in N of range; in S occurs in mopane (*Colophospermum mopane*) woods, *Combretum imberbe* woodland, *Commiphora* and acacia (*Acacia*) thornbush-scrub and savanna, mainly in denser patches of woody growth on rocky hillsides and along watercourses.

Food and Feeding. Insects, including beetles (Coleoptera), moths, butterflies and caterpillars (Lepidoptera), mantids (Mantidae) and grasshoppers (Orthoptera); drinks only rarely. Terrestrial and arboreal; forages in low, dense vegetation and on ground beneath, also commonly in trees at all levels up to canopy, 25 m above ground. Active, shy but inquisitive. Gleans insects from trunks, branches and foliage, where sometimes hangs momentarily upside-down when feeding; occasionally flies out to catch insect in flight. On ground moves restlessly, hopping in long bounds, short tail pointing straight down, seizing prey from soil surface or jumping up to take insect from tip of grass stem. Singly and in pairs, in winter also in flocks of up to twelve individuals; joins mixed-species foraging flocks; in Angola (N Huíla), group forages on ground often with White-headed Black-chats (*Pentholaea arnotti*), Sharp-tailed Starlings (*Lamprotornis acuticaudus*) and White-winged Babbling Starlings (*Neociehla gutturalis*).

Breeding. Birds in breeding condition in Nov–Dec and eggs in Feb in Angola; Sept–Apr (mainly Feb–Mar) in Namibia. Male advertises and defends territory of c. 5 ha with loud, ringing crescendo whistles delivered from exposed bushtop or treetop, female sings antiphonally, both calling with raised bill and upstretched neck; competing males counter-sing at territory border, females often joining in; threaten intruder by adopting horizontal posture and glaring at it. In courtship display-flight male rises steeply with rapid wingbeats, then descends in bouncing glide, rump feathers fluffed out, repeatedly whistling; pursues female in low flight, climbing up through a bush, counter-singing, or hopping along ground, the two sometimes hopping in tandem. Nest built by both sexes, mainly female, taking c. 6 days, a neat deep cup, rounded and smooth, external diameter c. 75 mm, made from fine dry grasses and bark strips bound and plastered with spider web, scantily lined with fine grass stems; placed 0·4–8 m (generally c. 3 m) above ground on horizontal branch or in fork in canopy of acacia or other small tree, often quite exposed if tree leafless. Clutch 1–3 eggs; incubation by female, well concealed and very confiding, fed on and off nest by male; he arrives on nearby tree and utters trilling call, she immediately leaves nest, joins him and sometimes solicits with quivering wings, takes offered food, hops about with him for few minutes, returns to nest tree cautiously and indirectly, and resumes incubation; incubation period 15 days; chicks initially fed by female with food brought by male, after a few days fed by both parents, nestling period 19–21 days; fledglings dependent on adults for at least two weeks after leaving nest, and remain in parental territory for at least 19 weeks.

Movements. Mainly resident. In Namibia, some move into dry riverbeds and greener suburbs in winter; in Angola thought to be partial migrant into miombo woodlands in Apr–Aug, being uncommon there in Oct–Mar.

Status and Conservation. Not globally threatened. Common in Angola from NE Benguela S along coastal plain and escarpment to Namibe town, thence E to N Huíla and S to Cunene; sight record from NW of Funda, in Bengo Province; common in Iona National Park, in Namibe Province. In Namibia, common from R Cunene S through interior to Windhoek, Tsondab and R Sossus; Namibian population estimated at 1,500,000 individuals. Possibly expanding its range to E as a result of continuing desertification.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family PRIONOPIDAE (HELMET-SHRIKES)

- Medium-sized passerines with squat, hunched appearance, broad rounded wings, hook-tipped bill, tarsus scutellated on both sides and front, most species crested; plumage largely black, white, grey and brown, most with colourful eyewattles.
- 16–26 cm.

- Sub-Saharan Africa.
- Forest, woodland and savanna.
- 1 genus, 8 species, 19 taxa.
- 2 species threatened; none extinct since 1600.

Systematics

The family comprising the helmet-shrikes (Prionopidae) is confined to the Afrotropics. All eight of its members are placed in the one genus, *Prionops*. This generic name refers to the ragged, fleshy orbital rings characteristic of most of the species, *prion* meaning "saw" and *ops* signifying "appearance".

For many years, the systematic position of the helmet-shrikes has been notoriously obscure. Until relatively recently, they were viewed as a subfamily of the Laniidae, which was previously considered a large and diverse family that included all of the shrike-like passerines of the Old World. The only unifying features of the original members of this expanded Laniidae, however, were a hooked bill and a reduced muscle in the hind limb (Musculus flexor perforatus digitii III). Past treatments have placed the helmet-shrikes between the "true shrikes" (*Lanius*) and the malaconotid "bush-shrikes", between the Madagascan vangas (Vangidae) and the bush-shrikes, between the bulbuls (Pycnonotidae) and the bush-shrikes, and between the cuckoo-shrikes (Campephagidae) and some of the bush-shrikes. Particularly distinctive attributes of the helmet-shrikes that have featured constantly in systematic treatises are the unusual pattern of tarsal scutellation, a strikingly communal gregariousness at all times, and the nest structure.

More recently, information from DNA–DNA hybridization studies suggested that both the helmet-shrikes and the bush-shrikes are quite distantly related to the true shrikes, and that the helmet-shrikes cluster with the Asian wood-shrikes (*Tephrodornis*) and the vangas, close to the batises (*Batis*), the wattle-eyes (*Platysteira* and *Dyaphorophyia*) and the Asian philentomas (*Philentoma*). These findings are supported by behavioural, morphological and biochemical comparisons.

Traditional approaches have tended also to include the two *Eurocephalus* white-crowned shrikes in the same subfamily as the helmet-shrikes. This treatment was based largely on putative similarities between the two groups in head plumage, tarsal scutellation, juvenile plumage, nest architecture, nesting habits, displays, gregariousness and flight action. It is now appreciated, from morphological, osteological and behavioural studies, and from the findings of DNA–DNA hybridization studies, that *Eurocephalus* lies firmly within the group of true shrikes in a restricted family Laniidae, of which the remaining two genera are *Lanius* and *Corvinella*, the genus *Urolestes* being subsumed in the latter. In past traditional treatments, the Brubru (*Nilaus afer*), currently included in Malaconotidae, and the wood-shrikes, at present in Campephagidae, have also been placed in the same subfamily as the helmet-shrikes, again apparently on the grounds of the tarsal scutellation.

Most recently, detailed molecular-genetic investigations, including analyses of both nuclear and mitochondrial DNA, have largely corroborated and refined the information provided by the earlier studies of behaviour, morphology and DNA–DNA hybridization. They suggest that the helmet-shrikes form a group with the Asian wood-shrikes, the philentomas, the poorly known African flycatcher-shrikes (*Bias* and *Megabyas*) and the vangas. Furthermore, these studies have indicated a hitherto unsuspected direct link with the Asian flycatcher-shrikes (*Hemipus*), traditionally viewed as members of the family Campephagidae, although a taxonomic link of this taxon to the Laniidae had earlier been argued.

Helmet-shrikes have the head relatively large and present a typically hunched appearance when at rest. The ***Chestnut-fronted Helmet-shrike*** *is the smallest member of the family at 16–18 cm and 20–40 g; the others range up to 26 cm and 49 g. It has a small, neat chestnut crest on its forehead. This species is one of five with a brightly coloured bill. Although sometimes found flocking with the similar Retz's Helmet-shrike* (Prionops retzii), *it is rather isolated from most other members of the family, being largely confined to the coastal strip between south Somalia and southern Mozambique.*

[*Prionops scopifrons kirki*, Arabuko-Sokoke Forest Reserve, Kenya. Photo: Steve Garvie]

The five subspecies of the ***White-crested Helmet-shrike*** *differ markedly in size, the length and shape of the crest, and the presence or absence of a white wingbar on the folded wing. With limited evidence of hybridization between subspecies, it is possible that this taxon comprises more than one species. All eight helmet-shrike species are currently placed in the genus* Prionops. *Once considered a subfamily of true shrikes (Laniidae), DNA studies suggest that they are quite distantly related, and much closer to groups such as the Asian wood-shrikes* (Tephrodornis)*, vangas (Vangidae) and wattle-eyes (Platysteiridae).*

[*Prionops plumatus poliocephalus*, Kruger National Park, South Africa. Photo: Warwick Tarboton]

Indeed, the wood-shrikes and Asian flycatcher-shrikes, followed by the philentomas, may be the helmet-shrikes' closest relatives, and these three Asian genera probably stem from one or two colonization events from Africa to Asia, following an ancestral colonization of Africa, through Asia, of original Australian corvoid stock. A potential link between the helmet-shrikes and the vangas had previously been mooted, based on bill structure, jaw musculature, tarsal scutellation and gregarious habits. The finding that the African flycatcher-shrikes, *Bias* and *Megabyas*, are closer to helmet-shrikes than to batises and wattle-eyes is, however, surprising. In these studies, the group containing the helmet-shrikes was one of three forming a distinct clade. The second group comprised the White-tailed Shrike (*Lanioturdus torquatus*), the batises and the wattle-eyes, and the third contained the bush-shrike genera *Malaconotus*, *Chlorophoneus*, *Laniarius*, *Rhodophoneus*, *Telophorus* and *Bocagia*, the puff-backs (*Dryoscopus*), the tchagras (*Tchagra*) and the Brubru. The genus *Bocagia*, incidentally, is often subsumed in *Tchagra*, and *Rhodophoneus* has recently been merged with *Telophorus*. All the members of these last two groups are confined to the Afrotropics.

Understanding of species limits and relationships within the helmet-shrikes has proved almost as challenging as the higher-order placement of these passerines. The Red-billed (*Prionops caniceps*), Rufous-bellied (*Prionops rufiventris*), Retz's (*Prionops retzii*), Gabela (*Prionops gabela*) and Chestnut-fronted Helmet-shrikes (*Prionops scopifrons*) have previously been united in the genus *Sigmodus*. The argument for this treatment was primarily that these species differ from the remaining three prionopids in having a brightly coloured bill and a reduced crest, with an additional possible difference, specifically between the Rufous-bellied Helmet-shrike and the White-crested Helmet-shrike (*Prionops plumatus*), in jaw musculature and nestling plumage; further, a possible difference in begging calls between the White-crested Helmet-shrike on the one hand and, on the other, Retz's and Chestnut-fronted Helmet-shrikes has recently been proposed. It is widely conceded that the White-crested and Grey-crested Helmet-shrikes (*Prionops poliolophus*), the Red-billed and Rufous-bellied Helmet-shrikes, and Retz's and Gabela Helmet-shrikes form three respective superspecies, but the grouping of the somewhat aberrant and poorly known Yellow-crested Helmet-shrike (*Prionops alberti*) close to the first of these superspecies is more controversial.

At the species level, it is possible that the most widespread member of the family, the White-crested Helmet-shrike, may comprise more than a single species. This taxon exhibits fairly extensive geographical variation across several quite distinctive subspecies. Differences in both the length and the shape of the crest feathering, the presence or absence of a white bar in the folded wing, differences in vocalizations and size, and apparently limited evidence of hybridization between some of the subspecies, prompt further investigations in this regard. The recognition of the Red-billed and Rufous-bellied Helmet-shrikes as two separate species, as in the present arrangement, is by no means uncontested. For example, the largely clinal nature of plumage variation across the four relevant subspecies, coupled with similarities in vocalizations, suggests that this division requires further confirmation. Both species have common double whistles and a "kyop-kyop" vocalization, but the "watch-winding" call of the Red-billed Helmet-shrike has not been recorded for the Rufous-bellied Helmet-shrike, and a "chaja" call of the latter taxon is not known to be produced by the former. Verification of the specific status of the poorly known Gabela Helmet-shrike as a full species has also been called for, some authorities suggesting that this form should be treated as a subspecies of Retz's Helmet-shrike.

Morphological Aspects

Helmet-shrikes are medium-sized passerines, 16–26 cm in total length, with fairly uniform proportions. They are shrike-like in general appearance, having a relatively large head and a rather squat and hunched appearance when at rest. The sexes are alike, and there are no seasonal differences in plumage.

The feathers on the forehead of prionopids are stiffened, and some project forwards over the oval-shaped nostrils. Similar feathers extend to the crown, and on some species, especially the dark-beaked ones, they form a distinctive crest up to 45 mm in length. The English vernacular name for the family stems from these unusual head adornments. The feather pigments on the head are unstable, and on study skins are easily washed out with soap. Plumage colours tend to be a combination of black, white, grey and sometimes brown. The black upperparts of the White-crested, Grey-crested, Yellow-crested, Red-billed and Rufous-bellied Helmet-shrikes are glossed greenish. Interestingly, the closely related wattle-eyes (see Systematics) also have greenish-tinged upperparts and, of course, similar eye adornments. In the folded wing, the White-crested and Grey-crested Helmet-shrikes have a white wingbar formed by white in the secondaries and upperwing-coverts, but, intriguingly from a systematic point of view, this is

absent in the eastern races *cristatus* and *vinaceigularis* of the former. The Yellow-crested Helmet-shrike is unique in the family in having yellow in the plumage.

Helmet-shrikes have broad and rounded wings, each of which has ten primaries. Counting from the innermost outwards, primaries P8–P5 are the longest and P10 is half the length of P8. The flight action is distinctively buoyant and dipping, with much gliding, and is decidedly fluttering and butterfly-like. Groups move through the woodland in a leap-frog fashion, those individuals at the rear continually flying forwards and supplanting those at the front. Characteristically, there is a striking white bar through the primary feathers that is highly noticeable in flight, although this feature is reduced or absent on Yellow-crested and Gabela Helmet-shrikes, on the subspecies *graculinus* of Retz's Helmet-shrike, and on the two races *kirki* and *keniensis* of the Chestnut-fronted Helmet-shrike. The tail consists of twelve rectrices, and five of the eight species, the exceptions being the Yellow-crested, Red-billed and Rufous-bellied Helmet-shrikes, show much white in the tail, especially towards the outer feathers. Thus, there is some tendency for the species most associated with forested environments to have a reduced amount of white in the wings and tail. The undertail-coverts of helmet-shrikes are unusually plush.

A distinctive feature of the Prionopidae is the bill, which is stout, and hooked at the tip, with a notch at the base of the hook on the lower surface of the upper mandible. Five species have a bright reddish bill, that of the remaining three, the White-crested, Grey-crested and Yellow-crested Helmet-shrikes, being blackish. The base of the bill is fringed with the long, widely radiating rictal bristles that are associated with the habit of feeding on aerial insects. Most members of the family possess bright pectinate, or scalloped, orbital rings, which are yellow, orange, red or greyish-blue in colour, and the iris is typically bright yellow. There is some evidence, provided by the White-crested and Retz's Helmet-shrikes, to suggest that the dominant breeding pair in a group sports the best-developed orbital rings, as well as boasting the heaviest body weights. Interestingly, orbital rings are reduced or absent on three species, namely the Grey-crested, Red-billed and Rufous-bellied Helmet-shrikes. Finally, the helmet-shrikes are unusual in having tarsi that are scutellated on both the sides and the front. The legs and feet are short but strong, designed for arboreal life, and normally bright reddish in colour, and the claws are sharp.

Juveniles typically appear bewilderingly unlike the adults, as they initially lack the features characteristic of helmet-shrikes, in particular the crest, the orbital rings, well-defined head markings and brightly coloured eyes, legs and feet. Moreover, they have duller and browner plumage, frequently with barring and mottling, which is absent on the adults. Although the details are poorly known, juveniles probably moult directly into adult dress, a process complete only by the time when they are about one year of age. It has been suggested, however, that Retz's Helmet-shrike has an intervening immature plumage, thus apparently extending the period before the acquisition of full adult plumage to two years, but this requires confirmation.

Habitat

The helmet-shrikes inhabit environments with a good cover of trees, as provided by woodland, savanna and forest.

White-crested, Grey-crested and Retz's Helmet-shrikes are characteristic of deciduous woodland and savanna. Examples of the normal woodland types inhabited by the White-crested and Retz's Helmet-shrikes include "teak" (*Baikiaea*), miombo (*Brachystegia*), mopane (*Colophospermum*), bushwillow (*Combretum*), bloodwood (*Pterocarpus*), cluster-leaf (*Terminalia*) and *Burkea* woodlands. Of the two, the White-crested Helmet-shrike is the more tolerant of the least well-developed savanna in the driest regions, and hence, in the Afrotropical context, is the most widespread of the Prionopidae. This species and Retz's Helmet-shrike, the latter the next most widespread member of the family, also display an obvious preference for broadleaf woodland over acacia (*Acacia*) woodland. Outside the breeding season, however, both of these helmet-shrikes, especially the White-crested, will wander widely into other habitats, such as coastal and riparian forest and forest edge, thickets, scrub, lightly wooded grassland, mangroves, and plantations of oil palm (*Elaeis guineensis*), eucalypt (*Eucalyptus*) and pine (*Pinus*), and will even enter gardens and urban areas.

The poorly known Grey-crested Helmet-shrike, restricted to a small area of Tanzania and adjacent Kenya, inhabits whistling-thorn (*Acacia drepanolobium*) and camphor-bush (*Tarchonanthus*) savanna, and riverine woodland. It prefers better-developed, higher-rainfall woodland than that occupied by the White-crested Helmet-shrike, which it replaces locally at higher altitudes.

The generic name Prionops *means "saw-appearance", and refers to the ragged, fleshy wattles around the eyes. There is evidence from* **Retz's Helmet-shrike** *that the dominant breeding pair in a group have the most developed eye wattles. The colour of the wattles varies between species: in Retz's, it is orange-red, matching its bill; in the White-crested Helmet-shrike* (Prionops plumatus) *it is yellow; and in the Chestnut-fronted Helmet-shrike* (Prionops scopifrons) *it is grey-blue. Iris colour in all these species is yellow. Helmet-shrikes also have a strong, stout bill with a hooked tip, and a corresponding notch in the lower mandible.*

[*Prionops retzii retzii*, Save Valley Conservancy, Zimbabwe.
Photo: Peter J. Ginn]

Helmet-shrikes have broad, rounded wings. Their flight action is buoyant and dipping, with much gliding. Most species have a striking white bar through the primaries that is very noticeable in flight. Some, like the ***White-crested Helmet-shrike****, also have white outermost tail feathers. In this species, the tips of the black inner tail feathers are also white, except on the central pair, which are completely black.*

[*Prionops plumatus plumatus*, Western Division, Gambia. Photo: Dick Forsman]

Yellow-crested, Red-billed, Rufous-bellied, Gabela and Chestnut-fronted Helmet-shrikes are essentially denizens of forest, although the last two of these species will also wander into woodland areas. The poorly known Yellow-crested Helmet-shrike, a western Albertine Rift endemic restricted to far eastern DRCongo, inhabits montane forest, *Hagenia* and bamboo forest and, at lower altitudes, primary rainforest. Its altitudinal range is mainly 1400–2500 m, but the type specimen was apparently first discovered in atypical habitat at about 4400 m in the alpine zone. In contrast, the Red-billed and Rufous-bellied Helmet-shrikes are inhabitants of lowland forest in, respectively, West and Central Africa. Neither is entirely confined to primary forest, and both are regularly recorded in mature secondary forest, dense riverine vegetation, forest edge, logged forest and farmland, and old coffee plantations. The former species occurs at up to 700 m in Guinea, and the latter is recorded at up to 1450 m in DRCongo. The habitat requirements of the poorly known Gabela Helmet-shrike are not well understood. This species is restricted to a small region associated with the western Angolan escarpment, where it has been found in fairly dry forest, gallery forest and secondary forest, as well as in thickets and clearings, including coffee plantations in forest. It is apparently absent from nearby miombo woodland inhabited by the closely related Retz's Helmet-shrike.

The Chestnut-fronted Helmet-shrike is largely confined to the coastal strip along the eastern seaboard of Africa between south Somalia and southern Mozambique. It can occur as high up as 1200 m, but it lives mainly in lowland and riverine forest and adjacent miombo woodland, occasionally wandering to thickets and mangroves. It prefers better-developed woodland than that inhabited by Retz's Helmet-shrike. It is usually found close to the coast, but extends far inland in places: it is found, for example, in the Meru and Ngaia forests, in central Kenya; it occurs in the eastern Usambara, Uluguru and Udzungwa (Magombera and Mwanihana) Mountains and the Pugu Hills, in eastern Tanzania, from where there is a single record also from the north Pare Mountains; and it is recorded at the confluence of the Haroni and Rusitu Rivers, in eastern Zimbabwe.

General Habits

The helmet-shrikes are a poorly known family of birds. This is reflected in the paucity of primary literature reporting the results of field studies of these species. An ignorance of the general biology of the Yellow-crested and Gabela Helmet-shrikes is understandable when one bears in mind these species' limited ranges in highly inaccessible regions. Similarly, the Grey-crested Helmet-shrike has a remarkably truncated distribution. It is present, if not common, in some East African localities well frequented by ornithologists, but it is, however, easily mistaken for the White-crested Helmet-shrike. The heavily forested habitats and, for the most part, not easily accessible ranges of the Red-billed and Rufous-bellied Helmet-shrikes likely retard the study of these two attractive species. The Chestnut-fronted Helmet-shrike is only slightly better known.

Not surprisingly, the two best-known members of the family, the White-crested and Retz's Helmet-shrikes, are also the most widespread, and they inhabit the most open environments, which further facilitates study of their behaviour. These two helmet-shrikes also extend widely into southern Africa, a region of the continent in which ornithological research has been particularly good. Most of what is currently known about helmet-shrike biology comes from studies of these two species, especially the White-crested Helmet-shrike.

One of the most characteristic features of helmet-shrikes is their intensely social habits. All of the species live permanently in tightly knit groups of up to about 30 individuals, although some of the records of the largest group sizes may represent temporary aggregations of more than one group. For all members of the family, typical groups rarely contain more than about twelve individuals, and generally consist of about half that number. Groups tend to be larger immediately after the breeding period, when they are bolstered by the most recent crop of fledged juveniles. Records of solitary individuals or pairs are unusual. Group activities are regulated by a strict dominance hierarchy, headed by the alpha female.

All aspects of helmet-shrike life throughout the year, including breeding, territoriality, feeding, roosting and defence against predators, are communal in nature. During foraging forays, some individuals apparently act as sentries while others feed. Helmet-shrikes roost closely bunched together on branches in a leafy tree, such as an acacia, an apple-leaf (*Philenoptera*) or a tulip-tree (*Thespia*), among others.

Prionopids scratch indirectly, bringing the leg up over the wing, during maintenance behaviour, and they are known to bathe in pools of water trapped in vegetation. Otherwise, the general habits of this family are more or less unknown.

Voice

The vocalizations of the helmet-shrikes are one of the most remarkable features of the family. These are very noisy birds, with an astonishing array of calls, many of which are decidedly unavian in tenor. This garrulousness is doubtless directly related to the intensely social nature of the helmet-shrikes. A list of adjectives used by observers to describe helmet-shrike vocalizations gives some idea of the variety and tones represented, for the sounds have variously been said to be: bubbling, buzzing, chanting, chattering, chip-

ping, chomping, chuckling, churring, clicking, gobbling, grating, growling, guttural, harsh, hoarse, humming, leathery, nasal, piping, rattling, rolling, scolding, scratchy, screaming, shrill, slurred, squealing, tinkling, trilling, twittering, whirring, whistling and winding. In numerous cases, the same adjectives have been applied to the vocalizations of several different *Prionops* species.

Although the vocal behaviour of the White-crested Helmet-shrike has received the most study, followed by that of Retz's Helmet-shrike, the details are still poorly known. At least 20 different calls have been documented for the former and at least 16 for the latter. Vocalizations appear to be important in regulating social interactions within a group, and some calls may reflect individual social and gender status. Helmet-shrike calls have been likened to those of some barbets (Capitonidae), honeyguides (Indicatoridae), cuckoos (Cuculidae), nightjars (Caprimulgidae), crows (Corvidae) and Old World orioles (Oriolidae). Despite the highly vocal nature of these passerines, however, mimicry by helmet-shrikes has not been recorded.

Perhaps the nasal and flute-like whistling qualities, often disyllabic, of many helmet-shrike calls are the most characteristic. Vocalizations are typically given in duet or group chorus. Duetting apparently plays a role in maintaining the pair-bond between the dominant breeding male and female. Chorusing usually starts out fast, high-pitched and complex, winding down to slower, lower-pitched and simpler calls. The dominant group-members, especially the alpha female, apparently initiate most bouts of chorusing. Territory defence, greeting and contact seem obvious functions of chorusing. Other contact calls include soft nasal and simple high-pitched notes, given in flight. Lost individuals, separated from the rest of the group, may emit a louder, prolonged call. Chattering and chucking calls are uttered when an individual or group locates particularly desired food items and nesting material, although they may be uttered also in the face of predators. Similarly in alarm, helmet-shrikes produce other low, growling and churring sounds, which can escalate into sharp, shrill screams and squeals. Soft growling notes, and chuckling sounds, are associated also with roosting, when the birds huddle together on branches. Begging calls by young helmet-shrikes consist of low chattering and buzzing vocalizations, which serve also during courtship, when the breeding male may direct soft chick-like calls at the breeding female.

Another highly distinctive and characteristic sound made by helmet-shrikes is that produced by beak-snapping, which can be loud and prolonged. Beak-snapping is often interspersed with vocalizations, and is associated especially with alarm and aggression, but it may, at low intensity, have the function also of contact. The wings of the closely related Red-billed and Rufous-bellied Helmet-shrikes produce soft but clearly audible mechanical "wing-fripping" sounds in flight, and this, too, likely serves a contact function.

Food and Feeding

The diet of all helmet-shrikes consists predominantly of adult and larval invertebrates, especially insects. Vertebrate prey, such as geckos (Gekkonidae) and other small lizards, is taken occasionally. Fruits and seeds, such as those of *Musanga*, croton (*Croton*) and ochna (*Ochna*) trees, have been recorded in the diet of the White-crested, Red-billed, Rufous-bellied and Chestnut-fronted Helmet-shrikes, and they may be consumed more commonly by the species that inhabit forest compared with those in savanna. There are very few records of drinking by prionopids.

Documented invertebrate prey of the Prionopidae include ants (Formicidae), ant-lions (Myrmeleontidae), beetles (Coleoptera), butterflies, moths and caterpillers (Lepidoptera), cicadas (Cicadidae), flies (Diptera), grasshoppers and their relatives (Orthoptera), mantids (Mantodea), stick-insects (Phasmatodea) and termites (Isoptera), as well as spiders (Araneae) and centipedes (Chilopoda). In one quantified study of the diet of the savanna-dwelling White-crested Helmet-shrike, it was found that caterpillars represented 46% of items, butterflies and moths 19%, grasshoppers 7%, termites also 7%, mantids 5% and small reptiles 1%. Of the material identified in five stomachs, beetles accounted for 42%, ants for 32% and grasshoppers for 12%. The food of the Red-billed Helmet-shrike, a denizen of lowland forest, comprised 50% adult arthropods, 20% larvae and 30% fruit.

Foraging, as with all aspects of helmet-shrike life, is a group activity. The birds obtain most of their animal food by gleaning from vegetation or hawking in flight in the manner of a muscicapid flycatcher. They sometimes employ the technique of hovering, this being practised at least by the smallest species, the Chestnut-

The feathers on the forehead of all helmet-shrikes are stiffened, and in some species project forward over the nostrils, forming a forecrown crest. Similar feathers extend back on the crown, and in some species, especially dark-billed ones like the ***White-crested Helmet-shrike****, they can form a distinctive mid-crown crest. In this species, the mid-crown crest can measure up to 45 mm long in the nominate race; race* concinnatus *has a shorter mid-crown crest, about 25 mm long; and in race* poliocephalus *it is shorter still, and indistinguishable from the forecrown crest.*

One of the features that distinguishes helmet-shrikes from other shrike-like families is their extreme gregariousness. Records of solitary individuals or pairs are unusual. All species live in tightly knit groups which forage, roost, and breed together, within a strict dominance hierarchy, headed by the alpha female. ***Chestnut-fronted Helmet-shrikes*** *live in groups of up to twelve birds during breeding. They may share their home territories with other groups, and when not breeding, they can be found in flocks of up to 30. They also join mixed flocks including other helmet-shrikes.*

[*Prionops scopifrons kirki*, Arabuko-Sokoke Forest Reserve, Kenya. Photo: Steve Garvie]

fronted Helmet-shrike. The forest-dwelling species are the most arboreal in their habits; they tend to forage higher in the trees than their savanna counterparts; and they apparently hawk prey in flight more frequently. The technique of pouncing on prey on the ground seems to be common only for the White-crested Helmet-shrike, which inhabits the most open country and typically forages lower in trees than the other members of the family. It hunts primarily in trees during the summer months, but it obtains more of its food on the ground in the winter. Further, it is attracted to recently burnt ground. One study revealed that this helmet-shrike procured 51 % of its food in trees, 47% from the ground and 2% by aerial hawking. In another study, it took 32% of its prey in trees, 19% on the ground and 49% in flight. In contrast, Retz's Helmet-shrike caught 98% of its prey in trees, 1% on the ground and 1% by hawking in the air. The sighting of a helmet-shrike on the ground is likely to be a very rare to non-existent event for all prionopids with the sole exception of the White-crested Helmet-shrike.

When in the process of foraging, helmet-shrikes frequently tilt the head to one side, suggesting that they sometimes use auditory cues in the locating of prey. They will also hang upside-down in trees the manner of tits (Paridae) while searching for prey.

Helmet-shrikes are regularly associated with avian mixed-species foraging parties, particularly during the non-breeding season. Indeed, it is probable that, in many cases, they act as catalysts in the formation of such parties. Typical co-members of these foraging unions are other insectivores, including woodpeckers (Picidae), woodhoopoes (Phoeniculidae), cuckoo-shrikes, Old World orioles, drongos (Dicruridae), Brubrus, tits and malimbes (*Malimbus*). Sympatric helmet-shrike species often join together to form mixed feeding flocks, either within or separate from multi-species bird parties. The White-crested Helmet-shrike frequently flocks with Retz's Helmet-shrike, and less frequently with Grey-crested, Red-billed and Chestnut-fronted Helmet-shrikes. Similarly, Retz's and Chestnut-fronted Helmet-shrikes commonly associate with one another.

Helmet-shrikes are noisy, garrulous birds, with a wide and varied range of calls. ***Retz's Helmet-shrike*** *has at least 16 different vocalizations, some of which may reflect individual status and gender. Its whistled song is a repeated "tweeoo". Its calls include notes described as chattering, chomping, grating, guttural, rolling, slurred, whistling and, especially, nasal. Calls are often given in group chorus, initiated by the dominant female. Helmet-shrike contact calls include soft, nasal notes, but individuals may give louder, more prolonged notes when they become separated. Loud bill-snapping may be interspersed with vocalizations, and is especially associated with alarm and aggression.*

[*Prionops retzii tricolor*, Liwonde National Park, Malawi. Photo: Johannes Ferdinand]

Breeding

The nesting habits of the majority of helmet-shrikes are extremely poorly documented. The greatest amount of relevant information is available for the widespread White-crested Helmet-shrike, followed by Retz's Helmet-shrike and, to a lesser extent, the Chestnut-fronted Helmet-shrike. The breeding details of the remaining five species are almost or wholly unknown. The evidence that is available does, however, suggest that all members of this family are remarkably similar to one another in their reproductive habits. The White-crested Helmet-shrike serves as the primary model for the discussion that follows

Egg-laying, as with most insectivorous passerines, seems to be timed so that it reaches a peak at the beginning of the rains, although there is frequently no clear single breeding peak discernible close to the equator, where annual bimodal rainfall patterns are typical. In the case of Retz's Helmet-shrike, and probably also its two other savanna relatives the White-crested and Grey-crested Helmet-shrikes, laying is believed to be stimulated by the coming into leaf of the deciduous woodland in which these species breed. Among White-crested and Retz's Helmet-shrikes, at least, multiple brooding is common, both species exhibiting an average of about two nesting cycles per season. Double-brooding is known also for the Red-billed Helmet-shrike. Sometimes, however, these instances could be associated with the breeding by two different females within a group.

Helmet-shrikes are co-operative breeders, and all group-members assist in the tasks of nest construction, incubation of the eggs, brooding and provisioning of the chicks, removal of faecal sacs, and the defence of the eggs and young. The breeding pair, however, apparently shoulders most of the burden. A dominance hierarchy exists within the group, with the breeding female pre-eminent, followed by, in decreasing importance of rank, the breeding male, other adult females, other adult males, adult offspring, immatures and juveniles. The adults other than the breeding pair and their adult offspring are typically siblings of, respectively, the breeding female and the breeding male. The pair-bond between the two breeding adults can last for several years, and is maintained by such activities as perching together, allopreening and duetting. New groups are created when up to four sisters from one group link up with up to four brothers of another group. This means that breeding opportunities usually are not directly inherited in the natal group. On its demise, a dominant breeding bird is replaced by its next-ranking sibling of the same sex. Breeding groups can remain stable for up to ten years. The largest number of helpers, of both sexes, is associated with drier and lower-elevation sites, and with lower latitudes, whereas the absence of helpers and the presence of helpers of only one sex are most prevalent at wetter, higher-elevation sites, and also at higher latitudes.

*The technique of pouncing on prey on the ground seems to be common only in the **White-crested Helmet-shrike**, which inhabits the most open country, and typically forages lower in trees than other members of the family. It is particularly attracted to recently burnt ground for foraging. In winter, it forages primarily in trees, gleaning from the foliage, sometimes hanging upside-down like a tit (Paridae), or hawking flying insects like a flycatcher (Muscicapidae). Forest-dwelling helmet-shrikes are more arboreal in their habits, tending to forage higher in the trees, and apparently hawking prey more frequently. The diet of all helmet-shrikes is mostly adult and larval invertebrates.*

[*Prionops plumatus poliocephalus*, KwaZulu-Natal, South Africa. Photo: Hugh Chittenden]

Courtship by the male is marked by wing-opening and slow wing-flapping, and the male also approaches the female, sometimes with his wings drooped, while carrying nesting material in his bill. The ritual is characteristically simple, slow, silent and deliberate, and is conducted away from the other group-members. The absence of intricate mating displays probably relates to the pre-existing and complex group sociality of helmet-shrikes. Courtship feeding has been reported only for the Chestnut-fronted Helmet-shrike, and even for this species it probably requires confirmation. Interestingly, however, incubating adults of this helmet-shrike have apparently been recorded being fed by other group-members, such behaviour having seemingly not been reported for any other helmet-shrikes.

Nests of helmet-shrikes are exclusively solitary. Two nests of the same species are never built in adjacent trees, and are typically spaced at least 50 m apart, and usually much farther, in the case of the White-crested Helmet-shrike. Some prionopids, however, will nest fairly close to congeners, as illustrated by the finding of simultaneously active nests of White-crested and Retz's Helmet-shrikes less than 80 m apart. A group does not defend its home range and may share it with adjacent groups, the size of the home range tending to increase during the post-breeding period. Helmet-shrikes are territorial only during the breeding season, and all group-members participate in territory defence. In Zimbabwe, 140 home ranges of the White-crested Helmet-shrike varied in size from 4·5 ha to 30 ha, with an average of 18 ha, and 63 territories were 1–12 ha in extent, with an average of 5 ha. In South Africa, one non-breeding home range that was measured by using observations of a group containing a distinctive leucistic member, covered an area of 3·5 km². Markedly larger territory sizes, of about 30 ha and at least 20 ha, have been reported for Retz's and Rufous-bellied Helmet-shrikes, respectively. Territory size of White-crested Helmet-shrikes was found to be associated with rainfall and the density of adjacent groups, among other variables.

The two breeding partners choose the nest-site and undertake most of the work in constructing the nest, but are assisted to a varying degree by other members of the group. The nest tree is sometimes a dominant one within the landscape. Typically, broadleaf trees, such as bloodwood, bridelia (*Bridelia*) matumi (*Breonadia*), miombo, newtonia (*Newtonia*) and *Sarcoglottis* trees, are favoured. The nest is built 2–40 m above the ground, those of the forest-dwelling members of the family probably being located at the highest level. The building work takes at least four days, and the eggs are laid at any time from one day to three weeks later. The nest itself is a remarkably neat and compact cup of bark strips, leaf petioles, grass, tendrils, moss and lichen, extravagantly bound with spider web, which apparently is transported in the bill and on the erectile feathers of the frontal crest, and lined with bark, rootlets, grass and lichen. Camouflaged to resemble swellings on tree branches, helmet-shrike nests have been described as being "wonders of avian architecture". Their dimensions are up to 13 cm in external diameter, with a depth of 3·5–6·5 cm, and 6–8 cm internal diameter, with an interior depth of 1·5–3 cm. They are usually located on a horizontal tree branch or in an upright fork, and often in trees with greyish or lichen-covered bark. The same tree, and even the very same site, may be used in successive years. The White-crested Helmet-shrike will occasionally nest in non-native trees, for example in eucalypt plantations.

The ground colour of helmet-shrike eggs varies from white, pinkish or cream to blue-grey, blue and greenish-blue. The eggs are typically blotched and spotted with shades of purple, grey, blue and brown, the last overlying the first three, and are sometimes scrolled with black; the markings are usually concentrated in a ring at the obtuse end. Their dimensions are in the range 18·5–25·8 × 14·5–18·2 mm. The usual clutch consists of 2–5 eggs, with an average of 3–4, laid at daily intervals, and incubation probably commences only when the clutch is complete. Occasionally, two females within a group will lay in the same nest, resulting in about double the typical clutch size, but some eggs usually fall out of such nests. Repeat clutches are sometimes laid after failure of an earlier breeding attempt. For the White-crested Helmet-shrike, the period between nesting failure and the initiation of a new breeding attempt ranged from six days to 42 days, with an average of eleven days.

Incubation is undertaken by all group-members in the case of the White-crested and Retz's Helmet-shrikes, and members of the breeding pair contribute only about 35% of the work during the daytime. There is some evidence, however, that not all members of Chestnut-fronted Helmet-shrike groups incubate. Change-overs at the nest take place without ceremony. The incubation period spans about 16–21 days, with a mean of 17 days. The adults sit very tight when incubating, even when approached

closely by potential predators. Helmet-shrikes nevertheless are sensitive to disturbance at the nest and are prone to desert during nest-building and the early stages of incubation.

Nestlings of helmet-shrikes are altricial, being naked and blind on hatching. The chicks of Retz's Helmet-shrike, which is parasitized by cuckoos, and those of the Chestnut-fronted Helmet-shrike possess mouth spots. Interestingly, White-crested Helmet-shrike chicks lack such spots, despite some statements to the contrary in the literature. All group-members feed the nestlings, which leave the nest after a period of 17–22 days, the average being 20 days. Fledged young are fed by all members of the group until they are about 10–12 weeks old, by which time they are able to locate food for themselves. The juveniles achieve full independence when about five to seven months of age. They may then disperse and form single-sex flocks, or they may remain in their natal group as helpers.

Nest contents, and group-members themselves, are vulnerable to reptilian, mammalian and avian predators, such as snakes, monkeys, predatory cats, hawks and eagles (Accipitridae), and owls (Strigidae). All of the group will boldly direct aggression at such potential dangers. In addition, some chicks starve to death during seasons when food availability is poor or if other situations, such as weather conditions, are adverse.

Details of breeding success are available for only very few prionopids. For the White-crested Helmet-shrike, 25% of eggs laid produce fledglings, with a range of annual variation of 15–40%, and 30% of nests produce fledglings, the range of annual variation being 20–45%. An average of 0·9 fledglings is achieved per nesting attempt and a mean of 2·9 fledglings per successful nest, the respective ranges of variation being 0·6–1·3 and 2·3–3·2. This species produces 1·7 fledglings per group per year, with an annual variation of 1·4–1·9. Predation, especially during the hatching period, is the main cause of breeding failure of this species. Post-fledging survival, however, is relatively good, and 48–72% of young White-crested Helmet-shrikes survive their first year. Nesting success of Retz's Helmet-shrike is much lower, apparently as a result of cuckoo parasitism. Only 14% of this species' eggs produce fledglings, and just 18% of nests do so, the latter figure reduced from 30% by brood parasitism; productivity is 0·3 fledglings per nesting attempt, 2·0 fledglings per successful nest, and 0·6 fledglings per group per year. As with the White-crested Helmet-shrike, however, post-fledging survival is good, and an average of 79% of fledglings survive their first year, the figure varying annually from 49% to as high as 95%. Helmet-shrike breeding pairs without helpers are typically unsuccessful, but otherwise no clear positive relationship has been established between group size and breeding success.

As already noted, Retz's Helmet-Shrike suffers brood parasitism by cuckoos. The Thick-billed Cuckoo (*Pachycoccyx audeberti*) commonly lays its eggs in the nests of this species, removing both eggs and nestlings of its host. In one study in Zimbabwe, 55% of the helmet-shrike's nests were parasitized. The hosts feed the fledged cuckoo chick when it calls, the cuckoo mimics the begging calls of the host's nestling, but the helmet-shrikes mob the cuckoo when it flies. The breeding success of Retz's Helmet-shrike is poor and no more than half that of other insectivorous birds, and it is much lower than the success achieved by White-crested Helmet-shrikes in the same woodland. This is likely to be related to high levels of cuckoo parasitism. Both the Red-billed and the Rufous-bellied Helmet-shrikes, too, probably act as hosts of the Thick-billed Cuckoo, which occurs widely in West and Central Africa in regions where these two species, but not Retz's Helmet-shrike, occur. It is conceivable that the Gabela Helmet-shrike likewise hosts this cuckoo. Only three, almost certainly accidental, records of brood parasitism are known for the White-crested Helmet-shrike, one by each of the Thick-billed Cuckoo, the Red-chested Cuckoo (*Cuculus solitarius*) and the Black Cuckoo (*Cuculus clamosus*). A high rate of nest attendance by the White-crested Helmet-shrike may reduce opportunities for such parasitism. There are no documented records of brood parasitism being suffered by any of the other helmet-shrike species.

The start of reproductive activity by White-crested Helmet-shrikes is delayed. Although individuals can breed at two years of age, fewer than 50% breed before they are five years old. Similarly, Retz's Helmet-shrike probably can breed at two years, but it is likely that it usually begins later than this. The annual adult survival of both of these species is high, at 83–85%, with a yearly variation of 69–94%.

Movements

Overall, helmet-shrikes are mainly resident. They are not, however, sedentary, and most of the eight species show a marked

Termites feature on the recorded diet of the ***White-crested Helmet-shrike****, among others. All helmet-shrikes forage in groups, which progress in a "leap-frogging" movement through the woodland, the birds at the rear of the group regularly flying to the front. Some individuals act as sentries while the others feed. Parties of White-crested Helmet-shrikes may follow the same foraging path day after day. Outside the breeding season, this species often forms the core of mixed-species flocks that may include other helmet-shrikes, Old World orioles (Oriolidae), drongos (Dicruridae), tits (Paridae) and Brubrus* (Nilaus afer).

[*Prionops plumatus poliocephalus*, Kruger National Park, South Africa. Photo: Jurgen & Christine Sohns/FLPA]

tendency to wander widely away from their nesting territories during the non-breeding period. This post-breeding dispersal is especially apparent in the three most open-country species, namely the White-crested, Grey-crested and Retz's Helmet-shrikes. The general paucity of nutrients and low primary productivity associated with the broadleaf breeding habitats of the White-crested and Retz's Helmet-shrikes are likely to encourage such mobility. It seems that the nature of some of these movements approaches that of true migration, but this is poorly documented.

The White-crested Helmet-shrike apparently makes a regular north–south movement in Ghana and, on the opposite side of its range, another regular movement between Kenyan dry-season non-breeding grounds and Tanzanian nesting areas. Other movements made by this species are apparently altitudinal in nature, the birds regularly descending to lower-lying regions on the completion of breeding. Foraging ranges may be established on the non-breeding grounds, often in areas, such as urban environments, that are wholly unlike the nesting areas. In the case of the Grey-crested Helmet-shrike, regular movement between the Mara–Narok nesting grounds and the Nakuru, Longonot, Naivasha and Menengai Crater areas in the Rift Valley has been suggested, although this poorly known species is considered otherwise largely resident, but with nomadic tendencies. A seasonal east–west movement across its range, with a shift towards the moister east during the drier austral winter, has been claimed for Retz's Helmet-shrike. This, however, requires confirmation, and the species is thought to be mainly resident but with some post-breeding dispersal, especially during drought periods.

The forest-dwelling members of the family seem to be more sedentary, but even for most of these species there is evidence of some local movements. In southern Africa, the Chestnut-fronted Helmet-shrike may wander into adjacent miombo woodland from its forested breeding haunts. The montane and poorly known Yellow-crested Helmet-shrike could be expected to make some altitudinal movements, as evidenced by the unusually high elevation of the locality of the type specimen, at above 4400 m (see Habitat). Similarly, the equally poorly known Gabela Helmet-shrike has been recorded on several occasions below and away from its putative and restricted breeding grounds on the Angolan escarpment. Only the Red-billed and Rufous-bellied Helmet-shrikes, both lowland-forest inhabitants, appear to be entirely sedentary.

Far and away the most remarkable aspect of helmet-shrike movements relates to the large-scale irruptions that affect the White-crested Helmet-shrike, notably in southern Africa. These are associated with major drought periods, when large numbers of the species abandon the woodlands in the north of the region and move south across a broad front into otherwise totally unsuitable habitat, such as the open grasslands of the South African highveld plateau. Such irruptions on to the highveld occurred in 1953, 1970, 1979 and 1992. To the birdwatchers exposed to them, these irruptive events are unforgettable.

Relationship with Man

These engaging and eye-catching birds have found their way into local African folklore in many areas. The Ndebele and Tonga peoples in Zimbabwe believe that, if they encounter a flock of White-crested Helmet-shrikes while out hunting, this signifies good luck and that they will certainly eat meat on that day as a result. A local IsiZulu tribal name for the White-crested Helmet-shrike in south-eastern Africa is *uThimbakazane*, or "the wedding guests", alluding to the noisy, social and apparently festive habits of helmet-shrikes. On perhaps a more sinister note, White-crested Helmet-shrikes have been found in traditional medicine markets in Nigeria.

Overall, however, the members of this family do not feature prominently in human affairs. They are too small to garner significant interest from hunters, and their primarily insectivorous diet means that they pose no threat to crops, orchards or livestock; their effects in this field are likely to positive, if anything. They do not feature in the cagebird trade, although some zoos do hold captive stock. Furthermore, they occur in regions essentially distant from the developed world.

Nevertheless, humans do feature prominently in the fortunes of the helmet-shrikes. This is most worryingly in the form of habitat destruction, which threatens several helmet-shrike species and adversely affects most, if not all, of the members of the family (see Status and Conservation). In a number of regions, the

*More is known about the breeding of the **White-crested Helmet-shrike** than of any other species, but the available evidence suggests that all members of the family are very similar in this respect. Only the dominant pair in a group breeds. The male and female choose the nest-site, which may be used in successive years. They perform most of the construction work, though they are assisted to varying degrees by other members of the group. The nest is a neat, compact cup bound with spiders' web, and camouflaged to look like a swelling on the branch. The 2–5 eggs are laid at daily intervals; occasionally two females may lay in the same nest, resulting in clutches of up to nine eggs. Although non-territorial at other times, helmet-shrikes defend their territory when breeding.*

[*Prionops plumatus poliocephalus*, Modimolle, Limpopo, South Africa. Photo: Warwick Tarboton]

Helmet-shrikes are co-operative breeders, and while the breeding male and female do most of the work, all group-members assist in the tasks of nest construction, incubation, brooding and provisioning of the chicks, removal of faecal sacs, and defence of the eggs and young. The non-breeding females and males tend to be siblings of, respectively, the breeding female and the breeding male, with females dominant over their male counterparts. Breeding pairs without helpers are typically unsuccessful, but the number of helpers seems to have no positive correlation with breeding success. Nesting is timed to coincide with maximum prey availability, often with the onset of the rains, although ***White-crested Helmet-shrikes*** *are believed to be stimulated into laying by the coming into leaf of deciduous trees. Incubation takes 16–21 days, followed by a nestling period of around 20 days. Adults are very tenacious when incubating, sitting tight even when predators approach. However, they are sensitive to disturbance, and are prone to desertion during nest-building and the early stages of incubation. Despite the high level of attendance by group members at the nest, rates of brood parasitism are high in some species. Predation of hatchlings is the main cause of breeding failure in the White-crested Helmet-shrike, and only 25% of its eggs produce fledglings. If an early attempt fails, the birds may lay again, and at least in some regions this species is often double-brooded.*

[*Prionops plumatus poliocephalus*, Eshowe, KwaZulu-Natal, South Africa. Photos: Geoff McIlleron]

*All members of the group assist in feeding the fledglings. In the **White-crested Helmet-shrike** this continues for around ten weeks, after which the young birds start to locate food for themselves. Fledgling survival in this species is much higher than nestling survival, at around 60%. From around five months onwards, the young birds may disperse as single-sex groups. New groups are created when up to four sisters from one group link together with up to four brothers of another group. Other birds may remain as helpers with the natal group. Breeding groups can remain stable for up to ten years, with annual adult survival rates up to 87%. Although they are able to breed from two years old, fewer than half of White-crested Helmet-shrikes do so before they are five years old.*

[*Prionops plumatus plumatus*, Gambia. Photo: Steve Garvie]

White-crested Helmet-shrike appears to benefit to some extent from the drought refuges provided by plantations of alien trees and urban parks and gardens, although probably not enough to offset the damage that its populations suffer from habitat destruction and degradation.

The three species with the most restricted ranges, the Grey-crested, Yellow-crested and Gabela Helmet-shrikes, probably all have a particular value, or at least potential value, as notable ecotourism attractions. Such ecotourism can both benefit impoverished local human communities in the remote regions where these birds occur and also provide additional motivation for the conservation of the natural habitats in which these birds dwell. In this regard, the Yellow-crested and Gabela Helmet-shrikes are both members of large and particularly important communities of locally endemic bird species in the regions that they inhabit, respectively the Albertine Rift mountains and the western Angolan escarpment, further increasing the attractiveness of these areas to ecotourists. The two globally threatened helmet-shrikes (see Status and Conservation) may help by serving as flagship species for the conservation of these unique and scientifically important regions.

Perhaps the greatest value of the helmet-shrikes to humankind generally, however, will come from the scientific insights doubtless to be gleaned from detailed studies of their unusually intense social structure and unique vocalizations, when these long-overdue investigations are tackled in earnest. The Prionopidae, therefore, represent what will certainly be a most fruitful field of research for the serious ornithologist.

Status and Conservation

As a family, the helmet-shrikes face a rather disproportionately high level of threat. Of the eight members of the family, conservation concern has been expressed over the future of no fewer than three species and over that of a fairly distinctive subspecies of a fourth.

The virtually unknown Gabela Helmet-shrike is the most seriously threatened species and is ranked as Endangered. It is a restricted-range species, limited to a part of the Western Angola Endemic Bird Area, and its distribution is estimated at some 4600 km². Its global population is small, numbering about 1000–2500 individuals, is highly fragmented and is decreasing. It is threatened by habitat clearance by subsistence farmers, mainly for charcoal production but also for the growing of bananas, sweet potatoes, coffee, cassava and maize. With the apparent cessation of military conflict in Angola, one can expect human development and associated habitat destruction in this area to be rapid. Encouragingly, however, this species is clearly tolerant of some habitat modification, as it has been recorded in secondary forest and clearings, including coffee plantations in forest. The range of the Gabela Helmet-shrike includes Kissama National Park, which should afford it some protection.

*Helmet-shrikes may often suffer brood parasitism by cuckoos. This can be seen in the photo, where a **Retz's Helmet-shrike** is brooding a Thick-billed Cuckoo* (Pachycoccyx audeberti) *chick. This cuckoo species, in fact, is commonly known to lay its eggs in the nests of Retz's Helmet-shrike, removing both the eggs and the nestlings of its host. In Zimbabwe, one study found that 55% of the helmet-shrike's nests were parasitized. The breeding success of Retz's Helmet-shrike is poor, which is likely to be related to such high levels of cuckoo parasitism.*

[*Prionops retzii*, Stone Hills Game Sanctuary, Zimbabwe. Photo: J. R. Peek]

*The **Grey-crested Helmet-shrike** is a restricted-range species, confined to an area of south-west Kenya and adjacent parts of northern Tanzania, totalling just over 50,000 km². Between 1926 and 1979, it apparently disappeared from the Rift Valley, where it was first described and found breeding in 1884, but it subsequently recolonized the region, where it is now reported to be common. However it is generally scarce, groups having an extremely large home range during the non-breeding season, and it appears to have vanished from parts of its range in Tanzania. Its habitat is being degraded by grazing and cultivation, and because of its continuing population decline it is listed as Near-threatened.*

[*Prionops poliolophus*, Serengeti National Park, Tanzania. Photo: Pete Morris]

Little better in terms of its conservation status, the unusual and inscrutable Yellow-crested Helmet-shrike is ranked as Vulnerable. As with the preceding prionopid, it is a restricted-range species, and its distribution, estimated as covering about 34,000 km², is localized in four regions in the endemic-rich Albertine Rift Mountains Endemic Bird Area. Its population, too, is small, totalling about 2500–10,000 individuals, and is decreasing. This intriguing helmet-shrike is threatened by forest clearance, carried out by subsistence farmers for cultivation of crops, such as maize, and the establishment of cattle pastures, especially at Itombwe and particularly at higher altitudes. These problems are exacerbated by continuing civil unrest and the challenges posed by the presence of large numbers of human refugees. The Yellow-crested Helmet-shrike's range falls largely outside protected areas, but the species does occur in the Virunga National Park.

Another poorly understood member of the family, the Grey-crested Helmet-shrike, is considered globally Near-threatened, as it appears to have a moderately small population apparently undergoing a moderately rapid and ongoing decrease. As with the two aforementioned helmet-shrikes, it is a restricted-range species, but with a distribution encompassing a more comfortable 52,800 km². Part of its range falls within the Serengeti Plains Endemic Bird Area. This species appears to have vanished from the Kigoma and Tabora regions of Tanzania since the early 1900s. Its status in the Rift Valley region of Kenya is enigmatic. It apparently disappeared from this area, where it was first described and found breeding in 1884, during the period 1926–1979, and then recolonized the region, with evidence of breeding at Lake Nakuru in 1989 and subsequently. It is, however, conceivable that, in the intervening period, the species could have been overlooked and/or mistaken for the White-crested Helmet-shrike in the Rift Valley. The Grey-crested Helmet-shrike could be put at risk by habitat destruction and degradation brought about by overgrazing and cultivation. Its range, however, includes parts of the Serengeti, Masai Mara (buffer areas) and Lake Nakuru protected areas.

Although not yet formally considered threatened in any way, the Chestnut-fronted Helmet-shrike is decreasing in numbers and its range is relatively small and highly fragmented. The distribution of this species is concentrated along the vulnerable and heavily exploited East African coastal zone, with its concomitantly high human densities and severe pressure on habitat. It is known to be in decline, in many places dramatically so, along most of its coastal range in Kenya, Tanzania and Mozambique. In Mozambique, it is known to be threatened by the destruction of forest and woodland by logging and for subsistence cultivation. The tiny and peripheral Zimbabwe population, if still extant, must be at serious risk from habitat destruction wreaked by subsistence farmers. The inland Kenyan subspecies *keniensis* is now entirely restricted to the Meru and Ngaia Forests and is rare and endangered; it has disappeared from the Kulal and Marsabit mountains and from Embu District, apparently for unknown reasons largely unrelated to habitat destruction. Current trends strongly suggest that the Chestnut-fronted Helmet-shrike is likely to become threatened in the foreseeable future.

The conservation status of the remaining four members of the family currently seems secure. For example, the White-crested Helmet-shrike is common in suitable habitat over large parts of its extensive range. Nevertheless, each of these four species has certainly lost habitat to a greater or lesser degree to anthropogenic modification. Retz's Helmet-shrike, as an example, is known to be vulnerable to woodland degradation, such as the destruction of miombo woodland in Zimbabwe, and in East Africa it has apparently disappeared from the Nairobi, Kiambu and Ngong regions. Similarly, the Red-billed Helmet-shrike has decreased around major urban centres, such as the Nigerian metropolis of Lagos, although it is present in numerous protected areas, including Taï Forest National Park, in Ivory Coast, Kakum National Park, in Ghana, and Korup National Park, in Cameroon. The Rufous-bellied Helmet-shrike has likewise decreased in some regions. For example, it is now extinct in Rwanda, and in Uganda its numbers have dwindled in Bwamba and Bugoma forests, perhaps to local extinction in the latter. It does, however, occur in numerous protected areas, including the Dzanga-Ndoki National Park, in Central African Republic, and the Odzala and Nouabalé-Ndoki National Parks, in PRCongo.

*The all-black plumaged **Gabela Helmet-shrike** went unrecorded from 1970 to 2003. Previously thought to be confined to higher elevations of remnant escarpment forest in Angola, it has now been found in more widespread open forest near the foot of the escarpment. It occurs in Kishama National Park, but there is currently no information on how effectively this area is being protected. With its tiny range and small and probably declining population of 1000–2500 birds, this species is listed as Endangered.*

[*Prionops gabela*, Bimbe, Angola. Photo: Fabio Olmos]

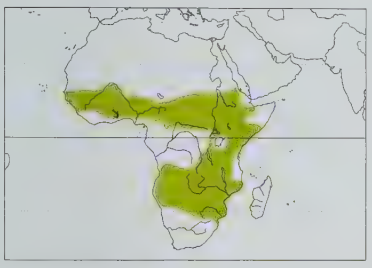
Genus *PRIONOPS* Vieillot, 1816



1. White-crested Helmet-shrike

Prionops plumatus

French: Bagadais casqué **German**: Weißschopf-Brillenwürger **Spanish**: Prionopo Crestiblanco **Other common names**: White/Common/Long-crested Helmet-shrike; Straight-crested Helmet-shrike (*plumatus*); Curly-crested Helmet-shrike (*cristatus*); Southern/Smith's Helmet-shrike (*poliocephalus*)

Taxonomy. *Lanius plumatus* Shaw, 1809, Senegal.
Forms a superspecies with *P. poliolophus*, and *P. alberti* possibly part of same group. Other proposed races are *adamauae* (described from Kontcha, in NC Cameroon), synonymized with *concinnatus*; *melanopterus* (from Fer Liban, in SE Ethiopia), synonymized with *vinaceigularis*; and *angolicus* (from Malanje, in N Angola), synonymized with *poliocephalus*. Five subspecies currently recognized.

Subspecies and Distribution.
P. p. plumatus (Shaw, 1809) – Senegal E to N Cameroon.
P. p. concinnatus Sundevall, 1850 – C Cameroon E to C & SW Sudan, NW Ethiopia, NE DRCongo and N Uganda.
P. p. cristatus Rüppell, 1836 – Eritrea, N, W & C Ethiopia, SE Sudan, E Uganda and NW Kenya.
P. p. vinaceigularis Richmond, 1897 – Somalia, E & S Ethiopia, N & E Kenya and NE Tanzania.
P. p. poliocephalus (Stanley, 1814) – S Uganda and C & S Kenya S to SE DRCongo, Angola, Namibia, Botswana and NE South Africa.
Descriptive notes. 19–25 cm; 25–49 g. Nominate race has extensive elongated (up to 45 mm) crest of greyish-white feathers on mid-crown, shorter (c. 10 mm) crest of whitish spiky feathers on forecrown to lores; hindcrown grey, blackish crescent behind white cheek and ear-coverts (feather pigments on head unstable, and easily washed out with soap); neck and underparts whitish, flanks with blackish smudges (at rest, often concealed by wings); upperparts black, glossed greenish; upperwing black, primaries with broad white central bar (conspicuous in flight), outer five secondaries tipped narrowly white, innermost with broad white tip and outer edge, outermost tertial with broad white tip and outer edge, middle tertial with narrow white outer edge, inner greater and median upperwing-coverts white (white in secondaries, tertials and coverts shows as obvious bar in folded wing); outer tail feathers completely white, inner tail feathers glossy black with white tips, white decreasing in extent towards central two rectrices, which completely black; underwing-coverts and axillaries black;

iris dark greenish-grey with yellow outer ring, conspicuous broad orange-yellow orbital ring with scalloped fringe; bill blackish; legs and feet pinkish-orange to red. Sexes similar. Juvenile has shorter crest on mid-crown, no dark crescent behind face, plumage tinged browner, with buff feather tips on upperparts, eyes brown, no orbital ring, legs and feet yellower; adult appearance acquired at c. 12 months. Other races have iris bright yellow; race *concinnatus* has shorter, forward-curving mid-crown crest (c. 25 mm) and narrower wingbar than nominate; *cristatus* also has short, forward-curving mid-crown crest, lacks white in secondaries, tertials and upperwing-coverts, has central tail feathers tipped white; *vinaceigularis* lacks white wingbar, has mid-crown crest even shorter (c. 15 mm) and not distinct from forecrown crest; *poliocephalus* is small, has white wingbar as broad as nominate but mid-crown feathers as short as preceding race, entire crest from lores to mid-crown uniformly greyish, head greyer than nominate and with darker crescent behind eye, whiter tail. Voice. Noisy, vocalizations important in regulating intra-group social interactions; at least some calls may reflect individual social status. Wide variety of calls (at least 20 documented), many of which striking and protracted, including buzzing, chanting, chattering (on locating food or nest material), chipping, churring, clicking, gobbling, growling (during aggression), rolling, scolding, slurred, twittering, whistling, winding and, especially, nasal notes. Loud bill-snapping also characteristic, especially when provoked. Many calls given in group chorus and duets, including during territorial display, often initiated by dominant female. Breeding male and female maintain pair-bond through duetting, male giving "yuki-yuki" call, female responding with "kidoki-doki". Main call distinctive "cherow-cherow"; soft flight contact call "whit-whit", and louder "treeu" by lost individuals; alarm call shrill "tzzee-tzzee". Vocalizations apparently vary among subspecies, e.g. in E Africa reportedly between *poliocephalus* and *cristatus*.

Habitat. Breeds mainly in deciduous broadleaf savanna woodlands, including those dominated by *Baikiaea*, *Brachystegia*, *Burkea*, *Colophospermum*, *Combretum*, *Pterocarpus* and *Terminalia*. In non-breeding season, wanders widely to acacia savanna and other woodlands, coastal and riparian forest and forest edge, lightly wooded grassland, and oil-palm (*Elaeis guineensis*), eucalypt (*Eucalyptus*) and pine (*Pinus*) plantations; also visits gardens, even urban areas. Attracted to recently burnt ground for foraging. To 2200 m; usually below 1500 m, and rare above 1800 m.

Food and Feeding. Diet small invertebrates, also small reptiles, and fruit. Among invertebrates, caterpillars account for 46% of items, butterflies and moths (Lepidoptera) 19%, grasshoppers (Acrididae) 7%, termites (Isoptera) 7%, praying mantises (Mantidae) 5%, with ants (Formicidae), beetles (Coleoptera), centipedes (Chilopoda), cicadas (Cicadidae), flies (Diptera) and spiders (Araneae) also represented; small reptiles, mainly geckos (Gekkonidae), form 1% of recorded prey. Identified material in five stomachs contained 42% beetles, 32% ants and 12% grasshoppers. May use auditory cues in prey location. Hunts at all levels, mainly in middle to lower vegetation layers among leaves, branches and twigs, and on ground. In summer hunts primarily in trees, in winter more on ground. In study in Zimbabwe, prey taken on ground and arboreally (from bushes, leaves, trunks, branches and twigs) apparently in approximately equal proportions but only rarely in flight; in another study, 41% of prey taken from twigs and stems, and 32% while perched, 49% in flight and 19% on ground. Sometimes hangs upside-down in manner of a tit (Paridae) while foraging, and also hawks flying insects in air in manner of a flycatcher (Muscicapidae). Lives and forages in tightly knit groups of 2–22 (average seven) individuals in undefended home range, which may be shared with adjacent groups, home-range size tending to increase during post-breeding period; groups smallest during breeding season, at least in S of range. Progresses in "leap-frogging" movement through woodland, birds at rear of group regularly flying to front; may trace identical foraging path day after day, and some individuals act as sentries while others forage. Especially in non-breeding season, joins mixed-species bird parties with *P. retzii*, towards which sometimes markedly aggressive, and, far less frequently, *P. scopifrons*, *P. caniceps* and *P. poliolophus*, as well as other birds, e.g. Old World orioles (Oriolidae), drongos (*Dicrurus*), tits and Brubrus (*Nilaus afer*), and likely catalytic in formation of these parties.

Breeding. Egg-laying virtually throughout year, especially Mar–Nov (mainly Mar–Jul and Oct–Nov), in W Africa, mainly Feb–Jun in NE Africa, Feb–Nov (mainly Feb–Mar and Oct–Nov) in E Africa, and mainly Aug–Apr (peak Sept–Nov) in C & S of range; often double-brooded, and in Zimbabwe, average of two (annual range 1·5–2·6) nesting attempts per season. Monogamous, pair-bond can last 2–3 years. Co-operative breeder, all group-members assisting in all aspects of nesting duties, breeding pair apparently doing most, intra-group hierarchy (in descending order of dominance) breeding female, breeding male, other adult females (typically siblings of breeding female), other adult males (typically siblings of breeding male), adult offspring, immatures and juveniles; breeding group stable for up to ten years, dominant breeding bird replaced on demise by next-ranking sibling of same sex; new group created when up to four sisters from one group join with up to four brothers of another group; some pairs without helpers, these are normally unsuccessful. Nest solitary, inter-nest distance typically at least 50 m, usually much greater; territorial during breeding, all group-members participate in territory defence, 63 territories in Zimbabwe 1–12 ha, average 5 ha. Courtship marked by wing-opening and slow wing-flapping, and male with nesting material in bill approaching female. Breeding pair chooses nest-site and does most of construction work, but assisted by other group-members, nest-building taking at least four days; nest a neat, compact cup of bark strips extravagantly bound with *Microstigma* spider web (web apparently transported in bill and on erectile frontal crest feathers), lined with bark, rootlets, grass and lichen, camouflaged to resemble swelling on branch, external diameter 8·1–9 cm, depth 3·5–6·5 cm, internal diameter 6·3–7·1 cm, depth 2·4–2·8 cm; placed 2–10 m (mainly 3–6 m) above ground on horizontal tree branch or in upright fork, often in tree with greyish or lichen-covered bark, sometimes in eucalypt plantation; has nested less than 80 m from *P. retzii*; same tree, even same site, may be used in successive years. Clutch 2–5 eggs, average 3·9 in Zimbabwe, occasionally two females lay in same nest (then up to 9 eggs in nest), eggs laid at daily intervals; replacement laid if clutch lost, in Zimbabwe average 11 days between nesting failure and new attempt; incubation by all group-members, breeding pair doing only c. 35% of it during daytime, incubation period 16–21 days, typically 17 days; chicks brooded and fed by all of group, nestling period 17–22 days, generally c. 20 days; fledged young fed by group-members until c. 10 weeks old, when able to locate food for themselves; from c. 5 months juveniles disperse from groups and form single-sex flocks with others, or remain in natal group as helpers. Three records of brood parasitism, one each by Thick-billed (*Pachycoccyx audeberti*), Red-chested (*Cuculus solitarius*) and Black Cuckoos (*Cuculus clamosus*); high rate of nest attendance may reduce opportunities for brood parasitism. In Zimbabwe, average of 25% of eggs and 30% of nests produce fledglings, 0·9 fledglings per nesting attempt, 2·9 fledglings per successful nest, and mean productivity 1·7 fledglings per group per year; average of 60% of fledglings survive first year; main cause of failure is predation by mammals, reptiles, and other birds e.g. Bateleur (*Terathopius ecaudatus*), Ayres's Hawk-eagle (*Hieraaetus ayresii*), African Harrier-hawk (*Polyboroides typus*), Gabar Goshawk (*Micronisus gabar*) and Peregrine Falcon (*Falco peregrinus*); some chicks starve to death. Can breed at two years, but fewer than 50% breed before five years old. In Zimbabwe, annual survival of adults 76–87%.

Movements. Largely resident, but with widespread seasonal movement out of breeding home range, including apparent migrations, e.g. N–S seasonal movement in Ghana, and regular migration (by race *poliocephalus*) between Kenyan dry season non-breeding grounds and Tanzanian nesting areas. Some movements apparently altitudinal, with descent to lower-lying regions in non-breeding season. In S of range apparently particularly nomadic in dry season, wandering to wooded regions not suitable for breeding and even into urban habitats, e.g. Bulawayo (Zimbabwe). Establishes foraging home ranges on non-breeding grounds and uses traditional roost-sites in leafy trees, e.g. *Acacia*, *Lonchocarpus* and *Thespia*. Also prone to large-scale irruptions associated with major drought periods, e.g. S Africa in 1953, 1970, 1979 and 1992, when large numbers move through and into otherwise unsuitable habitat, e.g highland grasslands to S of main range.

Status and Conservation. Not globally threatened. Frequent to common over large parts of range. Density of up to 1 group/10 ha in far S of range. In Zimbabwe, 140 home ranges 4·5–30 ha, average 18 ha, size associated with variables such as rainfall and density of adjacent groups; one non-breeding home range in South Africa 3·5 km². Occurs in numerous national parks and other protected areas throughout its range. May have benefited from drought refuges provided by plantations and urban parks and gardens.

Bibliography. 2. Grey-crested Helmet-shrike

Prionops poliolophus

French: Bagadais à huppe grise **Spanish**: Prionopo Crestigrís
German: Grauschopf-Brillenwürger

Taxonomy. *Prionops poliolopha* G. A. Fischer and Reichenow, 1884, Lake Naivasha, Kenya. Forms superspecies with *P. plumatus*, and *P. alberti* possibly part of same group. Monotypic.

Distribution. SW Kenya and adjacent N Tanzania.

Descriptive notes. 23–26 cm; one male 49 g. Has long (c. 20 mm) bushy crest of grey to dark grey feathers on mid-crown, shorter crest of whitish-tipped grey spiky feathers on forecrown to lores, dark grey hindcrown and nape, blackish crescent behind grey cheek and ear-coverts; chin and throat grey, flanks greyish, neck and remainder of underparts whitish, blackish patch at side of chest; upperparts black, glossed greenish; upperwing black, primaries with broad white central bar (conspicuous in flight), innermost primaries tipped white, outer five secondaries tipped broadly white and innermost with broad white tip and outer edge, outermost tertial with broad white tip and outer edge, middle tertial with narrow white outer edge, inner greater and median upperwing-coverts white (white in secondaries, tertials and coverts shows as obvious bar in folded wing); outer tail feathers almost completely white, remainder black with white tips, white decreasing in extent towards central two rectrices; underwing-coverts and axillaries black; iris bright yellow, orange outer ring; bill blackish; legs and feet orange-red to pink-red. Distinguished from *P. plumatus* mainly by larger size, darker grey head, blackish patch at side of chest and absence of orbital ring. Sexes similar. Juvenile not described in detail, has eyes dark and crest shorter and straighter than adult's. Voice. Poorly documented. Vocalizations include chattering, churring, descending, harsh, rolling and scratchy notes; deeper and more guttural than voice of *P. plumatus*. Bill-snapping characteristic, as is group chorusing.

Habitat. Open savanna dominated by *Acacia dephanolobium* and *Tarchonanthus*, and riparian forest characterized by *Acacia xanthophloea*, *Acacia abyssinica* and *Protea*, as well as lightly wooded grassland and scrub; 1200–2200 m. Usually in better-developed, higher-rainfall woodland than that occupied by *P. plumatus*, which it replaces locally at higher altitude.

Food and Feeding. Little known. No details of adult diet; likely mainly insects. Nestling diet at L Naivasha (Kenya) mostly insect larvae, grasshoppers (Orthoptera) and praying mantis (Mantidae). Lives and forages in tightly knit groups of 4–9 (typically about seven) individuals, rarely up to 17. Perches in low bushes. Sometimes joins mixed-species parties, locally (Loliondo region, in Tanzania) including those with *P. plumatus*.

Breeding. Poorly known. Egg-laying reported as Apr–May, but nest-building recorded Sept–Nov and incubation in Oct and Dec in L Naivasha area (Kenya). Co-operative breeder, in groups of up to twelve individuals, sometimes more; all group-members assist in nesting activities. In study of twelve groups around L Naivasha during Sept 2003 to Mar 2004, 16 nests (built by eight groups) were found; following details based on results of this study. Nest built by all group-members, an open cup of grass c. 3·5–5 cm in diameter and 1·4 cm in depth, coarser material (such as bark) used for framework, lined with finer materials (spider web), outer wall entirely covered with spider web, and structure bound to branch with cobweb, placed either 3–5 m above ground in *Tarconanthus camphoratus* bushland or higher, up to 18–20 m, in *Acacia xanthophloea* woodland (height varied with habitat and site). Clutch 3–4 eggs, occasionally up to 7 (very likely result of two females laying in same nest), typically laid at intervals of 1–2 days; up to four replacements, always in new nest some distance away from original tree, if breeding attempt failed; incubation of eggs and brooding and feeding of chicks by all members of group, including juveniles, at four nests incubation period 16–18 days and nestling period 22–24 days. Of 16 nests found, one was disturbed

On following pages: 3. Yellow-crested Helmet-shrike (*Prionops alberti*); 4. Red-billed Helmet-shrike (*Prionops caniceps*); 5. Rufous-bellied Helmet-shrike (*Prionops rufiventris*); 6. Retz's Helmet-shrike (*Prionops retzii*); 7. Gabela Helmet-shrike (*Prionops gabela*); 8. Chestnut-fronted Helmet-shrike (*Prionops scopifrons*).

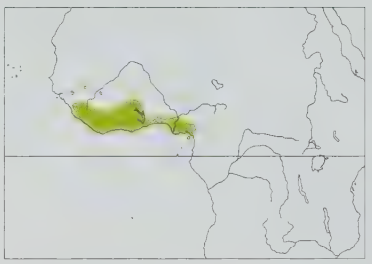
before eggs laid, eight preyed on during incubation, two lost some eggs but incubation continued until rest hatched but both then preyed on, one other suffered predation at nestling stage, and only four (25%) produced fledged young.
Movements. Apparently largely resident; some post-breeding movement likely from Mara–Narok nesting grounds NE in Rift Valley to L Nakuru, Longonot, Naivasha and Menengai Crater areas during Oct–Feb.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Serengeti Plains EBA. Has rather small range of c. 52,800 km², within which moderately small population believed to be undergoing moderately rapid decrease. Occurs from lakes Nakuru, Elmenteita and Naivasha, and Kedong valley through Narok District, Masai Mara and Sabaringo valley to Loita and Nguruman Hills, Loliondo and Serengeti; also Mwanza; main concentration Narok to Serengeti. Present in Kigoma and Tabora regions in early 1900s, but no subsequent records. Apparently disappeared from Rift Valley region (where first described and found breeding in 1884) during 1926–79, although conceivably overlooked; subsequently recolonized region, with evidence of breeding at L Nakuru in 1989 and later, e.g. at L Oloidien (Naivasha area). Generally scarce, e.g. Masai Mara, groups having extremely large home range during non-breeding season; common in some areas, e.g. extreme N Serengeti and Rift Valley. Potentially threatened by habitat destruction and degradation through overgrazing and cultivation. Range includes parts of Serengeti National Park, the buffer areas of Masai Mara National Park, and Lake Nakuru National Park.
Bibliography. Anon. (2008d), Anti (2000), Bennun (1994), Butchart & Stattersfield (2004), Chapin (1954), David & Gosselin (2002b), Enniskillen (1999), Fry *et al.* (2000), Harris & Franklin (2000), Lewis (1981a, 1982, 1983), Lewis & Pomeroy (1989), Malaki *et al.* (2009), Ng'weno (1999), Stattersfield & Capper (2000), Williams (1963).

3. Yellow-crested Helmet-shrike

Prionops alberti

French: Bagadais d'Albert **Spanish**: Prionopo Crestigualdo
German: Gelbschopf-Brillenwürger

Taxonomy. *Prionops alberti* Schouteden, 1933, summit of Mount Mikeno, 4467 m, Kivu District, DRCongo.
Possibly part of the superspecies formed by *P. plumatus* and *P. poliolophus*. Monotypic.
Distribution. Mountains of W Albertine Rift in E DRCongo.



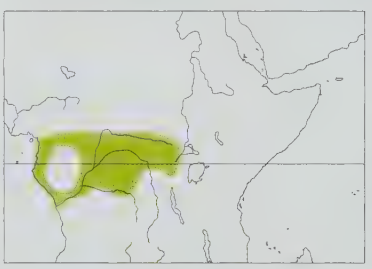
Descriptive notes. 22–24 cm; 61–62 g. Has rounded yellow crest (up to 20 mm) from lores to hindcrown, yellow extending down to level with eye (yellow crest feathers not always obvious in field, and can be fringed brown or grey); remainder of plumage black, glossed greenish; reported as sometimes showing white or grey bar across inner primaries; iris greenish-yellow, narrow orange orbital ring; bill black; legs flesh-coloured to reddish. Sexes similar. Juvenile has whitish, brownish or pale yellow crest, duller, less glossy, body plumage, brown eyes, brownish bill. Voice. Poorly known. Typical call described as "tlu-uk" note, repeateed up to six times, musical and far-carrying. Also noisy chorusing and duetting, and bubbling, chattering, descending, nasal, piping, rolling and slurred notes.
Habitat. Montane forest, *Hagenia* and bamboo forest, also, at lower altitudes, primary rainforest; 1100–2600 m, primarily 1400–2500 m, but apparently first discovered at c. 4400 m in alpine zone.
Food and Feeding. Diet apparently insects, e.g. grasshoppers (Orthoptera). Lives and forages in tightly knit groups mostly of 4–8 individuals (up to 20 recorded), which move at speed. Concentrates hunting in upper canopy, and frequently catches insects in flight in manner of flycatcher (Muscicapidae). Sometimes perches in open. Occasionally in mixed-species bird parties.
Breeding. Poorly known. Egg-laying apparently during rains, recorded Dec–Apr and Jun–Jul. Co-operative breeder. Nest reported as built with twigs and lichen, lined with rootlets, placed 6–7 m above ground (about half-way up) in fork of tree in montane forest. No other information.
Movements. No details. Probably resident, perhaps with some seasonal altitudinal movements.
Status and Conservation. VULNERABLE. Restricted-range species: present in Albertine Rift Mountains EBA. Generally rare to uncommon. Global population likely to be small, estimated as in range c. 2500–10,000 and decreasing. Present at four localized regions in Albertine Rift: Itombwe Mts (Mwana to Kitongo and Kilize), mountains W of L Edward (Bitakongo, Kanyabisika and Pinga to Bilati) and L Kivu (Kamatemba, Virunga to Butokolo) and, at 1770–2474 m, Mt Misotshi-Kabogo (formerly Mt Kabobo) and Muganja Hills. No longer present at type locality. Report of presence in Bwindi-Impenetrable Forest, in SW Uganda, requires confirmation; claimed Rwandan record unacceptable. During surveys in S & C Itombwe in 1996, was observed many times W of the C plateau, but apparently absent in similar habitat to E. Threatened by forest clearance for subsistence cultivation, e.g. maize, and cattle pastures, especially at Itombwe (particularly at higher altitudes). Problems exacerbated by civil unrest among human population and military activity, with large numbers of refugees. This species' geographical range is largely outside protected areas, but it occurs in Virunga National Park.
Bibliography. Anon. (2008d), Butchart & Stattersfield (2004), Chapin (1954), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Franklin (2000), Hendrickx (1946), Omari *et al.* (1999), Plumptre, Behangana *et al.* (2003), Plumptre, Kujirakwinja *et al.* (2007), Prigogine (1949, 1953a, 1971, 1985), Schouteden (1933, 1935), Stattersfield & Capper (2000).

4. Red-billed Helmet-shrike

Prionops caniceps

French: Bagadais à bec rouge **German**: Rostbauch-Brillenwürger **Spanish**: Prionopo Piquirrojo
Other common names: Red-billed Shrike, Chestnut-bellied/Western Helmet-shrike

Taxonomy. *Sigmodus caniceps* Bonaparte, 1850, West Africa = Boutry (Butré) River, Ghana.
Forms a superspecies, and often considered conspecific, with *P. rufiventris*. Two subspecies currently recognized.
Subspecies and Distribution.
P. c. caniceps (Bonaparte, 1850) – SW Mali (including Mandingues Mts), Guinea and Sierra Leone E to Ghana and S Togo.
P. c. harterti (Neumann, 1908) – Benin, Nigeria and W Cameroon.



Descriptive notes. 20–22 cm; 42–62 g. Nominate race has crown down to eye level and lores blue-grey, rest of head and neck, including chin and throat, black; upperparts black, glossed greenish; flight-feathers black, primaries with broad white central bar (conspicuous in flight), uppertail black and glossy; breast and upper belly white, well demarcated from buff lower underparts; underwing-coverts and axillaries dark grey; iris yellow, narrow orange-red orbital ring; bill red; legs orange-red. Sexes similar. Juvenile is browner than adult and more streaked in appearance, lacks blue-grey crown, has dark line through lores, orbital ring inconspicuous, eyes brown, bill blackish (later yellow), legs duller. Race *harterti* has blue-grey of crown extending below eye on to cheek and upper ear-coverts, and paler buff on belly resulting in less clear differentiation from white chest. Voice. Highly vocal. Commonest call (probably contact) of nominate race "wrrraak, wrraak", described as fairly soft and "dry and leathery"; other, more penetrating harsh and grating contact calls rather corvid-like. Song comprises loud whistling, either rising in pitch in middle of song or descending in pitch overall. Duetting recorded. Most characteristic call of race *harterti* on Mt Kupé (Cameroon) "kui-kui, kui-kui", similar to that of *P. rufiventris*. Aggressive chattering call directed at monkeys and accompanied by bill-snapping. Wingbeats noisy.
Habitat. Lowland primary and gallery forest, also mature secondary forest, dense riverine vegetation, forest edge, logged forest and farmland, and old coffee plantations; lowlands, to 700 m in Guinea.
Food and Feeding. Diet insects, e.g. beetles (Coleoptera), caterpillars, cicadas (Cicadidae), grasshoppers (Orthoptera), praying mantises (Mantidae) and stick-insects (Phasmatodea), as well as spiders (Araneae), fruits and seeds. Food in Ivory Coast 50% adult arthropods, 20% larvae and 30% fruit. Hunts mainly in middle forest layer, 10–20 m up, less frequently in canopy. Apparently more sluggish than woodland members of family. Catches most prey in flight in manner of flycatcher (Muscicapidae); also gleans insects from leaves and twigs, but avoids thicker trunks. Lives and forages in groups of usually 4–8 individuals (up to 20 recorded); group-members remain within 1–4·5 m of one another when foraging. Joins mixed-species foraging parties, especially during non-breeding season, with *P. plumatus* and other birds, e.g. cuckoo-shrikes (Campephagidae), drongos (*Dicrurus*) and malimbes (*Malimbus*), but keeps to rear of party.
Breeding. Poorly known. Egg-laying apparently mainly Dec–Feb, also Jul; reported as double-brooded. Likely co-operative breeder, e.g. five individuals seen at one nest. One nest described as a compact, greyish-green cup, that appeared too small for incubating bird, placed 15 m up in subcanopy fork in secondary forest, another 40 m up in *Sarcoglottis* tree. Possibly parasitized by Thick-billed Cuckoo (*Pachycoccyx audeberti*). No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Frequent to common across large parts of range. Apparently decreased around major urban centres, e.g. Lagos (Nigeria). Present in several protected areas, e.g. Taï Forest National Park, in Ivory Coast, Kakum National Park, in Ghana, and Korup National Park, in Cameroon.
Bibliography. Balchin (1988), Bannerman (1939a), Borrow & Demey (2001), Fry *et al.* (2000), Gatter (1997), Greig-Smith (1976), Hall & Moreau (1970), Harris & Franklin (2000), Hart (1971), Rodewald *et al.* (1994), Thiollay (1973).

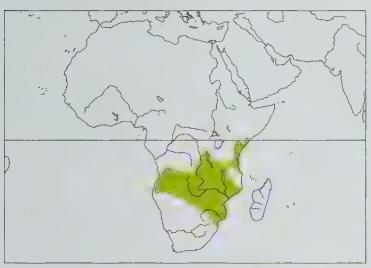
5. Rufous-bellied Helmet-shrike

Prionops rufiventris

French: Bagadais à ventre roux **German**: Gabunbrillenwürger **Spanish**: Prionopo Ventrirrojo
Other common names: Gabon/Gaboon/Chestnut-breasted Helmet-shrike

Taxonomy. *Sigmodus rufiventris* Bonaparte, 1853, Mozambique; error = Gabon.
Forms a superspecies, and often considered conspecific, with *P. caniceps*. Two subspecies recognized.
Subspecies and Distribution.
P. r. rufiventris (Bonaparte, 1853) – S Cameroon E to Central African Republic and NW DRCongo, S to Equatorial Guinea, Gabon, PRCongo and N Angola (Cabinda).
P. r. mentalis (Sharpe, 1884) – C & NE DRCongo and W Uganda.

Descriptive notes. 20–22 cm; 37–63 g. Nominate race has most of head from crown and nape down to ear-coverts, cheek and chin blue-grey, whiter on forehead, lores and around eye, lower throat and neck black; upperparts black, glossed greenish; flight-feathers black, primaries with broad white central bar (conspicuous in flight), uppertail black and glossy; breast white, sharply differentiated from rufous lower chest and belly; underwing-coverts and axillaries blackish; iris yellow, narrow orange-red orbital ring; bill red; legs orange-red. Sexes similar. Juvenile is browner than adult, more streaked in appearance, lacks blue-grey crown, has dark line through lores, orbital ring inconspicuous, eyes brown, bill blackish (later yellow), legs duller. Race *mentalis* is smaller than nominate, with narrower black collar, narrower white breastband, latter with blue-grey along upper edge, darker rufous on lower chest and belly, and paler orbital ring. Voice. Highly vocal. Song lengthy and constant fluid "tyooyoo". Common call a harsh and strident "chaja" and variations thereof, repeated; other calls comprise hoarse and whistling notes, sometimes combined, and other clicking, nasal and slurred sounds. Duetting recorded. Some vocalizations, e.g. "kyop-kyop, kyop-kyop" double note, very similar to those of *P. caniceps*. Bill-snapping common, and wingbeats noisy.
Habitat. Primary forest, including both open-canopy and closed-canopy forest and forest on slopes; also mature secondary forest and forest edge. Mostly lowlands, to 1450 m in DRCongo.
Food and Feeding. Diet insects, e.g. beetles (Coleoptera), butterflies and moths (Lepidoptera), caterpillars, cicadas (Cicadidae), grasshoppers (Orthoptera), praying mantises (Mantidae) and stick-insects (Phasmatodea), as well as spiders (Araneae); also seeds and fruits, e.g. of *Musanga* and *Croton*. Hunts just beneath or inside canopy; hops along branches, and searches among leaves and lianas while in flight. Lives and forages in groups of usually 4–8 individuals (up to twelve recorded). Often in mixed-species bird parties, especially in non-breeding season; probably a catalyst species of such flocks.



Breeding. Poorly known. Egg-laying apparently May–Jul and Nov–Dec. Likely co-operative breeder. Territorial, and all group-members participate in territory defence; territory large, e.g. at least 20 ha. Fledglings fed by all group-members. Possibly parasitized by Thick-billed Cuckoo (*Pachycoccyx audeberti*). No other information.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Frequent to common across large parts of range. Formerly occurred in Rwanda, but now extinct there. Seems to have decreased in Bwamba and Bugoma forests in Uganda, and possibly extinct in latter. Present in numerous protected areas, e.g. Dzanga-Ndoki National Park, in Central African Republic, and Odzala and Nouabalé-Ndoki National Parks, in PRCongo.
Bibliography. Borrow & Demey (2001), Brosset & Érard (1986), Carswell *et al.* (2005), Chapin (1921, 1954), Christy & Clark (1994), Dowsett (1993), Fry *et al.* (2000), Harris & Franklin (2000), Prigogine (1971), van Someren & van Someren (1949).

6. Retz's Helmet-shrike

Prionops retzii

French: Bagadais de Retz **German**: Dreifarben-Brillenwürger **Spanish**: Prionopo de Retz
Other common names: Red-billed(!)/Black Helmet-shrike, Retz's Shrike, Retz's Red-billed Shrike/Helmet-shrike

Taxonomy. *Prionops retzii* Wahlberg, 1856, "ad flumen Doughe" = Okavango River, southern Africa.
Forms a superspecies, and conceivably conspecific, with *P. gabela*. Other proposed races are *intermedius* (described from Mwanza, S of L Victoria, in Tanzania), synonymized with *tricolor*, and *neumanni* (from Fanole, in Somalia), synonymized with *graculinus*. Four subspecies recognized.
Subspecies and Distribution.
P. r. nigricans (Neumann, 1899) – Angola (except N & extreme S), NW Zambia and SE DRCongo.
P. r. graculinus Cabanis, 1868 – S Somalia, Kenya and NE Tanzania.
P. r. retzii Wahlberg, 1856 – extreme S Angola (S Huila and probably Cubango) and S Zambia S to N Namibia, N & E Botswana, Zimbabwe and N South Africa.
P. r. tricolor G. R. Gray, 1864 – W & S Tanzania and S & E Zambia S to Malawi, Mozambique, NE South Africa and E Swaziland.

Descriptive notes. 19–24 cm; 33–61 g. Nominate race has head, neck, upper mantle and underside from chin to belly glossy black, including slight crest on forecrown to lores; lower mantle and scapulars to rump, including inner upperwing-coverts, grey-brown, long black uppertail-coverts; remiges and outer primary coverts black, primaries with broad white central bar (conspicuous in flight), tail glossy black, broad white tips on outer rectrices, white decreasing in extent on inner tail feathers towards central pair, which is completely black; lower belly to undertail-coverts white, underwing-coverts and axillaries grey-brown; iris yellow, conspicuous broad orange-red to red orbital ring with scalloped fringe; bill red, tip orange-yellow; legs orange-red. Sexes similar. Juvenile is largely grey-brown above and below, with buff feather tips on upperparts, wing feathers often with narrow white tips, no orbital ring, eyes brown, bill blackish (later yellow), legs blackish (later yellow); juvenile plumage apparently followed by similar intermediate immature plumage, and full adult dress possibly acquired only after 24 months, but confirmation required. Race *nigricans* has upperparts darker grey, with less contrast between head to upper mantle and rest of upperparts; *tricolor* is slightly smaller, with upperparts lighter grey-brown, lower belly whiter, central two tail feathers sometimes have narrow white tips; *graculinus* is like previous but even smaller, with fairly pronounced crest (up to 20 mm) on forehead and forecrown, upperparts even paler and browner, wingbar reduced or absent, and central two tail feathers tipped white. Voice. Highly vocal; at least 16 different vocalizations identified, and some calls may reflect individual social status or gender. Louder and more musical than *P. plumatus*. Whistled song a repeated "tweeoo", similar to that of Old World orioles (Oriolidae), also as "cheeeow, cheeee-owp". Typically, calls comprise chattering, chomping, grating, guttural, rolling, slurred, whistling, winding and, especially, nasal notes, often given in tandem, can be ascending or descending, and sometimes alternating; some calls likened to those of nightjars (Caprimulgidae) and barbets (Capitonidae). Calls often given in group chorus, and duetting common and believed important in pair-bond maintenance; dominant female apparently initiates much of calling. Contact calls "chuk", "wik-horr", "chewherrrr" and "chullit"; "chucker" call associated with location of prized food, and growling with aggression at roost; alarm calls sharp squealing, screaming and churring notes. Breeding male directs soft chick-like soliciting call at breeding female. Bill-snapping also characteristic.
Habitat. Well-developed, moist deciduous broadleaf woodland, including *Baikiaea*, *Brachystegia*, *Colophospermum* (the last only when particularly tall and profuse) and, especially in drier areas, riverine woodland; also lowland forest and juniper (*Juniperus*) forest. When non-breeding, wanders to isolated thickets and scrub, drier tall savanna and mixed acacia (*Acacia*) woodland, forest, plantations and mangroves. Prefers damper woodland than that occupied by *P. plumatus*. Usually below 1500 m, but occasionally to 1900 m.
Food and Feeding. Diet mainly insects, e.g. beetles (Coleoptera), butterflies and moths (Lepidoptera), caterpillars and other larvae, cicadas (Cicadidae), grasshoppers (Orthoptera), praying mantises (Mantidae), termites (Isoptera); also spiders (Araneae) and small reptiles, e.g. geckos (Gekkonidae) and other lizards. Hunts among branches, twigs and leaves in upper vegetation levels, typically higher than levels preferred by *P. plumatus*. At times hangs upside-down in manner of tits (Paridae), and seems also to utilize auditory cues in prey location. Sometimes catches prey on ground, also in flight in manner of muscicapid flycatcher. In study in Zimbabwe, 48% of hunting on branches, 25% on trunks, 22% on twigs, 2% on leaves, 1% in bushes, 1% on ground and 1% aerially. Apparently more arboreal and more mobile than *P. plumatus*. Lives and forages in tightly knit groups of usually 2–15 individuals (4·7), sometimes more, up to 30 recorded. In winter period, joins mixed-species parties with *P. plumatus* and *P. scopifrons*, as well as other birds, e.g. Old World orioles (Oriolidae), drongos (*Dicrurus*), tits and woodpeckers (Picidae), and may be a catalyst species in formation of these parties.
Breeding. Egg-laying mainly Jan–Mar and Sept in E Africa and Aug–Mar (peak Sept–Oct) in C & S Africa, nesting believed stimulated by trees coming into leaf; sometimes double-brooded, and in Zimbabwe mean of 1·9 nesting attempts per season (sometimes conceivably associated with group splitting, with two breeding females). Monogamous; pair-bond maintained by allopreening and duetting. Co-operative breeder, all group-members assisting in nest-building and all other aspects of nesting duties (breeding group typically slightly smaller than non-breeding ones), likely intra-group dominance hierarchy, with breeding female at top, followed by breeding male, and then other group adults and offspring (subordinate males and females likely respective siblings of dominant pair); rarely, breeding pair nests alone. Nest solitary, in large territory of c. 30 ha. Courtship marked by slow wing-flapping, and male with nesting material in bill and wings drooped approaching female. Nest, one of which took seven days to build, a shallow cup of lichen, leaf petioles, grass, tendrils and thin bark, bound with spider web (web transported in bill and on erectile frontal crest feathers), lined with fine grass and bark strips, external diameter 10–13·3 cm, depth 3·5–5 cm, internal diameter 7–7·7 cm, depth 1·5–3 cm; placed 3–17 m (typically c. 7 m) above ground and usually in fork on horizontal branch, often one covered in lichen, in S of range frequently in *Pterocarpus* or *Brachystegia*, often in dominant tree in landscape; nest less neat, wider, shallower and thicker-walled, and situated higher in tree, than that of *P. plumatus*; some nests less than 80 m from nest of latter. Clutch 2–5 eggs, usually 3–4, in Zimbabwe average 3·9 and in S of range 3·4, probably laid on consecutive days; replacement laid if early clutch lost; incubation, probably commencing when clutch complete, by all group-members, bird sitting very tight even when predator in close proximity, incubation period c. 17 days; chicks fed by all members of group, nestling period c. 20 days; post-fledging dependence period at least 3 months, young fully independent at c. 7 months, young remain in natal group until adult. Nests parasitized by Thick-billed Cuckoo (*Pachycoccyx audeberti*), e.g. 55% of 29 nests in Zimbabwe. Breeding success, at least in S Africa, only half that of other insectivorous birds in region and lower than that of *P. plumatus*, this likely related to high levels of cuckoo parasitism; in Zimbabwe, 14% of eggs produce fledglings, 18% of nests produce fledglings (reduced from 30% by cuckoo parasitism), average of 0·3 fledglings per nesting attempt, 2 fledglings per successful nest, 0·6 fledglings per group per year; nest contents and group-members vulnerable to avian predators, e.g. African Little Sparrowhawk (*Accipiter minullus*), and other predators; some chicks apparently starve to death. Can probably breed at 2 years. In Zimbabwe, 85% annual survival of adults (yearly variation 69–94%), 79% of fledglings survive first year (annual variation 49–95%).
Movements. Poorly known. Probably largely resident, with some post-breeding dispersive wandering out of breeding home range, especially during drought periods. Possibly some general E–W movement across range, numbers decreasing in W during austral winter.
Status and Conservation. Not globally threatened. Locally common to frequent across large parts of range. Densities typically five times less than those of *P. plumatus*; in S Mozambique, 35 birds/100 ha in *Brachystegia* but fewer than 5 birds/100 ha in other woodlands. Vulnerable to habitat degradation, such as destruction of *Brachystegia* woodland in Zimbabwe; in Kenya has apparently disappeared from Nairobi, Kiambu and Ngong regions.
Bibliography. Chapin (1954), Clancey (1960c), David & Gosselin (2002b), Dowsett *et al.* (2008), Friedmann (1937), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Arnott (1988), Harris & Franklin (2000), Harrison *et al.* (1997), Heinrich (1958), Hockey *et al.* (2005), Newman & Hanmer (1991), Oatley (1969), Short & Horne (1985a), Tarboton (1963), Vernon (1971, 1980, 1984a, 1984b).

7. Gabela Helmet-shrike

Prionops gabela

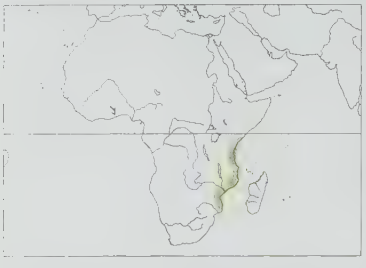
French: Bagadais de Gabela **German**: Gabelabrillenwürger **Spanish**: Prionopo de Gabela
Other common names: Angola Helmet-shrike, Rand's (Red-billed) Helmet-shrike

Taxonomy. *Prionops gabela* Rand, 1957, Gabela area, Angola.
Forms a superspecies, and conceivably conspecific, with *P. retzii*. Monotypic.
Distribution. W Angola from Chio S along and below escarpment to Gabela.

Descriptive notes. 18–19 cm. Has head and neck to upper chest glossy black, slight crest on forecrown to lores projecting over beak; mantle and scapulars to rump grey, tinged brown, long black uppertail-coverts; remiges and outer primary coverts black, outer primaries with white central spots forming bar (visible in flight), inner upperwing-coverts grey; tail black, outer feathers with broad white tips, white decreasing in extent on inner tail feathers towards central pair, which narrowly tipped white; lower chest and upper belly grey, lower belly to undertail-coverts white, underwing-coverts and axillaries dark grey; iris yellow, conspicuous broad orange-red orbital ring with scalloped fringe (especially above eye); bill red, tipped orange-yellow; legs orange-red. Distinguished from very similar *P. retzii* by smaller size, grey (not black) lower breast and upper belly, crest projecting forwards over beak, and less pronounced wingbar restricted to outer primaries. Sexes similar; primary patch possibly smaller on female. Juvenile largely grey-brown above and below, with buff feather tips on upperparts, wing feathers often with narrow white tips, no orbital ring, eyes dark, bill blackish, legs yellow-orange. Voice. Almost unknown. Churring and clicking notes similar to those of *P. retzii*.
Habitat. Dry forest, gallery forest and secondary forest, also thickets and clearings, including coffee plantations in forest. Absent from nearby *Brachystegia* inhabited by *P. retzii*. Mainly 100–900 m; most recent records from dry forest at c. 300 m.
Food and Feeding. Diet insects, including larvae. Usually forages in canopy. Lives and forages in tightly knit groups of 3–8 individuals.
Breeding. Egg-laying apparently Jun–Sept. Likely co-operative breeder. No other information.
Movements. No information. Probably mainly resident, but records from dry thicket and open woodlands below escarpment suggest some post-breeding wandering.
Status and Conservation. ENDANGERED. Restricted-range species: present in Western Angola EBA. A very poorly known species. Has very small, fragmented range of c. 4600 km², and probably very small and declining population of c. 1000–2500 individuals. Previously known only from Gabela area, Londa, Mumbondo, and Roça Cassembo, and not uncommon in Amboim Forest. No records since 1970s until 2003, when group of eight individuals found in open woodland between Kumbira and Seles, at base of escarpment. In 2005, ten groups located in Kissama, Bimbe and Bango regions at elevation of 300 m, and away from base of escarpment. Threatened by habitat clearance by subsistence farmers, mainly for charcoal production but also for bananas, sweet potatoes, cassava, coffee and maize. In Gabela area, c. 30% of forest cleared prior to 1992 and large areas of forest currently being cleared for agriculture. This species is, however, tolerant of some habitat modification. With end of hostilities, human development in this area expected to be rapid. Relict coffee plantations, abandoned after onset of civil war in mid-1970s, now being encroached upon by subsistence agriculture; commercial activities on Angolan escarpment almost certain to

resume, including probable replacement of shade coffee with sun-tolerant varieties. Although marketing of local produce restricted by poor state of the Sumbe–Gabela road, this route is scheduled for early reconstruction, which would lead to increased development and agriculture in region. This species' range includes Kissama National Park.

Bibliography. Anon. (2008d), Butchart & Stattersfield (2004), Collar & Stuart (1985), David & Gosselin (2002b), Dean (2000b, 2001), Fry *et al.* (2000), Hall & Moreau (1962, 1970), Harris & Franklin (2000), Heinrich (1958), Rand (1957a), Ryan *et al.* (2004), Stattersfield & Capper (2000).



8. Chestnut-fronted Helmet-shrike

Prionops scopifrons

French: Bagadais à front roux **Spanish**: Prionopo Frentirrufo
German: Braunstirn-Brillenwürger

Taxonomy. *Sigmodus scopifrons* W. K. H. Peters, 1854, Mozambique.
Three subspecies recognized.

Subspecies and Distribution.
P. s. kirki (W. L. Sclater, 1924) – S Somalia (Boni Forest), coastal Kenya and NE Tanzania.
P. s. keniensis (van Someren, 1923) – C Kenya (Meru and Ngaia forests).
P. s. scopifrons (W. K. H. Peters, 1854) – coastal SE Tanzania, E Mozambique and extreme E Zimbabwe.

Descriptive notes. 16–18 cm; 20–40 g. Smallest member of family. Nominate race has slight, neat chestnut crest on forehead, forecrown light grey, lores white, upper chin sometimes with some white, hindcrown, nape and rest of head (ear-coverts and cheek) blackish-grey, upperparts paler grey with brown tinge; remiges and outer primary coverts blackish, primaries with broad white central bar (conspicuous in flight), tertials and inner upperwing-coverts grey; uppertail slightly glossy black, broad white tips on outer feathers, white decreasing in extent on inner feathers towards central pair, which narrowly tipped white; throat dark grey, chest and upper belly grey, lower belly to undertail-coverts white, underwing-coverts and axillaries grey; iris yellow with red-orange outer ring, bare skin at rear of eye purplish, conspicuous broad blue-grey orbital ring with scalloped fringe; bill red, tipped orange-yellow; legs red. Differs from *P. retzii* mainly in smaller size, greyer appearance, with chestnut crest and blue-grey orbital ring. Sexes similar, female slightly duller than male. Juvenile has brown head and crown feathers tipped whitish, body and wings paler and browner, feathers of upperparts tipped whitish and underparts faintly barred, wing feathers often with narrow white tips, no orbital ring, eyes brown, bill and legs blackish (both later yellow); acquires full adult appearance in second year. Race *kirki* is paler and browner above and below than nominate, forecrown even paler and more contrasting, pale throat contrasts strongly with darker cheeks, but lacks white on lores and chin, wingbar less pronounced; *keniensis* is larger, lacks light grey forecrown, wingbar even less pronounced than on preceding race (absent on upperwing, only faintly discernible below). Voice. Highly vocal and many calls similar to those of sympatric *P. retzii*, e.g. whistled song of both similar to that of Old World orioles (Oriolidae). At least some calls may reflect individual gender and social status. Typical call of nasal, grating notes likened to aggressive trill of Lesser Honeyguide (*Indicator minor*). Also other buzzing, chattering, chuckling, churring, gobbling, growling, humming, rattling, slurred, tinkling, trilling, whirring and winding calls, frequently alternated with whistling notes. Sharp "shuk" possibly in alarm. Bill-snapping characteristic.

Habitat. Mainly lowland and riverine forest and adjacent *Brachystegia* woodland, occasionally wandering to thickets and mangroves; in even better-developed woodland than that occupied by *P. retzii*. Sea-level to 1200 m. Typically occurs close to coast, but extends far inland in places, e.g. Meru and Ngaia forests (in C Kenya), E Usambara Mts, Uluguru Mts, Udzungwa Mts (Magombera and Mwanihana), Pugu Hills and single record from N Pare Mts (in E Tanzania), and Haroni–Rusitu confluence (in E Zimbabwe).

Food and Feeding. Diet insects, e.g. ant-lions (Myrmeleontidae), beetles (Coleoptera), caterpillars, grasshoppers (Orthoptera) and moths (Lepidoptera), as well as spiders (Araneae), small vertebrates, also fruit, e.g. *Ochna* berries. Hunts at all levels of forest; apparently prefers small-leaved trees and seeks prey among branches, trunks and thickets. Sometimes suspended upside-down in manner of a tit (Paridae) when hunting, and seems also to utilize auditory cues in prey location. Frequently takes flying prey on wing in fashion of muscicapid flycatcher (more so than *P. plumatus* and *P. retzii*), often while hovering. Sometimes flops into leaf cluster, apparently to flush prey. Occasionally takes prey on ground. Lives and forages in groups of 3–12 individuals (average seven) during breeding; up to 30 when non-breeding, but largest flocks likely aggregations of more than one group. Group-members more spread out and hence less conspicuous than those of *P. plumatus* and *P. retzii*. In winter months frequently joins parties of *P. retzii*, over which apparently dominant (and reported as outnumbering that species where the two occur together), and also, rarely, *P. plumatus*, as well as those of other bird species, e.g. Old World orioles, woodpeckers (Picidae) and, especially, Green Woodhoopoes (*Phoeniculus purpureus*); apparently does not attract such parties so often as do other members of family. Less shy than *P. retzii*.

Breeding. Egg-laying Dec–Jul (peak Jan–Apr) in N of range and Oct–Dec in S. Co-operative breeder, all group-members assisting in all aspects of breeding; groups likely comprise breeding pair and helpers. Nest solitary; territory large, and all group-members participate in territory defence. Courtship marked by soliciting, and wing-spreading and wing-flapping; claims of courtship feeding require corroboration. Several, probably all, group-members assist in nest construction; a shallow cup of grass and thin bark strips, bound with fibre, moss, lichen and, especially, spider web (web apparently transported in bill and on erectile frontal crest feathers), similar to that of *P. plumatus*, external diameter 6–6·5 cm, depth up to 4 cm, internal depth 2·5 cm; placed 4·5–23 m (average 12 m) up on branch or in fork in middle to upper canopy of large forest tree, e.g. *Brachystegia*, *Breonadia*, *Bridelia* or *Newtonia*, may prefer small-leaved trees for both nesting and foraging. Clutch 3 eggs; incubation, apparently initiated when clutch complete, by variable number of group (division of labour seems to be less marked than for *P. plumatus* and *P. retzii*, with fewer group-members incubating and for longer periods), sitting individual occasionally fed by other group-members; no information on duration of incubation and nestling periods; fledglings probably fed by all or most of group-members. No data on breeding success; aggressive towards, and will strike, potential predators, such as monkeys, eagles (Accipitridae) and owls (Strigidae).

Movements. Appears to be mainly resident; evidence of some post-breeding wandering in S of range.

Status and Conservation. Not globally threatened. Locally common within relatively small and highly fragmented range; numbers decreasing. In Mozambique, uncommon S of R Save but common N of it. Claimed record from Malawi retracted by observers. Reported occurrence in Honde Valley, in E Zimbabwe, and in NE South Africa require confirmation, owing to possible confusion with juvenile *P. retzii*. This species is concentrated along vulnerable and heavily exploited coastal zone with concomitantly high human densities and habitat destruction. Decreasing along most of coastal range, i.e. in Kenya, Tanzania and Mozambique, in many places dramatically, and in Mozambique, at least, threatened by forest and woodland destruction through logging and for subsistence cultivation. Tiny and peripheral Zimbabwe population, if still extant, seriously threatened by habitat destruction by subsistence farmers. Inland Kenyan race (*keniensis*) rare and endangered; has disappeared from Mt Kulal and Mt Marsabit and from Embu District, apparently for reasons largely unrelated to habitat destruction. Current trends suggest that this species is likely to become threatened in foreseeable future.

Bibliography. Britton & Britton (1971, 1977), Fry *et al.* (2000), Hall & Moreau (1970), Harris & Arnott (1988), Harris & Franklin (2000), Harrison *et al.* (1997), Hockey *et al.* (2005), Newman (1991), Newman & Hanmer (1991), Short & Horne (1985a), Solomon *et al.* (1996), Zimmerman *et al.* (1996).

Class AVES

Order PASSERIFORMES

Suborder OSCINES

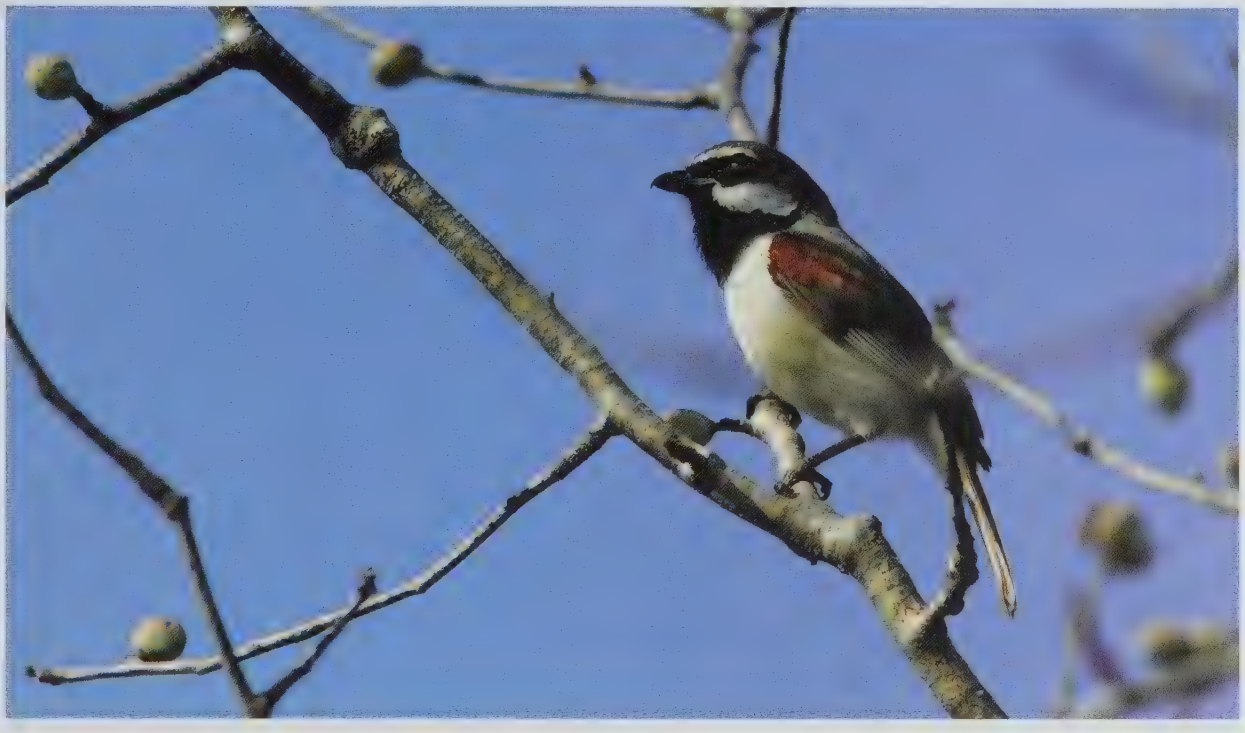
Family VANGIDAE (VANGAS)

- Small to medium-sized passerines varying considerably in morphology and plumage.
- 13–32 cm.

- Madagascar, one species also in Comoro Islands.
- Forest, scrub and thorn-scrub, plantations and wooded areas near forest.
- 12 genera, 15 species, 22 taxa.
- 4 species threatened; none extinct since 1600.

Systematics

According to O. Langrand, in his 1990 *Guide to the Birds of Madagascar*, the family Vangidae consisted of 14 species, of which only the Blue Vanga (*Cyanolanius madagascarinus*) extends beyond the boundaries of Madagascar, being found also in the nearby Comoro Islands. Historically, the majority of the vangids were placed with the shrikes in the family Laniidae, and they have, until recently, generally been considered to be closely related to laniids. In 1932, J. Delacour recognized the vangas as a separate family, for which he used the name *Vangidés*, although this, being a French word, was inappropriate according to the rules of the International Code of Zoological Nomenclature. Four years later, the American ornithologist A. L. Rand renamed the family, employing the name "Vangidae", which is a Latinized version of Delacour's original French name.



Although Rand was thus the first to establish the family Vangidae, his account is very different from the current classification. He assigned the genus *Tylas* to the bulbul family (Pycnonotidae), and he accorded the monotypic genera *Euryceros* and *Hypositta* family status, as, respectively, Eurycerotidae and Hyposittidae. In 1960, in J. L. Peters's *Check-list of Birds of the World*, Rand continued to place *Tylas* with the bulbuls, but he aligned *Hypositta* with the tit family (Paridae). In that same year, however, J. Dorst presented another classification of the vangas, in which he included 14 species, those currently recognized as constituting the family. At the time, the Red-shouldered Vanga (*Calicalicus rufocarpalis*) had not been described. Dorst based his treatment on the morphological similarities among the members of this family, features such as the shape of the skull, the attachment of the jaw muscles, the pterylae of nestlings and the scutellation of the tarsus, and he placed both *Hypositta* and *Tylas* in the Vangidae. Others have assigned *Tylas* either to Pycnonotidae, as had Rand, or to the Old World orioles (Oriolidae), the thrushes (Turdidae) or the starlings (Sturnidae).

It has for long been recognized that the vangas represent a radiation confined within the Madagascar region. The question of the monophyly of this group, however, remained unresolved. Recent research, using DNA-sequence data from several different genes, both mitochondrial and nuclear, supported the validity of the traditional view, namely that the Vangidae formed a monophyletic group, and that the Tylas Vanga (*Tylas eduardi*) was a member of this family. More remarkably, recent authors not only retained all of the current taxa of the Vangidae within this family, but included in it, on the basis of DNA analyses, several additional taxa previously assigned to other families. These are the newtonias (*Newtonia*), which have generally been placed with the Old World warblers (Sylviidae) or the Old World flycatchers (Muscicapidae), Ward's Shrike-flycatcher (*Pseudobias wardi*), often included with the batises and wattle-eyes (Platysteiridae), and the Madagascar Groundhunter (*Mystacornis crossleyi*), which has been aligned with the babblers (Timaliidae), although frequent doubts have been expressed over the true affinities of these species. It seems very likely that all of them should, indeed, be placed in Vangidae, and this has been the preferred arrangement by most recent authors, including E. C. Dickinson in the third edition of *The Howard and Moore Complete Checklist of the Birds of the World*.

The radiation of the Vangidae may surpass that of Darwin's finches (Emberizidae) or Hawaiian honeycreepers (Drepanididae) in terms of the number of genera into which they have differentiated, and the diversification of body size, bill shape and plumage coloration. Recent DNA-sequence analysis suggests that they form a monophyletic group with an African origin. Some forms fill niches that are occupied elsewhere by woodpeckers (Picidae), shrikes (Laniidae), tits (Paridae) and nuthatches (Sittidae), all of which are absent from Madagascar. The ***Hook-billed Vanga*** *is a shrike-like, sit-and-wait predator found in many forest habitats.*

[*Vanga curvirostris curvirostris*, Ampijoroa, Madagascar. Photo: Ketil Knudsen]

*The **Red-tailed Vanga** is a small vanga reminiscent of a tit (Paridae). The inclusion of the genus* Calicalicus *in Vangidae has been generally accepted for over half a century. But though recent molecular-genetic analysis places it close to other vanga genera, analysis of morphological characters suggests it may not belong in the family at all, but could be closer to the drongos (Dicruridae) and the monarch-flycatchers (Monarchidae). The same analysis contradicts the DNA evidence for an African origin, suggesting that the most recent common ancestor of the vangas reached Madagascar from the east.*

[*Calicalicus madagascariensis*, Madagascar. Photo: Jürgen Schneider]

S. Yamagishi and colleagues undertook a detailed study of the phylogenetic relationships of the Vangidae and produced a dendrogram to illustrate the results. They used the Bull-headed Shrike (*Lanius bucephalus*), in the family Laniidae, and the Australian Magpie (*Cracticus tibicen*), a member of the butcherbird family (Cracticidae), as outgroups. The phylogenetic relationships revealed in this study suggest that the Vangidae have a closer relationship with the cracticids than they do with the shrikes. It appears that, within a relatively short period of time after arriving in Madagascar, the common ancestor of the vangids simultaneously differentiated into five lineages. The first of these, "group 1", contains the Tylas Vanga, and "group 2" the Nuthatch Vanga (*Hypositta corallirostris*); the third group contains the ancestor of the Chabert Vanga (*Leptopterus chabert*) and the Common Newtonia (*Newtonia brunneicauda*), while "group 4" consists of the ancestor of the Sickle-billed Vanga (*Falculea palliata*), White-headed Vanga (*Artamella viridis*), Bernier's Vanga (*Oriolia bernieri*) and Van Dam's Vanga (*Xenopirostris damii*); the final lineage, "group 5", is the ancestor of the Blue Vanga, Red-tailed Vanga (*Calicalicus madagascariensis*), Hook-billed Vanga (*Vanga curvirostris*), Helmet Vanga (*Euryceros prevostii*) and Rufous Vanga (*Schetba rufa*). The order in which the groups diverged is not clear from the molecular data, but these do indicate that the ancestor of group 3 split into the Chabert Vanga and the Common Newtonia approximately 2·3 million years ago, and that of group 4 differentiated into the White-headed, Bernier's and Van Dam's Vangas approximately 1·1 million years ago, after the Sickle-billed Vanga had separated from the ancestor. Lastly, the ancestor of group 5 differentiated into the Helmet Vanga and the Rufous Vanga approximately 800,000 years ago.

A high degree of similarity exists between the group consisting of the Sickle-billed, White-headed, Bernier's and Van Dam's Vangas and that comprising the Helmet and Rufous Vangas, which has differentiated relatively recently. Although there is great diversity in bill shape within each group, as demonstrated by the Sickle-billed and White-headed Vangas, and the Helmet and Rufous Vangas, there are close similarities in plumage coloration. The vangas belonging to the former group show black-and-white coloration with the mouth deep black (see Morphological Aspects), whereas the plumage of the latter group is rufous-brown and black. The coloration resemblance within a group is especially marked in the case of the Sickle-billed and White-headed Vangas in group 4 and, in group 5, the Helmet and Rufous Vangas, although all of the species differ in the type of bill that they possess. In other words, the development of such variation as is found in bill size and shape appears to have occurred in a relatively short timespan of one million years or so. In contrast, variation in plumage coloration appears to have been more conservative and gradual.

There are two well-known examples of avian adaptive radiation on remote islands. These are the group of birds commonly known as "Darwin's finches" (Emberizidae), on the Galapagos Islands, and the Hawaiian honeycreepers (Drepanididae), in the Hawaiian Islands. Darwin's finches are textbook examples of the diversification of a single founding population into an array of taxa adapted in varying ways to diverse environmental niches of the Galapagos and Cocos Islands. Hawaiian honeycreepers likewise have adapted to the new environments through evolutionary changes in bill shape and coloration. The radiation of

Sole member of the genus Oriolia, ***Bernier's Vanga*** *is a medium-sized vanga with a stout conical bill. This species is sexually dimorphic: the male is entirely glossy black, whereas the female is dark rufous-brown with fine black barring. Within a relatively short period of time after arriving in Madagascar, the common ancestor of the vangas simultaneously differentiated into five lineages. Bernier's Vanga is part of a lineage which includes the Sickle-billed* (Falculea palliata)*, White-headed* (Artamella viridis)*, and Van Dam's Vangas* (Xenopirostris damii)*. These vangas have each taken on part of the role of woodpeckers (Picidae); Bernier's is able to cling to almost vertical trunks in woodpecker fashion.*

[*Oriolia bernieri*, Masoala National Park, Madagascar. Photo: Andrew Moon]

Ten of the twelve currently recognized vangid genera are monospecific, and the extraordinary diversity in size, colour and bill shape leads to taxonomic confusion even today. There can be no such confusion with the three members of the genus Xenopirostris. *All are stocky and possess a thick, laterally compressed bill which they use as a tool for ripping bark from dead wood.* ***Lafresnaye's Vanga*** *has mostly black and white plumage. This bird is a female; the male has a black head with a broad white collar.*

[*Xenopirostris xenopirostris*, Berenty, Madagascar. Photo: Ketil Knudsen]

Malagasy vangas may surpass that of Darwin's finches or the Hawaiian honeycreepers in terms both of the number of genera into which they have differentiated and the diversification of body size, bill shape and plumage coloration.

Only very recently has a full cladistic analysis of the relationship of vangas based on morphological characters been undertaken. This study, carried out by A. Manegold, looked at 40 morphological characters of 36 vangid and non-vangid taxa, and the results were published in 2008. Most interestingly, Manegold's findings indicated that the Tylas Vanga, the Madagascar Groundhunter and the newtonias did not belong in the Vangidae, despite the preferences of most recent taxonomists. Moreover, he suggested that the Red-tailed Vanga, too, should be excluded from the family. Manegold's analysis led also to the hypothesis that the "true" vangas, as defined in his study, formed a monophyletic group with the Australasian woodswallows (Artamidae) and the Australo-Papuan butcherbirds, and that the sister-taxon of this clade was probably the New Guinean peltops (*Peltops*). If such a relationship were to be confirmed, it would imply that the most recent common ancestor of the vangas reached Madagascar from the east, following a process of dispersal across the Indian Ocean. This hypothesis conflicts with those derived from DNA-sequence analysis, which propose the helmet-shrikes, bush-shrikes and platysteirids as the closest relatives of the vangas, therefore indicating an African origin of this group. On the other hand, it accords in part with the findings of W. P. Pycraft, published a century ago, in 1907.

Although there are great differences between the bills of the Sickle-billed Vanga (Falculea palliata) *and* ***White-headed Vanga****, there are close similarities in their plumage coloration. These species apparently split from their common ancestor around 1·1 million years ago. A similar differentiation in bill size and shape, but similarity in plumage, is found in two members of another lineage, Helmet* (Euryceros prevostii) *and Rufous Vangas* (Schetba rufa). *Thus, while development of such variation as is found in bill size and shape appears to have occurred in a relatively short time span, variation in plumage coloration appears to have been more conservative and gradual. Two races of White-headed Vanga are tentatively recognized, based on a slight difference in bill size.*

[*Artamella viridis annae*, Ampijoroa, Madagascar. Photo: Ketil Knudsen]

Although the taxonomic position of *Calicalicus* in Vangidae has been generally accepted for well over half a century, this taxon lacks almost all of the derived characters which the butcherbirds, vangas and woodswallows share. Manegold's findings suggest that the Red-tailed Vanga is probably closer to the drongos (Dicruridae) and the monarch-flycatchers (Monarchidae) than it is to the vangas. In this context, it is noteworthy that O. Appert, in his extensive study on the biology of the Vangidae, emphasized the fact that the Red-tailed Vanga differs from other members of the family in its nest-building behaviour, as well as in the colour and markings of its eggs.

Not only are ten of the twelve currently recognized vangid genera monotypic, but nine of the 15 species are likewise monotypic. Of the polytypic species, two exhibit rather poorly marked subspecific differentiation and are perhaps better considered monotypic. The western and southern race of the White-headed Vanga, *annae*, differs from the nominate race only in having a very slightly longer bill. Similarly, the western race of the Rufous Vanga, *occidentalis*, has a marginally longer and heavier bill than that of the nominate race, which it otherwise resembles closely.

On the other hand, the populations of the Blue Vanga inhabiting the Comoro Islands are sometimes treated as a separate species, distinct from those on Madagascar. The two Comoro subspecies are larger than the nominate, Madagascan race, and they appear to differ further from it in plumage and bill size, the

*The **Sickle-billed Vanga** is probably the most distinctive member of the family, with its exceptionally long, markedly decurved bill. At 32 cm, with a bill length of up to 7 cm, and weighing as much as 199 g, the Sickle-billed Vanga is the largest of the vangas. This species is not sexually dimorphic. The black upperparts have a blue sheen; in the otherwise similarly plumaged White-headed Vanga* (Artamella viridis) *the sheen is green. Like two other members of its lineage, the White-headed and Van Dam's Vangas* (Xenopirostris damii), *the Sickle-billed Vanga has the inside of the mouth an intense black, as though painted with black ink.*

[*Falculea palliata*, Ifaty, Madagascar. Photo: Jacques Erard]

male having the entire upperside washed lilac, the inner webs of the inner secondaries blue, rather than black, and the bill longer and thinner. In addition, the subspecies on Mohéli, *comorensis*, is reported as uttering a grating "prrrt" call which is softer than a similar note of the nominate race, and also a more protracted "teea". The Grand Comoro subspecies, *bensoni*, is extremely rare and very poorly known (see Status and Conservation). It seems to be very similar to *comorensis*, but with a shorter bill, and should perhaps be treated as a synonym of the latter.

Finally, the poorly known western subspecies *albigularis* of the Tylas Vanga appears to differ from the nominate race in plumage and voice, having a white throat and a pale pinkish-orange breast and belly, whereas the nominate race has a complete black hood extending down to the throat and uppermost breast and has deep orange-buff underparts. Because of these differences, *albigularis* has sometimes been thought to represent a separate species. In this case, however, there seems to be some individual variation and overlap in plumage characters, and a few individuals of each race exhibit plumage features typical of the other race. Moreover, observations at Ambohitantely and other higher-lying parts of its range have revealed that both white-throated and black-throated Tylas Vangas occur in one and the same area.

In 1996, D. S. Peters came across two odd specimens in a drawer in the bird collection of the Senckenberg Research Institute and Natural History Museum, in the German city of Frankfurt am Main. It was immediately obvious that these were unlike any other Madagascan bird species hitherto known. They were similar in size to the Nuthatch Vanga, and had the same loose plumage structure as the latter. The plumage was plain olive-brown, with a blackish forehead. In particular, the tarsus was much longer and the toes significantly shorter than those of the Nuthatch Vanga, which seemed to be the closest relative of this supposed new taxon. Both specimens were deemed to be recently fledged juveniles, and they were described as a new species, "*Hypositta perdita*". The two specimens had been collected in 1931, in primary forest near Eminiminy, a village north of Tôlanaro, formerly known as Fort Dauphin; the locality is adjacent to the Andohahela National Park, in south-east Madagascar. The apparent new species was given the English vernacular name of "Bluntschli's Vanga", after the original collector, H. Bluntschli. Unfortunately, no further individuals have ever been seen in the wild. It is impossible to determine the true taxonomic status of these two juveniles, and it could be that they are simply aberrant examples of, perhaps, the Nuthatch Vanga. Nevertheless, it remains feasible that they do, indeed, represent a different species, or a subspecies, but the little that is known of "Bluntschli's Vanga" precludes any valid assessment.

*Recent genetic analysis indicates that the ancestor of the **Chabert Vanga** split into this species and the Common Newtonia* (Newtonia brunneicauda) *around 2·3 million years ago. The Chabert Vanga is a relatively small, black-and-white vanga, with a ring of bright blue bare skin around the eye. The sexes are similar, whereas the juvenile lacks the blue eyering. The Chabert Vanga has a "generalized" bill, rather than one of the highly specialized bill types found in some other members of the family. It catches insects in the air, in the manner of a flycatcher, and makes use of all the forest types on Madagascar, including secondary growth and plantations, sometimes far from native forest.*

[*Leptopterus chabert schistocercus*, Ifaty, Madagascar. Photo: Jimmy Chew]

Morphological Aspects

Of the several avian families endemic in Madagascar, Vangidae is probably the best-known one. Such is the diversity in size,

*The **Blue Vanga** is the only member of the family found beyond the shores of Madagascar. The populations of the Blue Vanga inhabiting the Comoro Islands are sometimes treated as a separate species. The race* comorensis, *from Mohéli in the west-central Comoros, is larger than the Madagascan nominate form, with a longer, thinner bill, and with distinct differences in plumage, such as the very bright upperparts of the male; its calls also differ. The extremely rare and poorly known Grand Comoro race,* bensoni, *is very similar to* comorensis, *but with a shorter bill.*

[*Cyanolanius madagascarinus comorensis*, Mohéli, Comoro Is. Photo: Pete Morris]

colour and, in particular, bill size and shape shown by the 15 species currently included in the family that it is difficult to imagine that they are related at all. The high degree of morphological divergence leads to taxonomic confusion even today.

So far as body length is concerned, vangas range from 13 cm, as in the case of the Nuthatch Vanga, to 32 cm, the length of the Sickle-billed Vanga, a size increase of almost 250%. Plumage colour is diverse, with white, black, blue, auburn and ash-grey exhibited among the various species. The scientific names reflect this. For example, the Hook-billed Vanga is *Vanga curvirostris*, "vanga" being a Malagasy word for "black-and-white" and the specific epithet meaning "curved bill" in Latin. Thus, the nomenclature signifies "black-and-white bird with a curved bill". The plumage of the Hook-billed Vanga is pied. The White-headed Vanga also has a black-and-white body, but its body size and bill size are smaller than those of the Hook-billed Vanga.

Bill shape varies so widely across the family that one could be forgiven for thinking that the vangas belong to several different families. On the basis of the combined measurements of six bill elements, there are five basic types of bill. Using the analogy of gripping tools, these are: the "forceps type", as possessed by the Sickle-billed Vanga; the "radio pliers type", as on the White-headed and Hook-billed Vangas; the "strong pincers type", presented by Pollen's (*Xenopirostris polleni*), Lafresnaye's (*Xenopirostris xenopirostris*) and Van Dam's Vangas; the "pliers type", as on the Helmet Vanga; and the "generalized type", demonstrated by the Rufous, Blue, Chabert, Red-tailed, Nuthatch and Tylas Vangas. The last group can be split into two subgroups, the Rufous, Blue, Chabert and Red-tailed Vangas representing the "standard type" and the Tylas and Nuthatch Vangas representing the "flat forceps type". Thus, the vangas may be divided into six groups according to bill type.

The bill shape and foraging behaviour of vangas resemble those of, variously, the shrikes, the tits, and the treecreepers (Certhiidae), among others. Today, vangas fill niches that are occupied, in other parts of the world, by woodpeckers (Picidae), woodhoopoes (Phoeniculidae), shrikes, tits, treecreepers and nuthatches (Sittidae), all of which are absent from the Madagascar region.

Bill size and shape reflect the size of the insect prey taken, the precise site where it is caught and the mode of its capture. Larger species, such as the Hook-billed Vanga, have a robust bill with a characteristic hook at the tip, which help them in dealing with their carnivorous diet of large insects, chameleons (Chamaeleonidae) and other small vertebrates. The Helmet Vanga has a massive blue bill, 51 mm long and 30 mm deep, and this species likewise feeds on large insects and chameleons. Bernier's Vanga, which may not be a true vangid (see Systematics), is smaller than the Helmet Vanga and has a fairly stout, conical bill suited to its diet of invertebrates and very small vertebrates. The male is entirely glossy black, whereas the female is dark rufous-brown with fine black barring.

Members of the genus *Xenopirostris* use the laterally compressed bill as a tool for ripping bark from dead wood. All three species are stocky in build and possess a thick bill. In contrast, the much smaller and less bulky Chabert Vanga behaves in the manner of a flycatcher, employing its thick bill for the purpose of catching insects in the air. This species has a highly distinctive broad ring of bright blue bare skin around the eye.

The Sickle-billed Vanga is the largest and the most easily identifiable member of the family. It has an exceptionally long bill, up to 70 mm in length, which is markedly decurved, and light grey in colour. The extraordinary shape of this bill, which is used for probing crevices in the bark of trees, presents a stark contrast to the huge deep bill of the Helmet Vanga. The Sickle-billed, White-headed and Van Dam's Vangas have an intense black coloration inside the mouth, as if it had been painted with black ink.

Rather small to medium-sized for a vangid, the Rufous Vanga is distinctive in its tricoloured plumage, with black on the head, white on the breast and reddish-brown on the back. Whereas the Hook-billed, Helmet and Sickle-billed Vangas are not sexually dimorphic, the Rufous Vanga displays clear sexual differentiation in plumage. The male has the entire head and the region from the throat to the breast black, while the female has only the area from the head to just below the eyes black, the cheeks and the area from the throat to the breast being white. This species is a co-operative breeder (see Breeding), and helpers, all of which are males, exhibit two types of plumage coloration. One is fully black-throated and is identical to the plumage of the paired male, while the other type has the throat whitish with black spots, the latter representing the immature male.

The distinctive, tri-coloured ***Rufous Vanga*** *shows clear sexual dimorphism. The male has the entire head and the region from the throat to the breast black, while the female is black down only to just below the eyes, the cheeks and the area from the throat to the breast being white. There are two recognized subspecies of this medium-sized vanga, with its strong, broad, "generalized" bill. The western race* occidentalis *differs from the nominate only in its slightly longer, heavier bill, and the species may better be regarded as monotypic.*

[*Schetba rufa occidentalis*, Ampijoroa, Madagascar. Photo: Jacques Erard]

Similarly, the White-headed Vanga exhibits sexual dimorphism in plumage. The male is all white except for a glossy black mantle, rump and tail, but the female has the head greyish. This species, too, is a co-operative breeder, but in its case the helper, probably a male, is always in immature plumage, similar to that of the female.

The smaller vangid species, including Red-tailed, Red-shouldered, Nuthatch and Blue Vangas, have a much finer bill, one which is suited more to gleaning small insects on branches and tree trunks. The Tylas Vanga was once classified as a bulbul. It resembles Pollen's Vanga in plumage coloration, but has a much finer bill.

Habitat

Vangas are found in all forest habitats of Madagascar. They are distributed over the entire area of the island, except for the central highlands. The highlands support steppe vegetation, which is dominated by shrubs, but these are mostly small and patchily distributed. Several arboreal birds, including vangas, are therefore absent from the central highlands.

The island-wide distribution of this family does not imply that all species of vanga are found in almost all parts of the island. The central highlands divide the climate of Madagascar into two distinct regions, the dry western region and the humid eastern region, and the vegetation is likewise clearly separated into two main types, while the southern region has a semi-arid climate. The western region is vegetated with deciduous broadleaf forest, the eastern region is dominated by tropical or montane rainforest, and the southern region is characterized by thorn-forest with plant species adapted to arid environments.

General observations indicate that the Red-tailed Vanga lives in native forest of various types, including deciduous forest in the west and evergreen humid forest in the east, and extending into adjacent second growth, but it normally avoids sub-arid scrub. Sub-arid thorn-scrub seems, however, to be the primary or exclusive habitat of its sole congener, the recently described Red-shouldered Vanga. Hook-billed Vangas are denizens of native forest, including primary and degraded forest, and are particularly fond of dense scrub-forest. They can be seen also around villages, and are recorded even in plantations far from natural forest. Bernier's Vanga is confined to evergreen humid forest in the lowlands, ascending to about 1000 m, but it is patchily distributed and is generally scarce.

Lafresnaye's Vanga inhabits sub-arid thorn-scrub, exhibiting a strong preference for areas with plentiful dead wood. It is observed most frequently in native spiny forest with areas of euphorbia (*Euphorbia*) and octopus tree (*Didierea*), and occurs from sea-level to 100 m. This species' two congeners are found only in primary forest, Van Dam's Vanga in western deciduous forest and Pollen's Vanga in eastern evergreen humid forest; both will occasionally visit wooded areas immediately adjacent to these habitats. Sickle-billed Vangas occur in dry forest and thorn-forest, in savanna with sufficient trees, and in the wooded outskirts of villages.

The White-headed Vanga is common and widespread in Madagascar, where it is found in all types of native forest, as well as in savanna and in wooded areas distant from native forest. The nominate race occurs mainly in evergreen humid forest in the east of the species' range, while subspecies *annae* is distributed in various habitats in the west and south of the island. Similarly widespread, the Chabert Vanga also utilizes all forest types, including secondary growth and plantations, as well as scrubby vegetation, sometimes far from native forest. The nominate race is common in eastern forests, especially evergreen humid forest, and is particularly numerous on the edges of western primary forest, while the south-western subspecies, *schistocercus*, is reasonably common in wooded areas. The species is found at up to 1800 m, but it is most common below 1000 m.

The Blue Vanga is present on both sides of Madagascar, inhabiting deciduous dry forest and adjacent second growth in the west and evergreen humid forest in the east, and ranging from sea-level to about 1200 m. Very occasionally, it is recorded at higher elevations, to 1600 m, in areas where large trees are present, but it appears to be absent from the subdesert areas of the south-west and south. This is the only member of the family that occurs outside Madagascar, the races *comorensis* and *bensoni* being found in forest habitats in the Comoro Islands, between the north-east coast and the African mainland.

Lowland primary forest is the habitat of the Rufous Vanga, which occupies the deciduous forest of the west and the ever-

*The **Helmet Vanga** and the Rufous Vanga* (Schetba rufa) *were apparently the last vanga species to become differentiated, when they split from their common ancestor probably around 800,000 years ago. The Helmet Vanga's massive, arched and hooked blue bill, 51 mm long and 30 mm deep, is unmistakable. Despite this conspicuous feature, this species is difficult to find, as it is secretive and often sits immobile in the subcanopy for long periods. The bill of the juvenile is initially horn-coloured, and the plumage is buff where the adults are black, and dark brown where the adults are rufous.*

[*Euryceros prevostii*, Masoala National Park, Madagascar. Photo: Nick Garbutt/ Indri Images]

green humid forest of the east. It prefers an open understorey and large trees. Helmet Vangas are found only in dense evergreen humid forest, chiefly at 400–900 m, but sometimes down to 200 m and occasionally to 1800 m.

The remaining two species in the family have largely overlapping distributions in eastern Madagascar, each in undisturbed rainforest. The Tylas Vanga occasionally ventures into adjacent second growth, and both it and the Nuthatch Vanga are found from sea-level to 1800 m. A second subspecies of the Tylas Vanga occurs in western Madagascar, where *albigularis* has been recorded from sea-level to approximately 900 m in deciduous dry forest and, on a few occasions, in mangroves. It is, however, a very poorly known taxon, and appears to be rare and local.

The distribution of each species of vanga is closely related to and dependent on the climate and vegetation. For example, Bernier's Vanga and the Helmet Vanga are found primarily in the Masoala Peninsula, in the north-eastern part of Madagascar, whereas the Nuthatch and Pollen's Vangas are distributed in the rainforest of the humid eastern region. In contrast, the Sickle-billed Vanga is restricted to the dry forest of the western region. The Hook-billed and White-headed Vangas can be found throughout the eastern and western parts of the island. The Tylas Vanga, on the other hand, occurs chiefly in the eastern part of the island, its distribution on the western side being limited. Van Dam's Vanga is found only locally in the dry western region. The Red-tailed, Blue and Rufous Vangas are distributed extensively over the eastern and western regions of the island, but are absent from semi-arid thorn-forest, as well as the central highlands. Both Lafresnaye's Vanga and the Red-shouldered Vanga are found in south-western Madagascar, and the recently described Red-shouldered Vanga is known only from the Toliara region of the south-west.

General Habits

All vangas are distinctly arboreal, spending most of each day in foraging, often quietly, in the trees within their territories. Despite the the fact that the vangids are adapted to an arboreal life, one species, the Rufous Vanga, sometimes descends to the ground and even forages there, hopping along.

Although the vangas differ strikingly in their morphology and foraging behaviour, the differences between the species in terms of their social structure appear to be marginal. The vangas have speciated within forest habitats, but have barely colonized habitats beyond the forest. Although the habitat is structurally complex, the width of the habitat niche and the width of the feeding niche are relatively narrow. This situation seems not to have affected the social structure of the various species.

Outside the breeding season, vangas may be engaged in highly social activities in two distinct situations. These concern mixed-species flocks and communal roosts. A characteristic feature of forest-dwelling birds in tropical regions, including Madagascar and the Comoros, is the formation of mixed-species flocks, particularly outside the breeding season. These flocks are generally seen in the lower strata of forests. In Madagascar, vangas usually constitute the mainstay of multi-species foraging flocks, which sometimes include more than one species each of vanga and newtonia and often contain other small forest passerines, such as jeries (*Neomixis* and *Hartertula*), weavers (*Ploceus*), drongos, the Madagascar Cuckoo-shrike (*Coracina cinerea*), tetrakas (*Bernieria* and *Xanthomixis*), paradise-flycatchers (*Terpsiphone*) and *Cinnyris* sunbirds. The Rufous Vanga is often a leader in mixed flocks. This species exhibits no change in foraging behaviour when in mixed-species flocks and does not increase its foraging rate in line with that of other species.

During the non-breeding season, the Sickle-billed Vanga forms large flocks of 20–30 or more individuals, and at night it gathers in large communal roosts containing in excess of 50 individuals. The roosting behaviour of this gregarious species is accompanied by noisy babbling, cackling calls. A tall roadside eucalypt (*Eucalyptus*), an introduced tree species, is often selected as a roosting site by Sickle-billed Vangas, and it is thought that the birds use the same tree throughout the year as a communal roost-site. From mid-October to early December, the number of Sickle-billed Vangas present at the roost decreases as breeding pairs leave in order to build their nests in their respective breeding territories. The ones that remain at the roost during this period are likely, therefore, to be unpaired non-breeding individuals, which forage together in a group over a large area. From mid-December onwards, the number of individuals at the roost increases rapidly again, being augmented by the influx of non-

*Earlier authors placed the **Tylas Vanga** in the bulbul family, Pycnonotidae, while others situated it among the Old World orioles (Oriolidae), thrushes (Turdidae) or starlings (Sturnidae). Although recent genetic research indicates that it belongs in Vangidae, this is not supported by cladistic analysis of vanga relationships based on morphological characters. In the context of vangas, this species is medium-sized and rather slender, with a fine bill of the "flat forceps" type. The western race* albigularis *differs so markedly from the nominate in plumage and voice that it is sometimes thought to be a separate species. But a few individuals of each race exhibit characters typical of the other, and white-throated and black-throated forms can occur together.*

[*Tylas eduardi eduardi*, Masoala National Park, Madagascar. Photo: Ketil Knudsen]

breeding individuals and the juveniles which have fledged during the breeding season.

Two other species, the White-headed and Chabert Vangas, show communal roosting behaviour. Like the Sickle-billed Vanga, the Chabert Vanga apparently uses the same tree as a communal roosting site throughout the year. Surprisingly, perhaps, the Rufous Vanga has not been found to roost communally, although it regularly forages in small groups, frequently joins mixed parties, and breeds co-operatively (see Breeding).

Little information is available on the natural predators of vangas. In the dry deciduous forest of western Madagascar, it seems likely that certain raptors and other predators raid the nests of some species (see Breeding). Vangas mob potential predators, such as couas (*Coua*), drongos, brown lemurs (*Eulemur fulvus*) and snakes. The partners, or the flock-members, gather near the predator and utter short and sharp alarm calls. Often, they will cautiously approach the predator, some individuals displaying more aggressively than do others, by arching the neck and drooping the wings.

*Another species that has at various times been assigned to different families is the **Nuthatch Vanga**, the smallest vangid. As its name suggests, this species fills the niche of a nuthatch (Sittidae) in Madagascar. Two juvenile specimens found in a museum drawer, with similar plumage to the Nuthatch Vanga, but a much longer tarsus and shorter toes, were given the name "*Hypositta perdita*", Bluntschli's Vanga. No others have ever been found, and to date it has not been possible to determine their true taxonomic status.*

[*Hypositta corallirostris*, Perinet Special Reserve, Madagascar. Photo: Ketil Knudsen]

Voice

The vocal repertoire of vangas is rich and the pattern of their vocal communication is complex. The most powerful vocalization is the call of the Sickle-billed Vanga, similar to the cawing of a *Corvus* crow. This call is often delivered from the top of a canopy tree or from within vegetation. In contrast, the call given regularly by the Blue Vanga is a very characteristic angry and vowel-less rattle. The voice of Bernier's Vanga is poorly known.

Definite songs are delivered by the Hook-billed Vanga, all three *Xenopirostris* species, and the White-headed and Tylas Vangas. The song of the Hook-billed Vanga is a very penetrating, high-pitched whistle lasting for about two seconds, somewhat ventriloquial and very difficult to locate, repeated at brief intervals. This is often heard in the early morning, and two individuals occasionally counter-sing. The *Xenopirostris* species utter a similar protracted whistle. Male White-headed Vangas defend dispersed territories, in which they have regular songposts; from these the male sings a whistling "weety-woo weety-woo weety-woo". Similarly, the Tylas Vanga utilizes regular songposts, from which it delivers a repeated "weeta weet yew-ew".

In addition, Red-tailed and Red-shouldered Vangas have whistled songs. The former utters a delightful "per-whew", similar to a wolf-whistle made by a human, but in the western parts of its range this species gives a different song, typically "pew-poo-whee" or "oo-oo-whi", the last syllable higher than the preceding ones; moreover, in the area of Morondava, on the central part of the west coast, a song sounding like "plee-plee tick-che-weh" has been heard. The Red-shouldered Vanga's song is a loud "tyuh-tee" or "pu-teer", the second note louder and more whistled than the first, and it is often answered immediately by the female, which emits a contact call.

*The song of the **Hook-billed Vanga**, often heard in the early morning, is a very penetrating, high-pitched whistle lasting for about two seconds, and repeated monotonously at regular short intervals. Somewhat ventriloquial, it is very difficult to locate. Two individuals will often counter-sing. Basic information on territorial behaviour is lacking for most members of Vangidae. The most powerful vocalization is given by the Sickle-billed Vanga* (Falculea palliata), *which has a call like a crying baby. Its alarm call attracts many other birds to mob a predator, as does the call of the Rufous Vanga* (Schetba rufa), *the dominant species in mixed flocks.*

[*Vanga curvirostris cetera*, Reniala, Madagascar. Photo: Ian Merrill]

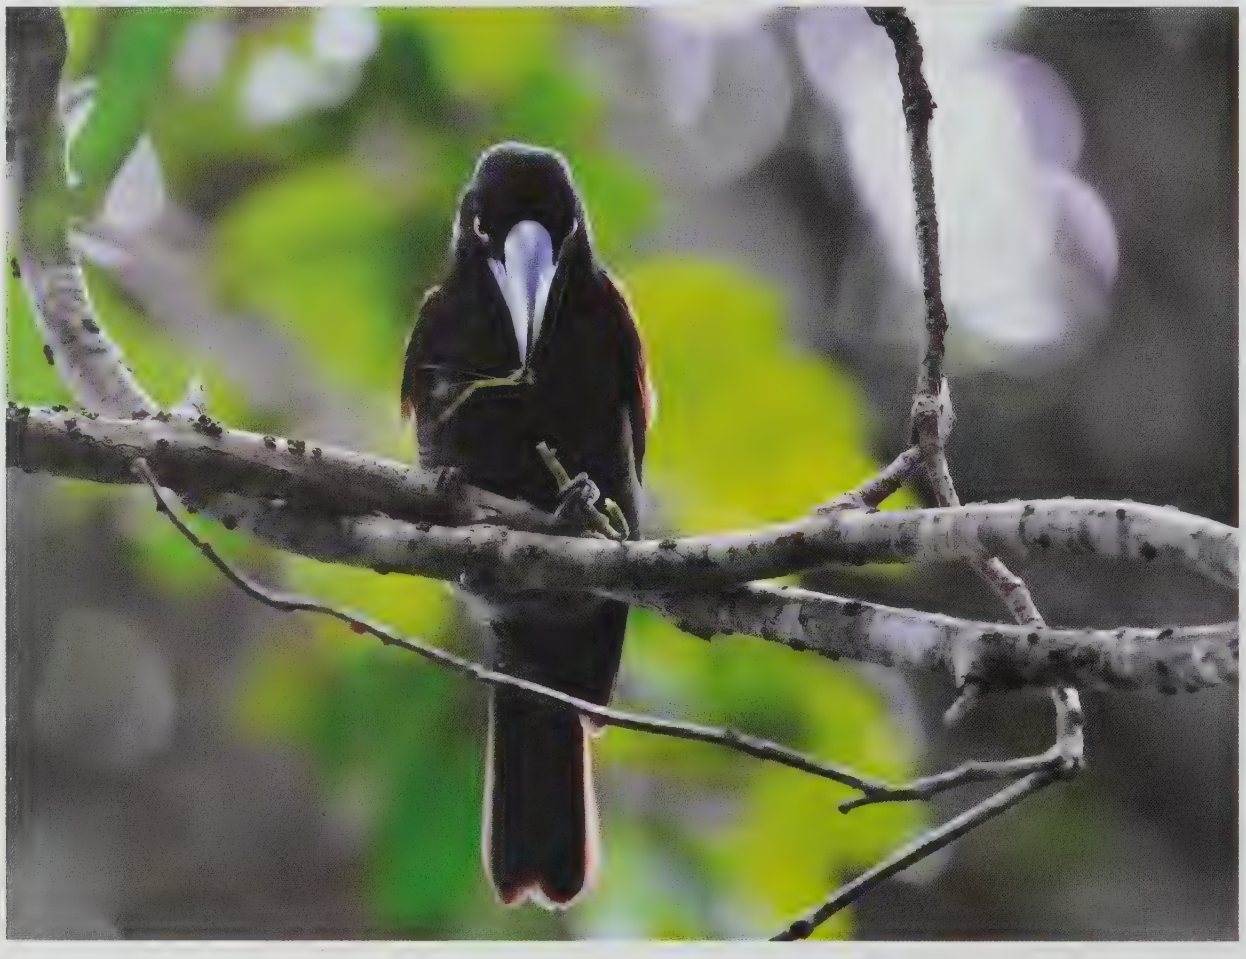
The calls of the Red-tailed, Red-shouldered, Chabert and Nuthatch Vangas are more rattled and complex, and include a trill. The Chabert Vanga, for example, has a characteristic "tch-tch-tch-tch" call, often emitted by several members of a group, and this frequently attracts the human observer's attention to the presence of a group of this species in flight overhead. Nuthatch Vangas emit series of quiet hissing or squeaking notes, including "tsee see see", as well as a soft rippling trill which increases in volume. The Red-tailed Vanga's calls are as variable as is its song; both sexes utter a wooden call described as "tk-tk trrt" or "trrk tikatik", repeated many times, and the males emit a hissing "kschrrr".

Rufous, Helmet and Sickle-billed Vangas have distinctive calls. The call of the Rufous Vanga consists of three different notes, sounding like "kwa kwa kwoo" on a falling scale, and penetrating deep into the forest. When a taped recording of the call is played back, many birds, of several species, approach the recorder and gather around in the vicinity. These include Madagascar Paradise-flycatchers (*Terpsiphone mutata*), Common Newtonias and Common Tetrakas (*Bernieria madagascariensis*), as well as Rufous Vangas. The Rufous Vanga, being the dominant species within mixed flocks, is usually the first to sound the alarm whenever a predator appears in the vicinity, when it makes a loud chirping noise. The alarm call, very similar to that of the Helmet Vanga, attracts many other birds, which join in the mobbing of the predator. Both species also produce a soft drumming sound by clicking the mandibles. The Sickle-billed Vanga, on the other hand, utters a noisy "ga ga ga" when it encounters a predator. This alarm call, likewise, attracts many birds to the scene.

Food and Feeding

The members of this family are primarily insectivorous, although they take some vertebrate prey, and a few species consume a small amount of fruit. Vangas feed mainly on small and medium-sized insects, including beetles (Coleoptera), cockroaches (Blattodea) and Orthoptera, as well as caterpillars. Some supplement this diet with worms (Annelida) or spiders (Araneae), and most of them also take small vertebrates, especially small and medium-sized chameleons and geckos (Gekkonidae). In addition, Hook-billed Vangas prey on frogs, small birds, bird eggs and even young *Microcebus* lemurs. Chabert and Blue Vangas consume some vegetable matter, primarily, it seems, in the form of berries, and the White-headed Vanga occasionally takes some fruits or seeds. The Helmet Vanga, one of the large species, with

The bill shapes and foraging behaviour of the different vanga species resemble those of shrikes, tits, nuthatches, treecreepers and flycatchers, among others. The techniques used by Xenopirostris *vangas, such as **Lafresnaye's Vanga**, include woodpecker-like probing, using the stout, laterally compressed bill to search methodically in crevices and underneath bark in dead and broken wood. As a family, the vangas exploit all strata of the forest, including, occasionally, the ground. Lafresnaye's Vangas forage at middle and lower levels, often close to the forest floor. Usually seen alone or in pairs, they occasionally forage in groups of up to eight individuals, and often join other large vangas in mixed-species flocks.*



[*Xenopirostris xenopirostris*, Ifaty, Madagascar. Photo: Nick Garbutt/ Indri Images]

Using the analogy of gripping tools, if some vangas have bills like different kinds of pliers, one species has a pair of forceps. The ***Sickle-billed Vanga*** *uses its long, slender, curved bill to extract insect larvae from holes or crevices in trees, suggesting that this species is a true vicariant for woodpeckers (Picidae), which are absent from Madagascar. However, neither this species nor any other in Madagascar has adaptations for boring through timber and probing the exposed tunnels to catch retreating larvae. The Sickle-billed Vanga generally favours large branches, living or dead, for foraging, and in addition to probing, uses its bill to lever off bark, and to glean insects from various surfaces. Prey includes spiders, cockroaches, crickets and grasshoppers, beetles, worms and small vertebrates such as geckos and chameleons. A gregarious species, in the non-breeding season in particular, the Sickle-billed Vanga may be found in flocks of 20–30 or more, although, when not calling, a feeding group can be remarkably inconspicuous. At night, Sickle-billed Vangas gather in large communal roosts, which can contain more than 50 individuals. From mid-October to early December, the number of birds at the roost decreases as breeding pairs leave to build their nests. The non-breeding birds that remain will forage together in a group over a large area. From mid-December onwards, the number of individuals at the roost increases rapidly again, being augmented by an influx of non-breeding individuals and the juveniles which have fledged during the breeding season.*

[*Falculea palliata*, Ankarafantsika National Park, Madagascar. Photo: Pete Oxford/ naturepl.com]

Like heavy-duty pliers for gripping large, awkward objects, the bill of the ***Helmet Vanga*** *enables it to cope with large insects, and vertebrates like frogs, geckos and chameleons. Vangas generally dismember large, spiky or armoured prey items before swallowing them. The Hook-billed Vanga* (Vanga curvirostris) *wedges chameleons into a horizontal fork and pulls off the victim's limbs. Helmet Vangas and others secure large prey items with one or both feet and then use the bill to tear them into manageable pieces. Helmet Vangas forage in the middle level of forest, usually perching 3–10 m from the ground, and often remaining motionless for long periods. Five main foraging techniques have been recognized as being employed by Vangidae. These are gleaning, hovering, probing, snatching and hawking. About 80% of observed Helmet Vanga foraging motions involved snatching, or jumping onto still prey and seizing it from the substrate, including the ground, and 20% were gleaning. Helmet, Hook-billed and Rufous Vangas* (Schetba rufa) *use snatching to a greater extent than other vanga species, and more frequently take non-insect prey, such as lizards and chameleons. It is thought that snatching is a relatively recent development among vangas, and that the ancestor of the Vangidae was probably an insectivorous bird with a generalized bill shape suited to gleaning.*

[*Euryceros prevostii*, Masoala National Park, Madagascar.
Photos: Ketil Knudsen]

an exceptionally deep bill, consumes such insects as cockroaches, butterflies and moths (Lepidoptera), crickets and katydids (Tettigoniidae) and beetles, as well as frogs, geckos, chameleons and lizards. The smaller Tylas Vanga eats, among other items, snails (Gastropoda), spiders and butterflies, in addition to caterpillars, dragonflies (Odonata), horseflies (Tabanidae) and other Diptera, and grasshoppers (Acrididae).

Large prey items are generally dismembered before being swallowed. The Hook-billed Vanga, for instance, wedges chameleons into a horizontal fork and pulls off the victim's limbs, and the Sickle-billed and White-headed Vangas secure large prey with one or both feet and then use the bill to dismember the item.

Vangids exploit most levels of the vegetation. Red-tailed Vangas frequent all strata of the forest; they tend to head upwards towards the upper level, as they favour small branches for their hunting. The Tylas Vanga feeds in the canopy and the upper shrub layer, often seizing prey on the wing. Of all members of the family, the Rufous Vanga is the one most inclined to feed on the ground. This species is a classic sit-and-wait predator, capturing its food typically by snatching, hovering or hawking. Not uncommonly it drops to the ground, where it hops around while searching for food. It tends to fly only infrequently, and then only for relatively short distances. White-headed Vangas very occasionally descend to the ground, and the Helmet Vanga sometimes snatches prey from the ground.

Five main types of foraging technique have been recognized as being employed by the Vangidae. These are gleaning, hovering, probing, snatching, and hawking. Hovering involves the catching of motionless prey while hovering close to it, and snatching involves jumping on to still prey and snatching it from the substrate. Hawking is the seizing of aerial prey while in flight. In the case of hawking, the foraging height is related to the height of the perch from which sallies are made.

The members of the phylogenetic groups 1 and 2 (see Systematics), respectively the Tylas Vanga and the Nuthatch Vanga, employ primarily the gleaning technique. Those in group 3, the Chabert Vanga and the Common Newtonia, the latter currently treated as a sylviid warbler (see Systematics), use various techniques in almost equal proportions. Group 4 species, the Sickle-billed, White-headed, Bernier's and Van Dam's Vangas, utilize probing techniques that involve poking and winkling out, as practised by many woodpeckers. Among the species in group 5, namely the Blue, Red-tailed, Hook-billed, Helmet and Rufous Vangas, which were the earliest to become differentiated, the Red-tailed Vanga forages primarily by gleaning, while in the case of the Blue Vanga the suggestion of a snatching technique is evident. It seems that the later the time of differentiation, the greater the utilization of snatching techniques. The Hook-billed, Rufous and Helmet Vangas, which were the last species to become differentiated, use snatching to a greater extent, and more frequently take non-insect prey, such as lizards and chameleons, than do the other species. Consideration of foraging techniques leads to the suggestion that the probing behaviour has evolved in group 4. Thus, the phylogenetic groups within the family reflect the foraging habits of the species, rather than the type of bill shape.

Another interesting insight may be gained by comparing this proposed phylogeny with the findings on foraging behaviour. All species of vanga capture prey by pouncing and picking: they pounce on sedentary prey items and pick them up. Although the extent to which they use the various techniques varies from one species to another, all members of the family capture prey by gleaning. Moreover, it seems that the older the lineage is, the higher is the frequency of gleaning when prey-catching. Since vangas subsist mainly on insects, the ancestor of the family was probably an insectivorous bird with a generalized bill shape suited to gleaning.

In Madagascar, the original absence of some terrestrial birds appears to have left various ecological niches vacant and thus available to the Vangidae. The rapid diversification of vangas is most likely to have occurred following the utilization of vacant niches normally occupied elsewhere in the world by other families. For example, the Sickle-billed Vanga uses its long, slender and curved bill as a means of extracting insect larvae from holes or crevices in trees, suggesting that this species is a true vicariant for woodpeckers. Even with this species, however, the niche filled usually by woodpeckers, with special adaptations for boring through timber and for probing the exposed tunnel to catch the retreating insect larvae, is not completely occupied in Madagascar. It seems that the various vangid species in group 4 (see Systematics) are each partially taking on the role of woodpeckers.

*The **White-headed Vanga** searches for food items on branches of all sizes, even near-vertical ones. Like the smaller Blue Vanga* (Cyanolanius madagascarinus), *it often hangs upside-down. Large prey is typically dismembered with the bill while it is held down with a foot. The main foraging techniques employed by this species are snatching and gleaning. Like other species of its lineage, it uses probing techniques involving poking and winkling out, as practised by many woodpeckers (Picidae). It uses its stout, conical bill to investigate insect refuges under peeling bark and epiphytes, occasionally removing bark fragments. It also breaks open dead twigs. A sociable species, it is often seen in mixed feeding flocks with other vangas.*

[*Artamella viridis annae*, Ampijoroa, Madagascar. Photo: Ketil Knudsen]

*The small and agile **Blue Vanga** often feeds while hanging upside-down, in leaf clusters near the ends of thin branches. Madagascar has no tit (Paridae) species, and among the Blue Vanga's adaptations to occupy this niche is a much finer bill than the larger members of the family. In Madagascar its prey consists of insects, including beetles and caterpillars, while spiders have also been recorded in the Comoros. The Blue Vanga is one of the few vanga species known regularly to take plant food, particularly berries. Again rather like tits, and unlike most vangas, which are normally seen alone or in pairs, this species forages in groups of up to six individuals. Like other vangas, outside the breeding season it is commonly found in mixed-species flocks.*

[*Cyanolanius madagascarinus madagascarinus*, Ankarana Special Reserve, Madagascar.
Photo: Pete Oxford/ naturepl.com]

*The female **Sickle-billed Vanga** takes the lead in courtship. On meeting a male, she adopts a horizontal posture, and quivers her wing and tail feathers. The male does not offer any display in return. Although most vangas are believed to be basically monogamous, several variations of co-operative breeding are found within the family. Male Sickle-billed Vangas participate in territorial defence and anti-predator defence, as well as less regularly with nest-building, incubation, and the brooding and rearing of the chicks.*

[*Falculea palliata*, Ankarafantsika National Park, Madagascar. Photo: Clifford & Dawn Frith]

The Nuthatch Vanga is a gleaning specialist. It climbs medium-sized and large tree trunks in the manner of a nuthatch, searching for invertebrates on the bark, and occasionally foraging along horizontal branches. It sometimes climbs relatively narrow stems or even lianas. Bernier's Vanga regularly strips moss and bark from trees and is able to cling to almost vertical trunks in woodpecker fashion. The small and agile Blue Vanga often forages in leaf clusters near the ends of branches while suspended, upside-down, by its feet, and the medium-sized White-headed Vanga likewise often hangs upside-down in order to reach food items.

With the exception of the Sickle-billed and Rufous Vangas, the members of this family are generally not gregarious. The majority of the species tend to forage alone or in pairs, or in small family parties. However, vangas are often to be seen in mixed foraging flocks (see General Habits). Indeed, such flocks are often led by a vanga species and not infrequently contain more than one vangid. As an example, the Tylas Vanga is found with other vangas in mixed-species feeding flocks which contain, among others, Madagascar Cuckoo-shrikes, Common Tetrakas, Madagascar Black Bulbuls (*Hypsipetes madagascariensis*) and Common Newtonias. These non-vangid associates are commonly observed in other vanga-led flocks, as also are Malagasy White-eyes (*Zosterops maderaspatanus*), Madagascar Paradise-flycatchers and Long-billed Green Sunbirds (*Cinnyris notatus*). Red-tailed Vangas forage in mixed-species flocks that sometimes include other vangas, but often include small forest passerines such as Common (*Neomixis tenella*) and Stripe-throated Jeries (*Neomixis striatigula*) and Sakalava Weavers (*Ploceus sakalava*) or larger species such as the Madagascar Crested Drongo (*Dicrurus forficatus*) and the Madagascar Cuckoo-shrike.

Breeding

Most vangas breed in the southern summer, starting in September or October and finishing in December or January, with some latitudinal and altitudinal variations. Only one breeding cycle is completed annually. If the first attempt fails, however, the pair will usually make a second attempt. For populations of the Rufous, Hook-billed, Van Dam's, Sickle-billed, White-headed and Chabert Vangas found in Ankarafantsika National Park, in the north-western region of Madagascar, breeding commences from the end of September to mid-October, coinciding with the end of the dry season, and continues until the early or middle part of January, the middle of the rainy season. In Ranomafana National Park, in the humid south-eastern region of Madagascar, the Tylas, Red-tailed and Pollen's Vangas likewise begin breeding in September and continue until January.

*In all the vanga species that have been studied, both pair-members help make the nest. In the case of the **Rufous Vanga**, which builds a cup-shaped nest of moss, plant fibres and cobwebs in the fork of a tree, they are sometimes assisted by a third individual. Approximately 30% of breeding pairs of this species are accompanied by one or more yearlings or older males. Most vangas breed in the austral summer. Rufous and other vangas in Ankarafantsika National Park, in the north-west of Madagascar, commence breeding from the end of September to mid-October, coinciding with the end of the dry season, and continue until early or mid-January, in the middle of the rainy season.*

[*Schetba rufa rufa*, Masoala National Park, Madagascar. Photo: Ketil Knudsen]

*The materials and structure of the nest built by the **Sickle-billed Vanga** are quite different from those of other vanga species. A large, untidy, bowl-shaped construction of smooth or thorny twigs is constructed 9–16 m up, usually in the fork of a tree. The materials used by different species usually reflect the habitat and availability of plant matter, from moss in humid rainforests to dry leaves in sub-arid scrub and dry forest. Within the open framework of the Sickle-billed Vanga's nest, the interior is lined with more delicate material, such as plant fibres. Spiders' webs are commonly used by most vangas to reinforce and secure the nest materials. Vangas lay between two and four eggs. The Sickle-billed Vanga's clutch is of three to four creamy white eggs, heavily mottled with grey, violet-grey or maroon; as with other species, markings tend to be denser at the larger end of the egg.*

The three Xenopirostris *species and the* ***Chabert Vanga*** *employ advanced nest-building techniques, such as weaving plant fibres into a small, neat basket shape, secured with spiders' web. Rather than being wedged into a fork like most vanga nests, the nest is often anchored firmly to a horizontal branch. The site may be 6–19 m above the ground. Brief observations of additional birds assisting with nest construction or attending the nest suggest that the Chabert Vanga may be a co-operative breeder; the age and relationship of the helpers is unknown. While "helping" may prove to be widespread among vanga species, there are some, like the Helmet Vanga* (Euryceros prevostii), *in which the basic breeding unit appears to be the unassisted pair.*

[*Leptopterus chabert schistocercus*, Tulear, Madagascar. Photo: Pete Morris]

Few details of the courtship of vangas have been documented. Perhaps the most interesting is that of the Sickle-billed Vanga. With this species, it seems that the female does the courting of the male, rather than the reverse. On meeting a male, the female Sickle-billed Vanga approaches him, and adopts a posture with the body held horizontal, and then proceeds to quiver the feathers of both wings and the tail feathers in what is evidently a courtship display. The male, meanwhile, does not offer any display in return. It is interesting to note that, unlike most other bird species, the Sickle-billed Vanga continues to display and to copulate until after the eggs have hatched and well into the brood-rearing stage of the breeding cycle.

The breeding biology of most vangid species is poorly known. Indeed, for several species, there are descriptions of only one or two nests, or merely of nests still under construction.

In the case of the Red-tailed, Van Dam's, Pollen's, Sickle-billed, White-headed, Rufous, Helmet and Tylas Vangas, it is known that both the male and the female participate in the task of nest-building. There is no reason to believe that other vangas are different in this respect. Vangids have four basic types of nest. The first, a large bowl-shaped nest made from piles of twigs, like those of a *Streptopelia* dove or a *Corvus* crow, is constructed by the Sickle-billed Vanga; the Nuthatch Vanga collects piles of moss and places these in the hollow of a tree trunk; the third nest type, built by the Rufous, Hook-billed and Helmet Vangas, is a small, bowl-shaped structure placed in the fork of a tree; and the remaining species build a cup-shaped nest, the size and location of which vary. In the last category, the three *Xenopirostris* species and the Chabert Vanga employ advanced nest-building techniques, such as the weaving of plant fibres into a basket shape and anchoring the structure firmly on a horizontal branch. In contrast, some other species that build cup-shaped nests, such as the Tylas, Blue, Red-tailed and White-headed Vangas, suspend the nest from the end of a branch. The nesting materials used by the Sickle-billed Vanga and the Nuthatch Vanga are often very different from those utilized by other species, which also commonly make use of cobweb. The material used, however, usually reflects the habitat and the availability of various plant matter. For instance, the Nuthatch and Helmet Vangas, which inhabit humid rainforests, use plenty of moss in the construction, whereas the Sickle-billed and White-headed Vangas and the members of the genus *Xenopirostris*, which inhabit relatively dry open forest, use leaves and dry twigs for nest-building.

Clutches laid by the Vangidae contain two to four eggs, with some variation from one species to another. The eggs range in colour from white or pinkish-white to bluish-green, with markings ranging from red or reddish to grey or violet-grey or olive-brown; the markings can be small and sparse or dense, and they tend to be denser at the larger end of the egg.

In the case of the Rufous Vanga, incubation begins once the first egg has been laid, but the hatching pattern varies from complete asynchrony to complete synchrony. The male of this species contributes greatly towards the task of incubation from the moment when the first egg is laid, and he appears to lack any distinct mate-guarding behaviour during the laying period. In contrast, the male Sickle-billed Vanga guards the female throughout the egg-laying period, as well as during the week prior to it. The contribution of the female Rufous Vanga in incubation increases gradually during the egg-laying period until the clutch is complete; thereafter, the two partners share the duties of incubation almost equally. It is known that both sexes of the Red-tailed, Van Dam's, Pollen's, Sickle-billed, White-headed, Helmet and Tylas Vangas participate in incubation, and it is likely that the same applies also to other vangas.

Incubation periods of vangids range from 16 days to 19 days, but the Hook-billed Vanga's eggs require a longer period, about 22–24 days. The nestling periods are similar in duration to the incubation period, generally from 15 days to 19 days, but the chicks of the Hook-billed Vanga do not leave the nest until they are 20–22 days of age, while the fledging periods of the young Sickle-billed and White-headed Vangas are in the range 19–24 days.

Vangas are basically monogamous. Since not all breeding systems of vangas have been identified, however, it would be presumptuous to reach any definitive conclusions about this aspect of their life. Nevertheless, it is evident that considerable diversity exists within the family. The vangas exhibit several variations in the mode of co-operative breeding, leading to different breeding systems. Of the 15 species currently recognized, three have been the subject of studies relating to breeding biology and in which individual birds have been colour-ringed. These are

The incubation period of the ***Helmet Vanga*** *is unknown. In other vanga species it ranges from 14 to 19 days, with the established exception of the Hook-billed Vanga* (Vanga curvirostris), *which takes 22 to 24 days. The Helmet Vanga's clutch is of two to three eggs, and the breeding pair will share the task of incubation equally. In the Rufous Vanga* (Schetba rufa), *the four eggs are laid at a rate of one per day, and incubation begins with the first. However, the hatching pattern varies from complete asynchrony to complete synchrony. The male Rufous Vanga contributes greatly towards the task of incubation, from the moment the first egg is laid. The female's contribution to incubation increases gradually during the egg-laying period, until the clutch is complete; thereafter, the two partners share the duties of incubation almost equally. The "helpers" found attached to some breeding pairs of Rufous Vanga do not appear to help with incubation. In the Tylas Vanga* (Tylas eduardi), *a monogamous species which breeds as a simple pair, the female does most of the incubation of the eggs and brooding of the chicks. Among the polyandrous species, an immature Bernier's Vanga* (Oriolia bernieri) *which copulated with a female also assisted with nest-building and, to a minor extent, with incubation. In most co-operative polyandrous species, the males' role is usually restricted to feeding the young, but in the Sickle-billed Vanga* (Falculea palliata) *too the males help with incubation and brooding, although infrequently. Unlike most other bird species, Sickle-billed Vangas continue to display and to copulate until after the eggs have hatched, and well into the brood-rearing stage of the breeding cycle.*

the Rufous, Sickle-billed and White-headed Vangas, the first having yielded the most detailed information.

The most striking aspect of the breeding behaviour of the Rufous Vangas is the fact that it breeds in groups of three or four individuals, as well as in simple pairs. In several cases, one of the supplementary members has been seen to be in attendance at the nest. Approximately 30% of the breeding pairs of this species are accompanied by a yearling male or an older male as a helper at the nest. A majority of these are sons of the breeding pair which have remained within the natal territory. These helpers participate in such activities as the mobbing of predators, territorial defence, and the feeding of nestlings, and their assistance can account for up to 30% of the total brood-feeding activity at a given nest. The degree of assistance with the feeding of the young, however, varies greatly among individuals. In fact, about half of these auxiliaries will play no part at all in the process of chick-feeding. The presence or absence of a helper, and whether or not that helper assists, appear not to affect the reproductive output of the pair.

White-headed Vangas breed as simple pairs, but this species, too, occasionally has a helper. In this case, however, the helper is a moulting male and is unable to provide food for the young. Instead, the immature moulting males contribute to the breeding efforts of the pair by participating in territorial defence and the mobbing of predators. The helper is involved in a close social relationship with the pair-members through preening activities. Helpers at Rufous Vanga nests do not undergo wing moult while they participate in the feeding of the nestlings. The co-operative breeding pattern of the White-headed Vanga, therefore, lags a step behind that of the Rufous Vanga. At Ampijoroa, in north-west Madagascar, an individual Blue Vanga which had not yet completed its moult was found in the company of a breeding pair. It is possible that this species has a breeding system similar to that of the White-headed Vanga.

The "helping" behaviour demonstrated by the Rufous and White-headed Vangas may be more widespread among the vangas, as brief observations of unmarked individuals attending the nest or assisting with nest construction have been reported for other species, the Chabert and Bernier's Vangas being examples. On the other hand, no helping behaviour has been observed at nests of the Helmet, Hook-billed, Van Dam's, Pollen's and Tylas Vangas. With these species, the basic breeding unit is a pair, and the sexes contribute equally to incubation and the feeding of young.

Sickle-billed and Bernier's Vangas breed in groups which consist of a single female and several males. The Rufous Vanga falls into the same category. In the Sickle-billed and Bernier's Vangas, however, a number of different males copulate with a single female. These are breeding males, not helpers, and the breeding system is that of co-operative polyandry. Although, in co-operative polyandrous species, the male's contribution is normally solely that of feeding the young, the male Sickle-billed Vanga assists with nest-building, the incubation of the eggs and the rearing of the chicks.

For those vangids for which sufficient data are available, breeding success is generally low. For example, only 25–33% of Rufous Vanga breeding pairs succeed in rearing the young to the fledging stage. At most failed nests, the entire clutch of eggs or the entire brood of nestlings disappeared at the same time, suggesting that they were taken by such nest predators as snakes, lizards, lemurs and hawks, at least in the cases of the Rufous, White-headed and Sickle-billed Vangas.

Almost nothing is known about the extent of the predation suffered by vangas. Furthermore, basic information on nesting biology, territory size, social behaviour, and other aspects of the breeding cycle remain unknown for most memers of this family.

Movements

So far as is known, the vangas are not migratory and have never been reported from the African continent. Although it was once claimed that the Blue Vanga disappeared from the broadleaf forest of the western part of Madagascar during the dry season, this is evidently not the case. Indeed, individuals of every species known locally have been observed in both the breeding and the non-breeding seasons.

Breeding pairs of Rufous Vangas in Ankarafantsika, in north-west Madagascar, were ringed and then monitored. It was found that males and females were sedentary throughout the year and held stable territories. In the same locality, seven ringed White-headed Vangas, comprising five males and two females, bred from November to December; three of the males and one female were observed in the same territories in the following year. Some Sickle-billed Vangas ringed in Ankarafantsika were sedentary, and bred in the same sites for several years. They were obviously residents, occupying the same habitat throughout the year, and seldom moving long distances.

Detailed studies of the presumed short-distance movements of vangids are needed urgently in order to develop conservation measures for the endangered species (see Status and Conservation).

Relationship with Man

Local people are obviously aware of the presence of vangas in the forests of Madagascar. Colloquial names for vangas are many and are fairly constant throughout the region, suggesting that there is some common knowledge of the species. The names of some members of this family are rooted in the life of people. As an example, the Sickle-billed Vanga noisily calls "ga-ga", but occasionally utters "kwa-kwa", like a crow. In Malagasy, this bird is referred to by the name Voronjaza, meaning a "bird of the children". It is so named because of the perceived similarity between its "kwa-kwa" call and the crying of an infant.

The Malagasy names of vangas are derived from their songs, their plumage colour or their behaviour. Vangasoratra means "the

Helpers—male offspring from earlier years—can account for up to 30% of the total brood-feeding activity at a given ***Rufous Vanga*** *nest. The degree of assistance with feeding the young, however, varies greatly among individuals. About half the helpers make no contribution at all, restricting their role to mobbing predators and defending the territory. Helpers at Rufous Vanga nests do not undergo wing moult while they participate in feeding the nestlings, whereas the occasional single helper found at White-headed Vanga* (Artamella viridis) *nests is a moulting male; it is unable to contribute to feeding the young. The presence or absence of a helper, and whether or not that helper assists, appears not to affect the reproductive output of the Rufous Vanga pair. The male and female hold their territory throughout the year, and the location of territories remains the same in successive years.*

[*Schetba rufa occidentalis*, Western Dry Forest, Madagascar. Photo: Pete Oxford/ naturepl.com]

*The male and female of **Pollen's Vanga** participate equally in the brooding and feeding of their young. This is a female, distinguishable by the blackish hood extending only to the chin and throat, not onto the upper breast, and by the combination of a white band below the hood, under which the breast is variably tinged orange. At the change-over, the arriving bird calls to alert the brooding bird, which departs immediately. There is little information on the diet of vanga nestlings. In observations of one Pollen's Vanga nest, food brought included crickets, a caterpillar, unidentified insects, and a chrysalis which was eaten by the female after being offered.*

[*Xenopirostris polleni*, Ranomafana National Park, Madagascar. Photo: Nick Garbutt/ Indri Images]

black-and-white bird", and is applied to the Hook-billed Vanga, while the Nuthatch Vanga's local name, Voronakodidina, means "bird turning and climbing around the tree". Totokarasoka, the Red-tailed Vanga, may be derived from its song, transcribed as "toto toto karasoka, toto toto kasaroka". The local people know all species of vanga except the Red-shouldered Vanga, which was only recently described from a small area of unprotected forest in south-western Madagascar.

This distinctive family is still relatively poorly known, even though it is of great interest to birdwatchers. It is true to say that, in Madagascar's growing ecotourism industry, vangas play a leading role as symbols of the uniqueness of the island's animal life.

Status and Conservation

Vangas are found throughout the wooded habitats of Madagascar. Most species are widely distributed and often are fairly common in suitable habitats, although, at the local scale, some are inexplicably scarce or absent. One member of the family, the Blue Vanga, occurs also in the Comoro Islands, where it is not uncommon in wooded parts of Mohéli and appears to be extremely rare on Grand Comoro.

The main threat to vangas is the clearing of forests. Since the early 1950s, Madagascar has lost about half of its forest cover, including most of its coastal lowland forests, which have been reduced by about 90%. All of the remaining native forests are under heavy pressure for conversion to agricultural land. Almost all of them are on relatively poor soil, and, once the forest is cleared, the soil nutrients disappear quickly; as a consequence, farmers are forced to move to another patch of fresh forest after only a few seasons of cultivation. This kind of slash-and-burn cultivation, known in Madagascar as *tavy*, would, if allowed to continue uncontrolled, ultimately remove about 95% of the endemic fauna and flora, including all forest-dependent species. Additional adverse factors are uncontrolled bushfires, commercial logging, and exploitation of timber for charcoal and firewood. The conservation of forests is, therefore, essential for the survival of most of Madagascar's endemic birds, including vangas.

Of the 15 species of vanga currently recognized, four are globally threatened and one is placed in the category of Near-threatened. Two of the threatened species have an extremely limited geographical range. Van Dam's Vanga, listed as Endangered, has been recorded in recent decades only at two widely separated localities, Ankarafantsika National Park and Analamerana Special Reserve, in north-west and north Madagascar. Although both of these are officially protected areas, there is no certainty that they will remain so in the future. Western forests are disappearing at an extremely fast rate, and many smaller forest blocks which were intact or little disturbed in the 1980s and early 1990s are now devoid of forest-specialist birds. The fact that the western forest is already so fragmented and is now under great pressure means that it is probably the most threatened forest ecosystem in Madagascar. Van Dam's Vanga is still locally common in suitable habitats, although, in Ankarafantsika, these are limited to patches of forest.

The second threatened vangid with a tiny global range is the Red-shouldered Vanga, a recently described species which is known only from a small area of unprotected forest in the Toliara region, in south-western Madagascar. This poorly known vanga appears to have a very small population, and is therefore classified as Vulnerable. The Red-shouldered Vanga was described as a new species in 1997, on the basis of two specimens collected 50 years earlier, in 1947. It was photographed in the wild in 1992, and in July 1997 about nine males were observed in the same area, on the road between La Table and St Augustin; these were in an area of suitable habitat extending over about 30 km^2, suggesting a possible population of 30–100 pairs. Farther south, the species has been found at several places on the Mahafaly Plateau, including Hatokaliotsy and Tsimanampetsotsa, but at an apparently low density. At the start of the twenty-first century, this species was located at Linta, some 50 km south of its previous known limit, and suitable habitat exists farther south of this site. Currently, the Red-shouldered Vanga's habitat is becoming degraded in patches, where it is subject to shrub clearance for charcoal and is being grazed by goats; timber extraction is a fur-

The nestling period of the ***Red-tailed Vanga*** *is around 16 days, during which both parents brood and feed the young. The nestling periods of vanga species in general are similar in duration to the incubation periods, usually ranging from 15 to 19 days. As with its longer incubation period, the Hook-billed Vanga* (Vanga curvirostris) *is again an exception, with a nestling period of up to 22 days; in the cases of Sickle-billed* (Falculea palliata) *and White-headed Vangas* (Artamella viridis), *it lasts up to 24 days. In those vangas for which sufficient data are available to make assessments, breeding success is generally low. For example, only 25–33% of Rufous Vanga* (Schetba rufa) *breeding pairs succeeded in rearing the young to the fledging stage. At most failed nests, the entire clutch of eggs or the entire brood of nestlings disappeared at the same time, suggesting that they were taken by nest predators, which might have been snakes, lizards, lemurs or raptors. However, almost nothing is known about the extent of predation suffered by vangas. If a first breeding attempt fails, the vanga pair will usually make a second attempt. Only one breeding cycle is completed annually.*

[*Calicalicus madagascariensis*, Ranomafana National Park, Madagascar. Photos: Dominique Halleux/ Bios]

*Most of the 15 vanga species are widely distributed, and are often fairly common in suitable habitat, but seven, including **Pollen's Vanga**, have restricted ranges. Confined to undisturbed primary forest in the East Malagasy Wet Forests Endemic Bird Area (EBA), Pollen's Vanga is commoner in the south of its range than in the north, where it is scarce or apparently absent from some seemingly suitable habitats. The lowland parts of its habitat in particular are at risk from logging and slash-and-burn agriculture, and if present trends continue, will disappear altogether within a few decades. Its population is already believed to be small, and the species is currently listed as Near-threatened.*

[*Xenopirostris polleni*, Ranomafana National Park, Madagascar.

ther problem at some sites. Nevertheless, much suitable habitat remains intact, as the soil is unsuitable for agriculture and the area is inhabited predominantly by fishermen and goat-herders. This situation could change, however, if people with different farming techniques move in to the area. If the Red-shouldered Vanga's habitat does become threatened and a population decline is recorded, the species' conservation category could be upgraded to that of Endangered.

Bernier's Vanga and the Helmet Vanga are the two other Vulnerable members of the family. Both are confined to the northern half of the eastern rainforest belt, in north-east Madagascar. Bernier's Vanga has been recorded at many sites from Marojejy south to Zahamena, and there is a single, as yet unconfirmed record from much farther south, in Vondrozo. This vanga, which is restricted to undisturbed humid evergreen forest, seems to be scarce and patchily distributed throughout its range. The Helmet Vanga is patchily distributed from Tsaratanana south to Mantadia, and has been recorded only in primary forest, generally below 800 m. It is uncommon throughout its range. Both of these vangids are considered to be at risk because their forest habitat, already severely fragmented, continues to disappear at a fast rate, leading to concomitant decreases in their populations. Like all forests in Madagascar, primary lowland rainforest is threatened mainly by slash-and-burn cultivation, which results in progressively more degraded regrowth and, finally, grassland or bracken-covered areas. Much of the coastal plain in east Madagascar has already been cleared, and many tracts which have not been cleared contain only highly degraded forest. The surviving areas of forest are under pressure from an increasing human population, and in some areas commercial logging poses a further threat. It is considered very likely that, if current trends continue, virtually all of the remaining forest, especially that at lower elevations, will have disappeared within a few decades.

Several protected areas exist within the north-eastern rainfororest belt. Both of these species are present in Marojejy National Park, Masoala National Park and Zahamena National Park, in Ambatovaky and Anjanaharibe-South Special Reserves, in Betampona Strict Reserve, and in Anjanaharibe, Bezavona and Haute Rantabe Classified Forests. Bernier's Vanga occurs also in Mangerivola Special Reserve, and the Helmet Vanga in Mantadia National Park and Tsaratanana Strict Reserve. Effective protection of the national parks is considered to be of particular importance, as these still contain significant areas of good-quality habitat.

Pollen's Vanga is another inhabitant of the primary humid evergreen forest of eastern Madagascar. Unlike the two aforementioned species, however, it is distributed through most of the length of this habitat. Significantly, it is more common in the south of its range, between Ranomafana and Andohahela, than it is in the seemingly suitable habitat in the northern part of the island, where, in common with Bernier's and Helmet Vangas, it is only patchily distributed and is scarce or apparently absent locally. Pollen's Vanga is believed to have a moderately small population which, owing to forest clearance and degradation, is thought likely to suffer a decline over the next decade or so. It is classified as Near-threatened. If it is found that this species has a small population, or that it is undergoing a rapid decline in numbers, this may be considered grounds for placing it in a higher threat category, that of Vulnerable.

The Tylas Vanga is common in the south-eastern rainforest. There is, however, considerable uncertainty with regard to the status and distribution of its western race, *albigularis*, which is known only from a very few sightings in western Madagascar and appears to be extremely rare. It has been recorded in the areas of Morondava, Morombe and Ankazoabo, and, farther north, at Baly, which lies about 120 km south-west of Mahajanga, but it is possible that it occurs elsewhere, too. On the other hand, fieldwork by a number of independent observers in western Madagascar has failed to produce any further locations for this taxon.

Mystery surrounds the status of what has been called "Bluntschli's Vanga", described on the basis of two apparently juvenile specimens from near Tôlanaro, in south-east Madagascar (see Systematics). This is sometimes treated as a genuine species, albeit an extremely rare and almost unknown one. It is possible that since 1931, when the two specimens were collected, the taxon has for some reason become extinct, although there is still forest of adequate quality at the single locality where they were found. In 1995, a survey of the fauna of Andohahela was undertaken, and this included forest near this same site, but only the Nuthatch Vanga was found. BirdLife International currently treats "Bluntschli's Vanga" as a Data-deficient species. If it does prove to be a valid species, it would surely be listed as Criti-

Four vanga species are globally threatened, and of these, two have very small ranges. The Vulnerable ***Red-shouldered Vanga*** *was described as recently as in 1997, from two specimens collected 50 years earlier near Toliara, in south-west Madagascar. In 1997, nine males were located in the same area, in an area of dense* Euphorbia *scrub covering some 30 km², suggesting a possible population of 30–100 pairs. It has subsequently been found at sites further south, but at low density. Its habitat is being irregularly degraded by shrub clearance for charcoal and grazing by goats, although much of what remains is still intact because the soil is unsuitable for agriculture.*

[*Calicalicus rufocarpalis*, Tulear, Madagascar. Photo: Pete Morris]

cally Endangered, as it clearly would have a tiny population and total range.

Only one member of the family has a range extending beyond Madagascar. This is the Blue Vanga, which occurs on two of the nearby Comoro Islands. The subspecies *comorensis* is fairly common on Mohéli, where it inhabits wooded areas at elevations of up to 300 m. The highest point of the island is little more than 700 m. In contrast, the Blue Vanga is extremely rare on Grand Comoro, where it was first sighted in June–July 1974. Since then, only two other confirmed sightings have been made, both in August 1981 and at an altitude of approximately 900 m. The Grand Comoro Blue Vanga represents a separate race of this species, *bensoni* (see Systematics).

Listed as Endangered, ***Van Dam's Vanga*** *is the most threatened species in the family.It is currently known only from two widely separated sites of dry deciduous forest in north-west Madagascar. Although both sites are officially protected, they are being reduced by clearance and bushfires, and their future is not secure. Nevertheless, there is suitable habitat between these sites that has not yet been thoroughly surveyed. Loss of habitat may be the main threat to vangas, but lack of information is the main handicap to developing conservation strategies, and many more studies of this family are needed.*

[*Xenopirostris damii*, Ankarafantsika National Park, Madagascar. Photo: Ian Merrill]

In order to conserve all species of vanga, it is essential that many more scientific studies be conducted with the aim of determining each species' precise habitat requirements, population size, dispersal pattern and reproductive output, as well as the causes of mortality. Such information will be indispensable with regard to the establishment of detailed conservation strategies. Madagascar has many forest reserves, and it is hoped that, as conservation programmes are implemented, the pressure on them may gradually be eased. The rate of forest clearance outside the protected areas, however, is still high, exerting renewed threats of commercial logging. Increased public awareness of environmental matters and of the importance of conserving the fauna and flora of such unique places as Madagascar is a vital ingredient in the conservation process. In the Comoros, Mohéli is the least disturbed of the four islands and has the smallest human population. Much of its original habitat remains. Grand Comoro, on the other hand, is highly disturbed and is threatened by further destruction and degradation of its native habitat.

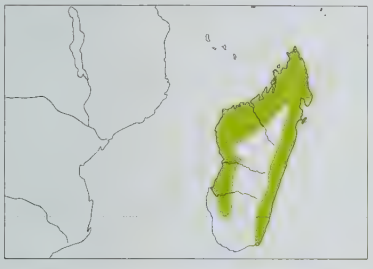
PLATE 8



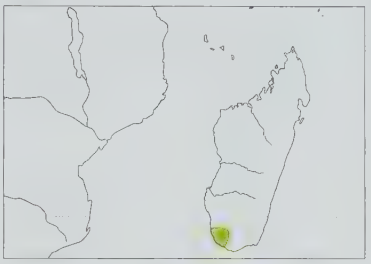
Genus *CALICALICUS* Bonaparte, 1854

1. Red-tailed Vanga

Calicalicus madagascariensis

French: Calicalic malgache **German**: Rotschwanzvanga **Spanish**: Vanga Colirrojo
Other common names: Red-tailed Shrike

Taxonomy. *Lanius madagascariensis* Linnaeus, 1766, Fort Dauphin (Tôlanaro), south-east Madagascar.
Recent molecular-genetic analysis indicates that genus may be closest to *Vanga*, *Cyanolanius*, *Schetba* and *Euryceros*; recent cladistic analysis based on morphological characters, however, suggests that it may not belong in the present family, but could be closer to drongos (Dicruridae) and monarch-flycatchers (Monarchidae). Monotypic.
Distribution. N, W & E Madagascar.



Descriptive notes. 13–14 cm; 14–18·6 g. A small vanga reminiscent of a tit (Paridae). Male has grey forehead to nape, black patch from base of bill extending backwards broadly around eye and with narrow white border above; upperparts grey, slightly tinged green, except for rufous rump and uppertail-coverts; upperwing green-grey, median and lesser upperwing-coverts rufous, primaries blackish with grey fringes; tail rufous, inner webs of central feather pair grey-brown; white cheek and ear-coverts, contrasting black chin and throat; underparts whitish, side of chest and flanks washed light tan, thighs often washed rufous; underwing-coverts white; iris dark brown; bill black; legs grey. Female has forehead to nape duller grey, conspicuous off-white eyering, upperparts olive-brown, rump and uppertail-coverts brick-red, upperwing dark brown, tail feathers brick-red with dark brown inner webs; lower ear-coverts, cheek and side of neck buffy, throat whitish, broad buffy breastband, grading to whitish on belly; bare parts as for male. Juvenile is similar to female, but has buff shaft streaks and tips on underpart feathers. Voice. In N & E, male sings "per-whew" with falling intonation (sounding like a human wolf-whistle); in W, male typically sings "pew-poo-whee" or "oo-oo-whi", last syllable higher; also a different song heard in W (near Morondava) was transcribed as "plee-plee tick-che-weh". Calls equally variable; both sexes utter wooden-sounding "tk-tk trrk" or "trrk tikatik", repeated many times, and male also gives hissing "kschrrr". Male calls often during foraging.
Habitat. Native forest of various types, including adjacent second growth; generally absent from sub-arid scrub. Sea-level to 2000 m.
Food and Feeding. Small and medium-sized insects, including Orthoptera, beetles (Coleoptera), caterpillars; also small vertebrates, mainly chameleons (of genus *Chamaeleo*). Frequents all levels of forest; tends to move towards upper level, as it prefers small branches for foraging. Gleans prey from branches; in one study, more than 90% of foraging manoeuvres involved gleaning. Generally in pairs during breeding season, sometimes in small groups; often within mixed-species flocks that may include other vangas, but often also include such small forest passerines as Common Jery (*Neomixis tenella*), Stripe-throated Jery (*Neomixis striatigula*) and Sakalava Weaver (*Ploceus sakalava*), or such larger species as Madagascar Crested Drongo (*Dicrurus forficatus*) and Madagascar Cuckoo-shrike (*Coracina cinerea*).
Breeding. Season Oct–Jan in E (Ranomafana). Monogamous. Nest built by both sexes, an open cup made from interwoven leaf stalks reinforced with spider webs, no special interior lining, usually high above ground (near treetop) in fork of tree. Clutch 2 eggs, green-blue with widely scattered chestnut and reddish-grey small spots increasing in density at larger end; incubation by both sexes, period c. 16 days; both also brood and feed chicks, nestling period c. 16 days.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Common to fairly common. The commonest vanga in E Madagascar; fairly common in N of range; more patchily distributed in W. Occurs in several protected areas, e.g. common in Mantadia Andasibe National Park, Ranomafana National Park and Zombitse-Vohibasia National Park.
Bibliography. Appert (1968a, 1970), Dee (1986), Goodman, Hawkins & Domergue (1997), Hartlaub (1861, 1877), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Rakotomanana *et al.* (2009), Schulenberg (2003), Sinclair & Langrand (1998), Yamagishi & Eguchi (1996).

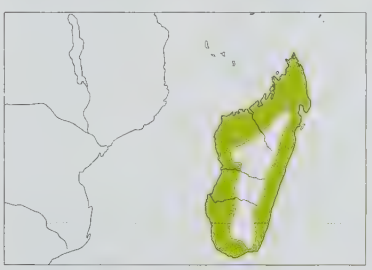
2. Red-shouldered Vanga

Calicalicus rufocarpalis

French: Calicalic à épaulettes **German**: Rotschultervanga **Spanish**: Vanga Hombrorrojo

Taxonomy. *Calicalicus rufocarpalis* Goodman, Hawkins and Domergue, 1997, Tuléar [= Toliara], Toliara Province, south-west Madagascar.
Recent molecular-genetic analysis indicates that genus may be closest to *Vanga*, *Cyanolanius*, *Schetba* and *Euryceros*; recent cladistic analysis based on morphological characters, however, suggests that it may not belong in the present family, but could be closer to drongos (Dicruridae) and monarch-flycatchers (Monarchidae). Monotypic.
Distribution. Toliara region, in SW Madagascar.
Descriptive notes. 14–15 cm; 15–17·4 g. A small vanga reminiscent of a tit (Paridae). Male has black lores and thin black line from upper eye to above bill, bordered above by narrow white line; pale grey crown, nape and mantle; flight-feathers and tertials brown, upperwing-coverts brick-red, greater and primary coverts oftenbrownish-grey distally; tail pale brick-red with central pair of feathers brownish; cheek and ear-coverts white, contrasting black chin, throat and lower side of neck; underparts whitish, breast and flanks with pale pink suffusion; iris pale lemon-yellow; bill black; legs pinkish-grey. Differs from *C. madagascariensis* in larger size, pale iris, longer bill, tail

and legs and shorter wing (giving rather elongated appearance), also in having red upperwing-coverts, different head pattern, black bib sometimes more extensive, pinkish wash below. Female is olive-tinged grey-brown above, with pale reddish rump and tail (reddish colour restricted to outer webs) and brick-red lesser and median wing-coverts, throat whitish, underparts washed buff, blending to whitish on belly, bare parts as for male; differs from very similar female *C. madagascariensis* mainly in larger size, reddish (not brown) shoulder, and pale (not dark) eye. Juvenile undescribed. Voice. Alarm or contact call a peevish "karr-trkkk", first note like that of a sunbird (Nectariniidae); also gives loud, rolling, descending rapid "ksisisisisususu" cadence with slight whistling quality, possibly as contact. Male song a loud "tyuh-tee" or "pu-teer", second note louder and more whistled; female often gives contact call immediately after male song, in duet-like fashion.
Habitat. Little known. Sub-arid thorn-scrub at c. 100 m.
Food and Feeding. Small invertebrates. Forages usually in dense low bushes 2–3 m tall. Principal techniques are gleaning and sally-gleaning. Often in small family parties.
Breeding. No information.
Movements. Probably sedentary.
Status and Conservation. VULNERABLE. Restricted-range species: present in South Malagasy Spiny Forests EBA. Has tiny global range and appears to have a very small population. Known only from a small area of unprotected forest in Toliara region, in SW Madagascar. Described as a new species in 1997, on basis of two specimens collected 50 years earlier; photographed in the wild in 1992, and in July 1997 about nine males observed in same area (on road between La Table and St Augustin), where suitable habitat of c. 30 km², suggesting possible population of 30–100 pairs. Subsequently found farther S at several sites on Mahafaly Plateau, including Hatokaliotsy and Tsimanampetsotsa, but at apparently low density; at start of 21st century was located at Linta, c. 50 km S of previous known S limit, and suitable habitat exists farther S of this site. Threatened by degradation and loss of specialized habitat, which currently subject to shrub clearance for charcoal and grazing by goats; timber extraction a further problem at some sites. Much suitable habitat still remains intact, as soil unsuitable for agriculture human inhabitants are predominantly fishermen and goat-herders. If loss of suitable habitat increases, species may become Endangered.
Bibliography. Anon. (1999, 2008m), Appert (1970), Butchart & Stattersfield (2004), Goodman, Hawkins & Domergue (1997), Hawkins, Rabenandrasana *et al.* (1998), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Nicoll & Langrand (1989), Schulenberg (2003), Sim & Zefania (2002), Sinclair & Langrand (1998), Stattersfield & Capper (2000).



Genus *VANGA* Vieillot, 1816

3. Hook-billed Vanga

Vanga curvirostris

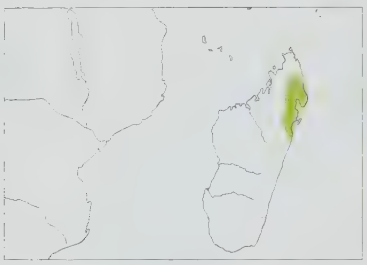
French: Vanga écorcheur **German**: Hakenschnabelvanga **Spanish**: Vanga Picudo

Taxonomy. *Lanius curvirostris* Linnaeus, 1766, Fort Dauphin (Tôlanaro), south-east Madagascar.
Recent molecular-genetic analysis indicates that genus may be closest to *Calicalicus*, *Cyanolanius*, *Schetba* and *Euryceros*. Two subspecies recognized.
Subspecies and Distribution.
V. c. curvirostris (Linnaeus, 1766) – N, W & E Madagascar.
V. c. cetera Bangs, 1928 – S Madagascar.

Descriptive notes. 25–29 cm; 53·5–80·5 g. A medium-sized vanga with long hook-tipped bill, legs long and sturdy. Nominate race has area from eye and central crown back to upper nape glossy black, rest of head and neck, including nuchal collar, white; upperparts black, median and greater upperwing-coverts with wide white outer fringes and tips (forming white panel on closed wing), primaries and secondaries with narrower white fringes; basal two-thirds of tail mid-grey, subterminal band black, tip white; underparts white; iris very dark brown; bill black, small silvery spot near tip, length 25–30 mm; legs dark blue-grey. Sexes similar. Juvenile is similar to adult, but black of upperparts variably marked with brown, base of bill initially grey. Race *cetera* differs from nominate in tending to have bill longer (27–30 mm) and thinner, black on head reaches to mid-crown but does not extend to lower nape, making white nape-collar broader, abdomen greyish-white. Voice. Song a very penetrating, high-pitched whistle, "te-ew", c. 2 seconds in duration, repeated monotonously at regular short intervals in early morning; somewhat ventriloquial. Often, two individuals counter-sing. Call in W of range usually "karr-karr-karr" (accompanied by two or three loud bill-claps) followed by angry "tew-tew-tew-tew"; in E & S often just the last part ("tew" notes). Contact call a quiet "pew".
Habitat. Various original forest types, dense scrub, degraded and primary forests, areas around villages, also plantations far from forest. Nominate race occurs in evergreen humid forest and degraded areas and plantations in lowlands; *cetera* in spiny forest. Sea-level to 1500 m, although scarce above c. 1000 m.
Food and Feeding. Large insects; also small vertebrates, including medium-sized chameleons (Chamaeleonidae), frogs, small birds, bird eggs, and even young *Microcebus* lemurs. Spends long

On following pages: 4. Bernier's Vanga (*Oriolia bernieri*); 5. Lafresnaye's Vanga (*Xenopirostris xenopirostris*); 6. Van Dam's Vanga (*Xenopirostris damii*); 7. Pollen's Vanga (*Xenopirostris polleni*); 8. Sickle-billed Vanga (*Falculea palliata*); 9. White-headed Vanga (*Artamella viridis*); 10. Chabert Vanga (*Leptopterus chabert*); 11. Blue Vanga (*Cyanolanius madagascarinus*); 12. Rufous Vanga (*Schetba rufa*); 13. Helmet Vanga (*Euryceros prevostii*); 14. Tylas Vanga (*Tylas eduardi*); 15. Nuthatch Vanga (*Hypositta corallirostris*).

intervals motionless, watching for prey; also searches for food by slowly inspecting branches and snatching items. Wedges chameleons into horizontal forks and pulls off limbs, before consuming them. Usually solitary, sometimes in pairs; also in mixed-species flocks of vangas or other forest species.
Breeding. Season Oct–Jan in NW (Ampijoroa). Monogamous. Nest built by two individuals (presumed male and female), a bulky cup-shaped structure consisting of dead leaves, covered with spider webs and mosses, usually 3–10 m above ground in fork of tree. Clutch 3 eggs, white and densely covered with small wine-red spots; incubation by both sexes, period c. 22–24 days; chicks brooded and fed by both sexes, nestling period c. 20–22 days.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Nominate race rather thinly scattered in evergreen humid forest and degraded areas and plantations in lowlands and is more common in W. S race *cetera* is common from R Mangoky S & E to near Tôlanaro. As this species is not strictly bound to undisturbed forest, its survival is considered not at any immediate risk.
Bibliography. Appert (1968a, 1970), Dee (1986), Hartlaub (1861, 1877), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Oberholser (1900), Rakotomanana *et al.* (2001), Schulenberg (2003), Sharpe (1871), Yamagishi & Eguchi (1996).



Genus *ORIOLIA* I. Geoffroy Saint-Hilaire, 1838

4. Bernier's Vanga

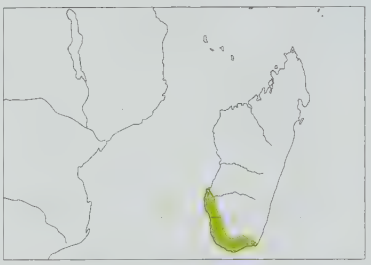
Oriolia bernieri

French: Oriolie de Bernier **German**: Schwarzvanga **Spanish**: Vanga de Bernier

Taxonomy. *Oriolia bernieri* I. Geoffroy Saint-Hilaire, 1838, Madagascar.
Recent molecular-genetic analysis indicates that genus may be closest to *Xenopirostris*, *Falculea* and *Artamella*. Monotypic.
Distribution. NE Madagascar.

Descriptive notes. 23 cm; 52–59 g. A medium-sized, dark-plumaged vanga with stout conical bill. Male has entire plumage black with blue sheen; iris greyish-white; bill and legs light grey. Female is dark tan-rufous, brighter on wing, almost all feathers with fine black bars (most conspicuous on upperparts and breast); upperwing with uniformly rufous primaries, basal part of primaries often brighter rufous; underwing rufous, underwing-coverts finely black-barred; bare parts as for male. Juvenile is similar to female. Voice. Poorly known. Loud "chew", like that of Common Greenshank (*Tringa nebularia*), and harsh chattering series; in flight, wingbeats produce loud whirring sound.
Habitat. Lowland evergreen humid forest, to c. 1000 m.
Food and Feeding. Invertebrates, including spiders (Araneae), crickets (Orthoptera), cockroaches (Blattodea); also small vertebrates, e.g. geckos (of genus *Phelsuma*). Forages at all levels of vegetation, mainly high in trees. Feeding techniques include gleaning and probing; probing involve poking and winkling, as practised by woodpeckers (Picidae). Regularly strips moss and bark from trees, and able to cling to almost vertical trunks in woodpecker fashion. Closely investigates leaves of pandanus (*Pandanus*), traveller's tree (*Ravenala madagascariensis*) and palms; tosses clumps of debris from bases of leaves. Found in isolated pairs, also in mixed-species flocks made up principally of vangas.
Breeding. Season Sept–Dec (Masoala Peninsula). Breeding system uncertain; sometimes in groups consisting of one female and several males, all of which copulate with female; at one of four nests studied, an immature male copulated with female and also assisted with nest-building and, to minor extent, with incubation of eggs. Nest built by both sexes, mostly by female, cup-shaped, consisting of root material, palm fibres, dry leaves and moss, placed usually 10·8–14·4 m above ground inside palm-leaf whorl. Clutch 3 eggs, pinkish-white and mottled with carmine-red, especially at larger end; incubation by both sexes, period c. 17 days; both brood and feed chicks, nestling period c. 17 days.
Movements. Probably sedentary.
Status and Conservation. VULNERABLE. Restricted-range species: present in East Malagasy Wet Forests EBA. Confined to N half of E rainforest, where rather scarce and patchily distributed. Recorded at many sites from Marojejy S to Zahamena; an unconfirmed report from much farther S, in Vondrozo (in S Fianarantsoa). Considered at risk because of continuing rapid loss and degradation of already severely fragmented forest habitat, leading to population decrease. Primary lowland rainforest threatened mainly by slash-and-burn cultivation; much of E coastal plain already cleared, and many of remaining tracts of forest highly degraded. Surviving areas of forest under pressure from increasing human population, and in some areas commercial logging. If current trends continue, virtually all remaining forest, especially that at lower elevations, will very likely have disappeared within a few decades. Occurs in several protected areas, i.e. in Marojejy, Masoala and Zahamena National Parks, in Ambatovaky, Anjanaharibe-South and Mangerivola Special Reserves, in Betampona Strict Reserve, and in Anjanaharibe, Bezavona and Haute Rantabe Classified Forests. Effective protection of national parks of particular importance, as these still contain significant areas of good-quality habitat.

(1999, 2008m), Butchart & Stattersfield (2004), Collar & Stuart (1985), Collar *et al.* (1994), Dee (1986), Delacour (1932), Du Puy & Moat (1996), Evans, M.I. *et al.* (1992), Hartlaub (1877), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Schulenberg (2003), Sharpe (1871), Stattersfield & Capper (2000), Thorstrom & René de Roland (1999, 2001), Thorstrom & Watson (1997), Yamagishi & Eguchi (1996).



Genus *XENOPIROSTRIS* Bonaparte, 1850

5. Lafresnaye's Vanga

Xenopirostris xenopirostris

French: Vanga de Lafresnaye **German**: Schmalschnabelvanga **Spanish**: Vanga de Lafresnaye

Taxonomy. *Vanga xenopirostris* Lafresnaye, 1850, Madagascar.
Recent molecular-genetic analysis indicates that genus may be closest to *Oriolia*, *Falculea* and *Artamella*. Monotypic.
Distribution. SW & S Madagascar from just N of R Mangoky S in subdesert biome to just E of Tôlanaro.

Descriptive notes. 24 cm; 52–63 g. A medium-sized vanga with plumage mostly black and white; bill stout and laterally compressed, with intermandibular gap. Male has black head, contrasting white throat and broad white collar, which is broken at rear; upperparts, including upperwing-coverts and tail, medium grey, tinged brown (can look darker), primaries, primary coverts and alula sooty grey; white below; iris dark brown; bill grey to bluish-grey, upper mandible with dusky tip variably extending along culmen, pale tip of lower mandible; legs grey-blue. Female differs from male in having black mostly restricted to top of head. Juvenile is similar to female, but has brown markings on scapulars and upperparts. Voice. Most frequent vocalizations a highly characteristic loud, whistled "tseeang" or "tseeeo", and loud "whip", usually given from easily viewed songpost, more rarely in flight; also a slow "chuck chuck chuck", not unlike a call of *Leptopterus chabert*. Also various descending whistles.
Habitat. Sub-arid thorn-scrub, with strong preference for areas with plentiful dead wood. Sea-level to 100 m.
Food and Feeding. Invertebrates, including beetles (Coleoptera), cockroaches (Blattodea), other insects, worms (Oligochaeta); also small vertebrates, e.g. chameleons (Chamaeleonidae). Forages at middle and lower levels, often close to forest floor. Searches methodically in crevices and in nooks and crannies in dead and broken wood, especially beneath dead bark and in twigs. Main techniques gleaning and probing. Usually alone or in pairs, occasionally in small groups of up to eight individuals; often joins other large vangas in mixed-species groups.
Breeding. Few data. Breeding observed in Nov–Dec. Cup-shaped nest of plant matter, reinforced on outside with spider webs, lined with leaf stalks and long rootlets, usually built 5 m above ground in fork of tree. Clutch 2 eggs, reddish-white, sprinkled with reddish-grey spots; incubation by both sexes. No other information.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in South Malagasy Spiny Forests EBA. Not common within its relatively small range.
Bibliography. Appert (1968a, 1968b, 1970), Dee (1986), Delacour (1932), Hartlaub (1861), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Schulenberg (2003), Yamagishi & Eguchi (1996).

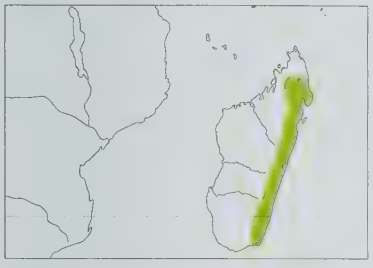
6. Van Dam's Vanga

Xenopirostris damii

French: Vanga de Van Dam **German**: Van-Dam-Vanga **Spanish**: Vanga de Van Dam

Taxonomy. *Xenopirostris damii* Schlegel, 1865, Ambassuan (Ambasohana), near Ambaro Bay, north-west coast of Madagascar.
Recent molecular-genetic analysis indicates that genus may be closest to *Oriolia*, *Falculea* and *Artamella*. Monotypic.
Distribution. N & NW Madagascar.

Descriptive notes. 23 cm. A medium-sized vanga with stout, laterally compressed bill. Male has black head, contrasting white throat and broad white collar, broken at rear; upperparts dark grey, somewhat darker on mantle; upperwing and tail dark grey, blackish or sooty-grey primaries, primary coverts and alula; chin, throat and underparts white; iris blackish; bill and legs dark grey. Female has forehead and lores whitish to pale buff, cheek, chin and throat whitish, front and top of head, nape and back of neck black with blue sheen, upperparts brown-tinged, breast and belly sometimes tinged buff; rest of plumage and bare parts similar to those of male. Juvenile is like female, but generally somewhat paler, with brown markings on scapulars and upperparts, breast and belly pale brown. Voice. Calls include "tseeang" or "tseeeo" whistle on falling scale, also a loud "whip", and quieter whistling or clucking notes as alarm or contact. Two individuals sometimes produce antiphonal duet.
Habitat. Primary dry deciduous forest and immediately adjacent vegetation.
Food and Feeding. Invertebrates, including beetles (Coleoptera), cockroaches (Blattodea), other insects, worms (Oligochaeta); also small vertebrates, e.g. chameleons (Chamaeleonidae). Strips loose bark from tree trunks and branches, investigates clumps of dead leaves, removes epiphytes; sound made by falling debris often gives away the species' presence. Gleans items, and extracts prey from dead trunks and branches by probing. Usually alone or in pairs, and sometimes in family parties of 4–8 individuals; often joins other vangas, e.g. *Schetba rufa*, and occurs in mixed-species feeding flocks.
Breeding. Season Oct to at least Jan. Monogamous. Territorial. Nest built by both sexes, cup-shaped, consists of dead leaves and covered with spider webs, usually 6·5–14·5 m above ground in fork of tree. Clutch 3–4 eggs, white with reddish-brown spots; incubation by both sexes, from first egg; chicks brooded and fed by both sexes. No other information.
Movements. Sedentary.
Status and Conservation. ENDANGERED. Restricted-range species: present in West Malagasy Dry Forests EBA. Locally fairly common. Has tiny global range, and in recent decades recorded at only two widely separated localities, Ankarafantsika National Park (in NW) and Analamerana Special Reserve (in N). Population thought to be relatively small; pairs occupy widely separated, non-contiguous home ranges of 5–8 ha, suggesting density of c. 4 pairs/km². Confined to undisturbed dry deciduous forest, a habitat which, at both sites, is under great pressure, especially from fire. Originally described from an area between its two current sites, but no further records from there; much apparently suitable habitat remains in this intervening area, but this has not been thoroughly surveyed. Nevertheless, this species' habitat is becoming reduced in extent and diminishing in quality; main causes are the clearing and burning of forest for subsist-



ence cultivation, uncontrolled bushfires, commercial logging, and exploitation for charcoal and firewood. Although both of its known localities are officially protected areas, their long-term future is not secure.
Bibliography. Anon. (1999, 2008m), Butchart & Stattersfield (2004), Collar & Stuart (1985), Collar *et al.* (1994), Dee (1986), Hartlaub (1877), Hino (2002), Langrand (1990), Lavauden (1932), Milon *et al.* (1973), Mizuta (2005), Mizuta *et al.* (2001), Morris & Hawkins (1998), Schulenberg (2003), Stattersfield & Capper (2000), Woolaver *et al.* (2004), Yamagishi & Eguchi (1996).

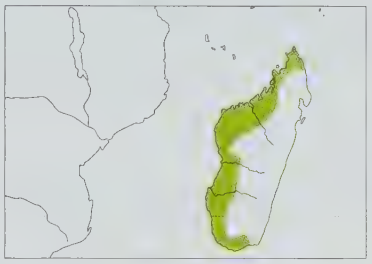
7. Pollen's Vanga

Xenopirostris polleni

French: Vanga de Pollen **German**: Pollenvanga **Spanish**: Vanga de Pollen

Taxonomy. *Vanga polleni* Schlegel, 1868, north-west coast of Madagascar.
Recent molecular-genetic analysis indicates that genus may be closest to *Oriolia*, *Falculea* and *Artamella*. Monotypic.
Distribution. E Madagascar.

Descriptive notes. 24 cm; 61·5–65 g. A medium-sized vanga with stout, laterally compressed bill. Male has black head and throat, white side of neck; upperparts, including upperwing and tail slaty grey, primaries, primary coverts and alula blackish; black of throat extends narrowly to upper breast, rest of underparts whitish, occasionally tinged pale orange; iris blackish; bill light bluish-grey; legs dark grey. Female is similar to male, except that blackish hood extends only to chin and throat (not to upper breast), breast variably (sometimes strongly) tinged orange, usually has white band below hood lacking orange coloration, and upperparts have stronger olive tinge. Juvenile is similar to adult, but when very young is pale orange below, like female but and with slightly less extensive hood, has pale pink bill and conspicuous orange gape; possible one-year-old male has breast blotchy orange with some black spots. Voice. Wide variety of calls, including characteristic loud descending "tseeang" or "tseeeo", also "whip". Other calls include quiet "chuck-chuk-chuk" in alarm, and various loud discordant whistles; "whit-whit-whit" contact call, similar to that of *Tylas eduardi*. Two individuals give antiphonal duet.
Habitat. Primary evergreen humid forest; sea-level to c. 2000 m.
Food and Feeding. Invertebrates, including beetles (Coleoptera), cockroaches (Blattodea), other insects and larvae, worms (Oligochaeta); also small vertebrates, e.g. chameleons (Chamaeleonidae). Forages mostly in middle and upper levels of forest. Investigates dead wood, seeks food under dead bark, examines twigs; main techniques are probing and gleaning. Singly, in pairs, and in family groups of 3–4 individuals, but most often within multi-species flocks with other vangas, including *Tylas eduardi*.
Breeding. Few data. Breeding observed in Sept–Dec; nestlings in Sept at Ranomafana. Cup-shaped nest made from leaves and grass blades, usually 5 m above ground in fork of tree. Clutch 2 eggs; male and female participate equally in brooding and feeding of young. No other information.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in East Malagasy Wet Forests EBA. Locally not uncommon to scarce, and rather patchily distributed. Quite common between 400 m and 2000 m in S of evergreen humid forest belt from Ranomafana S to near Andohahela; scarce or apparently absent from many forest blocks farther N, such as Mantadia, Masoala, Perinet-Analamazaotra and Marojejy. Population believed to be rather small, and expected to experience a fairly rapid decline within a decade or two owing to forest clearance and degradation. Forest habitat threatened by slash-and-burn cultivation and commercial logging; if present trends not halted, much of the remaining forest, especially at lower elevations, will have gone within c. 20 years. Status requires monitoring.
Bibliography. Anon. (2008m), Butchart & Stattersfield (2004), Collar & Stuart (1985), Collar *et al.* (1994), Dee (1986), Delacour (1932), Du Puy & Moat (1996), Goodman, Pidgeon *et al.* (1997), Hartlaub (1877), Hawkins & Goodman (1999), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Putnam (1996), Schulenberg (2003), Stattersfield & Capper (2000), Yamagishi & Eguchi (1996).



Genus *FALCULEA* I. Geoffroy Saint-Hilaire, 1836

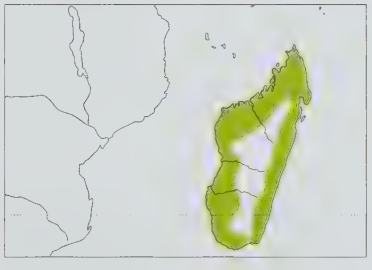
8. Sickle-billed Vanga

Falculea palliata

French: Falculie mantelée **German**: Sichelschnabelvanga **Spanish**: Vanga Piquicurvo
Other common names: Sicklebill, Falcule

Taxonomy. *Falculea palliata* I. Geoffroy Saint-Hilaire, 1836, Madagascar.
Recent molecular-genetic analysis indicates that genus may be closest to *Oriolia*, *Xenopirostris* and *Artamella*. Monotypic.
Distribution. N, W & S Madagascar.
Descriptive notes. 32 cm; 106–119 g. Distinctive; the largest vanga, and with exceptionally long (to 70 mm), strongly decurved bill and sturdy legs. Has white head, neck, chin and throat, and underparts; upperparts black with blue sheen, rump white, upperwing and tail black; white underwing-coverts; iris blackish-brown, orbital ring blackish-slate; bill bluish-grey fading to ivory tip, gape blackish-slate; legs dark grey to pale blue. Sexes alike. Juvenile is similar to adult, but black back and wing feathers tipped with buff. Voice. Various loud screeching, crying and chortling sounds, given by group-members in unison, particularly when going to roost. Most characteristic call a loud "wa-aah", like sound of a crying baby. Contact call a nasal "gaaa gaaa gaaa"; alarm "kekekeke...".
Habitat. Dry deciduous forest and thorn-forest; also savanna, even if sparsely wooded, and wooded areas around villages. Sea-level to 900 m.
Food and Feeding. Invertebrates, including spiders (Araneae), cockroaches (Blattodea), crickets and grasshoppers (Orthoptera), beetles (Coleoptera), other insects, worms (Oligochaeta); also small

vertebrates, e.g. geckos (Gekkonidae). Nestling diet includes similar range of invertebrates, also small vertebrates such as geckos and chameleons (Chamaeleonidae). Favours large branches, living or dead, for foraging. Uses long bill to probe into holes and crevices in trunks of dead and live trees and to lever off bark; gleans insects from surfaces. Holds large prey items with its feet and dismembers them with bill. Gregarious, more so during non-breeding season, when forms flocks of 20–30 or more individuals (and communal roosts numbering in excess of 50); foraging groups often mix with *Artamella viridis*, and often seen with Madagascar Crested Drongos (*Dicrurus forficatus*). When not calling, a feeding group of present species can be remarkably inconspicuous, startling the human observer by flying up from a tree while calling vigorously.
Breeding. Season Oct–Jan in NW (Ampijoroa). Polyandrous: more than two males copulate with one female, and all males (and female) feed young; males participate in territorial defence, in defence against predators and, infrequently, in nest-building, incubation and brooding. Nest cup-shaped, large (diameter 30–40 cm), made from thorny or smooth twigs, interior lined with more delicate material, built 9–16 m above ground and usually in fork of tree. Clutch 3–4 eggs, creamy white and heavily mottled, especially at larger end, with grey to violet-grey or maroon; incubation period 16–18 days; nestling period 19–23 days.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Common to fairly common in most of range, especially in W & S. Occurs in several protected areas, e.g. Ankarafantsika National Park (Ampijoroa), Kirindy and Andohahela National Parks and Berenty Reserve.
Bibliography. Appert (1968a, 1968b, 1970), Dee (1986), Eguchi, Amano & Yamagishi (2001), Langrand (1990), Marcordes & Rinke (2001), Milon *et al.* (1973), Morris & Hawkins (1998), Nakamura, Yamagishi & Okamiya (2001), Oxford & Bish (1999), Schulenberg (2003), Tingay & Gilbert (2000), Yamagishi & Eguchi (1996).



Genus *ARTAMELLA* W. L. Sclater, 1924

9. White-headed Vanga

Artamella viridis

French: Artamie à tête blanche **German**: Weißkopfvanga **Spanish**: Vanga Cabeciblanco

Taxonomy. *Lanius viridis* Statius Müller, 1776, Fort Dauphin (Tôlanaro), south-east Madagascar.
Genus sometimes subsumed in *Leptopterus*. Recent molecular-genetic analysis indicates that genus may be closest to *Oriolia*, *Xenopirostris* and *Falculea*. Races very poorly differentiated; species perhaps better treated as monotypic. Two subspecies tentatively recognized.
Subspecies and Distribution.
A. v. annae (Stejneger, 1879) – W & S Madagascar (S from R Sambirano).
A. v. viridis (Statius Müller, 1776) – N & E Madagascar.

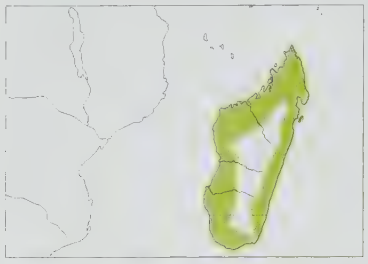
Descriptive notes. 20 cm; 44–57 g. A medium-sized vanga with stout, conical bill. Male has white head and underparts; upperparts black with green sheen, small white area on rump; upperwing and tail black with green sheen, primaries plain black; underside of wing black, except for white underwing-coverts; iris blackish-brown, orbital ring blackish-slate; bill blue-grey, paler tip, gape blackish-slate; legs blue-grey. Female is similar to male, but has head grey, usually lighter on throat, sometimes a dark post-ocular line, small area on rump grey (not white), chest pale grey, belly, flanks and undertail-coverts white with tan tinge. Juvenile is similar to male, but has dark crown and broad brown feather fringes above; immature like female, with grey head and breast, but has upperparts unglossed and much browner. Races differ only in bill size: *annae* has marginally longer bill than nominate. Voice. Male sings from regular songposts a whistling "weety-woo weety-woo weety-woo"; responds to songs of neighbouring males. Various loud chucking and whistling calls, including short "whert".
Habitat. Found in all native forest types, also in second growth, and sometimes in savanna and wooded areas far from native forest; nominate race mostly in evergreen humid forest in E. Sea-level to 1500 m, occasionally higher.
Food and Feeding. Invertebrates, including spiders (Araneae), caterpillars, grasshoppers and crickets (Orthoptera); also small vertebrates, e.g. chameleons (Chamaeleonidae); some fruits and seeds also consumed. Forages mainly in middle and upper levels of vegetation, sometimes lower; rarely observed on ground. Searches for food items on branches of all sizes, even if almost vertical. Probes under peeling bark, occasionally removing fragments; often hangs upside-down. Investigates insect refuges under bark and epiphytes, breaks open dead twigs. Main capture techniques are snatching and gleaning, also sally-gleaning, from leaves and branches. Holds large prey with one foot and uses large bill to dismember them. Sociable; often in mixed-species feeding flocks with other vangas.
Breeding. Recorded in Oct–Jan in NW (Ampijoroa). Sometimes breeds co-operatively; pair occasionally has a helper, apparently a moulting immature male, which participates in territorial defence and mobbing of predators, indulges in allopreening with pair, but does not assist with brood-feeding. Nest built by both pair-members, a cup-shaped structure made from woven plant fibres and twigs, covered with spider webs, usually 6–19 m above ground in fork of tree. Clutch 3 eggs, laid one per day, white, speckled with chestnut, grey and brown; incubation by both partners, period c. 19 days; chicks brooded and fed by both pair-members, nestling period 22–24 days.
Movements. Sedentary.
Status and Conservation. Not globally threatened. Widespread and generally common; possibly less common in S of range. Not reliant on undisturbed forest. Occurs in numerous protected areas throughout range.

Bibliography. Appert (1968a, 1970), Böhning-Gaese *et al.* (1995, 1999), Dee (1986), Hartlaub (1877), Hino (2002), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Nakamura, Yamagishi & Nishiumi (2001), Schulenberg (2003), Yamagishi & Eguchi (1996).

Genus *LEPTOPTERUS* Bonaparte, 1854

10. **Chabert Vanga**

Leptopterus chabert



French: Artamie chabert **German**: Elstervanga **Spanish**: Vanga Chabert

Taxonomy. *Lanius cha-bert* Statius Müller, 1776, Fort Dauphin (Tôlanaro), south-east Madagascar. Recent molecular-genetic analysis indicates that genus may be closest to *Newtonia*, which is currently placed in Old World warbler family (Sylviidae). Two subspecies recognized.

Subspecies and Distribution.

L. c. chabert (Statius Müller, 1776) – W, N & E Madagascar.

L. c. schistocercus (Neumann, 1908) – SW Madagascar.

Descriptive notes. 14 cm; 17·6–26·7 g. A small vanga with prominent, broad blue eyering. Nominate race has forehead, crown, lores, ear-coverts, nape and entire upperparts, including upperwing and tail, black with glossy blue sheen; chin, throat, side of neck and underparts white; iris dark red, fleshy eyering sky-blue above and ultramarine below; bill pale blue; legs blackish. Sexes similar. Juvenile is similar to adult, but lacks blue eyering, has white shaft streaks and tips on black head feathers (making head look pale, with just a dark line through eye), and white fringes on back and wing feathers; fringes gradually lost, on older juvenile reduced to white edges on upperwing-coverts. Race *schistocercus* differs from nominate in having outer tail feathers white for two-thirds of length, with tips black. Voice. Call a characteristic mechanical note, rhythmically repeated at 2–3 per second, "tch-tch-tch-tch", often by several individuals together; often the first indication of a group flying overhead. Also series of "teedee" notes. Clacks bill when irritated.

Habitat. All native forest types, also secondary regrowth, scrubby vegetation and plantations, sometimes far from native forest; also wooded outskirts of villages. Sea-level to 1000 m, occasionally at higher levels.

Food and Feeding. Invertebrates, including beetles (Coleoptera), cockroaches (Blattodea), other insects, worms (Oligochaeta); also small vertebrates, e.g. chameleons (Chamaeleonidae); also small berries. Forages mainly in canopy, where hangs upside-down from outer twigs; frequently feeds aerially in or above canopy. Techniques used are gleaning, sally-gleaning, hover-gleaning and aerial hawking. In one study, at least 50% of observed foraging actions were gleans and 20% involved hovering and hawking. Makes long swoops in air in pursuit of flying insects; skilled aerial sally-feeder, rather reminiscent of a woodswallow (Artamidae). Forages in small groups, occasionally in larger parties of up to c. 30 individuals; sometimes in mixed-species flocks, and then usually employs sally-gleaning as main capture technique.

Breeding. Recorded in Aug–Mar; season Sept–Jan in NW (Ampijoroa). Co-operative breeder, with one or more helpers, sex of which unknown. Cup-shaped nest made from plant fibres and twigs, woven into basket shape, bound together with spider webs, usually anchored to horizontal branch 6–19 m above ground in tree. Clutch 3–4 eggs, dull bluish-green with small violet-grey to olive-brown specks; incubation of eggs and brooding and feeding of chicks by both parents, chicks fed also by helpers; no information on duration of incubation and nestling periods.

Movements. Probably sedentary.

Status and Conservation. Not globally threatened. Widespread, and common or fairly common throughout range. Nominate race common in all forest types, somewhat less abundant in evergreen humid forest in E; probably most numerous at edges of primary forest in W of range. Race *schistocercus* restricted to subdesert in SW, where fairly common.

Bibliography. Appert (1968a, 1968b, 1970), Dee (1986), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Nakamura, Okamiya, Hasegawa & Hasegawa (2009), Nakamura, Okamiya, Hasegawa, Hasegawa & Yamagishi (2008), Schulenberg (2003), Yamagishi & Eguchi (1996).

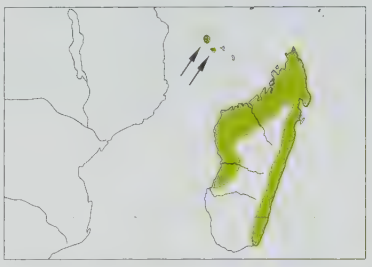
Genus *CYANOLANIUS* Bonaparte, 1854

11. **Blue Vanga**

Cyanolanius madagascarinus

French: Artamie azurée **German**: Blauvanga **Spanish**: Vanga Azul
Other common names: Comoro (Blue) Vanga (Comoro races)

Taxonomy. *Loxia madagascarina* Linnaeus, 1766, Fort Dauphin (Tôlanaro), south-east Madagascar. Genus sometimes subsumed in *Leptopterus*. Recent molecular-genetic analysis indicates that genus may be closest to *Calicalicus*, *Vanga*, *Schetba* and *Euryceros*. Comoro races *bensoni* and *comorensis* possibly represent a separate species, differing from nominate in plumage and voice; validity of *bensoni* requires confirmation. Three subspecies currently recognized.



Subspecies and Distribution.

C. m. bensoni Louette & Herremans, 1982 – Grand Comoro (Njazidja), in NW Comoro Is.

C. m. comorensis (Shelley, 1894) – Mohéli (Mwali), in WC Comoro Is.

C. m. madagascarinus (Linnaeus, 1766) – Madagascar (except C & S).

Descriptive notes. 16–19 cm; 19·3–24·5 g. A small, distinctive vanga. Male nominate race has crown, nape, cheek, ear-coverts and upperparts, including upperwing-coverts, blue, crown and nape with slight lilac tinge; black line through eye, extending to base of bill and narrowly above

and below it, including chin; rear ear-coverts edged by narrow, smudged black line; flight-feathers blackish, tail blue with blackish tip; throat and underparts bright white; iris pale sky-blue; bill brilliant pale blue, dark tip and cutting edges; legs blackish. Female is somewhat duller than male; underparts off-white, breast sometimes with light buffy or pale orange wash. Juvenile differs from adult in having grey-blue, less vivid blue, head and upperparts, brown iris and black bill. Race *comorensis* is larger than nominate, has top of head and all upperparts more intense blue, inner webs of inner secondaries and tertials blue (not black), lacks black smudging on rear ear-coverts, narrower black line around eye and bill, tail shorter with broader terminal black band, bill longer and thinner, female more buffish below, juvenile warm buff below; *bensoni* is very like previous, but bill shorter. Voice. Call a very characteristic angry hard rattle, "tccccccch", often repeated several or many times, similar to call of *Leptopterus chabert*; also a harsh "teea teea teea". On Mohéli (race *comorensis*) a softer grating "prrrt" and more protracted "teea".

Habitat. Nominate race inhabits deciduous dry forest in W and evergreen humid forest in E, also adjacent second growth; sea-level to c. 1200 m, rarely (only where there are big trees) to 1600 m. In Comoros found all types of woodland, especially evergreen forest, and coastal scrub, to c. 300 m on Mohéli; on Grand Comoro, confined to forest on slopes of Mt Karthala.

Food and Feeding. Insects, including beetles (Coleoptera) and Orthoptera, also caterpillars; occasionally berries. Stomach contents from Mohéli (race *comorensis*) included also spiders (Araneae). Forages in middle and upper levels of trees. Often feeds while hanging from its feet, upside-down, in leaf clusters near ends of thin branches. Gleans items from substrate; also sally-gleans from branches and leaves. Forages in groups of up to six individuals; commonly in mixed-species flocks with other vangas and with e.g. Common Newtonia (*Newtonia brunneicauda*), Malagasy White-eye (*Zosterops maderaspatanus*), Madagascar Cuckoo-shrike (*Coracina cinerea*), Madagascar Paradise-flycatcher (*Terpsiphone mutata*) and Long-billed Green Sunbird (*Cinnyris notatus*), and other small passerines.

Breeding. Few data. Nesting observed in Dec in Madagascar, where season probably from Sept; males with enlarged testes in Sept in Comoros (Mohéli). Cup-shaped nest placed c. 12 m above ground, often near end of horizontal branch; parents take turns to incubate eggs. No other information.

Movements. Probably mainly sedentary; previously reported as disappearing from broadleaf forest of SW Madagascar during dry season, but this is evidently not the case.

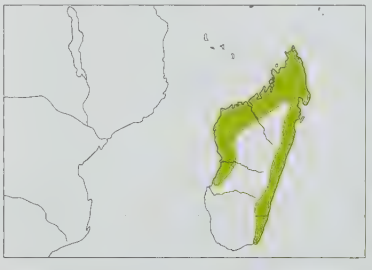
Status and Conservation. Not globally threatened. Fairly widespread; the only member of family found outside Madagascar. Common in most of Madagascar, but appears to be absent from S subdesert; able to live in deciduous dry forest, evergreen humid forest, and second growth. In Comoros, race *comorensis* is reasonably common and widespread on Mohéli. On Grand Comoro, *bensoni* is extremely rare and almost unknown; first definite sighting in Jun–Jul 1974, since when only two further observations, both in August 1981 and at an altitude of c. 900 m; believed possibly extinct by some authors.

Bibliography. Appert (1968a, 1970), Benson (1960), Dee (1986), Hartlaub (1861), Hino (1997, 2002), Langrand (1990), Louette (1988, 2004), Louette & Herremans (1982), Louette & Stevens (1992), Milon *et al.* (1973), Morris & Hawkins (1998), Safford & Evans (1992), Schulenberg (2003), Sinclair & Langrand (1998), Yamagishi & Eguchi (1996).

Genus *SCHETBA* Lesson, 1831

12. **Rufous Vanga**

Schetba rufa



French: Schetbé roux **German**: Rotvanga **Spanish**: Vanga Rufo
Other common names: Red Vanga

Taxonomy. *Lanius rufus* Linnaeus, 1766, Fort Dauphin (Tôlanaro), south-east Madagascar. Recent molecular-genetic analysis indicates that genus may be closest to *Calicalicus*, *Vanga*, *Cyanolanius* and *Euryceros*. Two subspecies recognized.

Subspecies and Distribution.

S. r. occidentalis Delacour, 1931 – W Madagascar.

S. r. rufa (Linnaeus, 1766) – N & E Madagascar.

Descriptive notes. 20 cm; 30·5–44 g. A medium-sized vanga with strong, broad bill. Male has head down to chest, nape and neck black with blue sheen; upperparts, including upperwing-coverts, rufous; primaries dark brown, edged lighter brown on outer side, secondaries and tertials brown-tinged rufous; tail rufous; side of breast, flanks, belly and rest of lower underparts white, white underwing-coverts; iris dark maroon-red; bill blue-tinged grey; legs blue-grey. Female has glossy black front and top of head and nape, rufous upperparts, except for grey nape-collar; rufous upperwing and tail, grey-brown inner half of primaries; whitish cheek, chin and upper throat, fading to light grey chest and flanks, white belly and undertail-coverts, white underwing-coverts; bare parts as for male. Juvenile resembles female, but black of head mixed with dull brown, upperparts and wing dull brown, tail dull rufous, chest tinged brown, iris dark brown, bill black with white tip; one-year-old immature male has black spots extending from neck to throat. Race *occidentalis* differs from nominate only in slightly longer, heavier bill. Voice. Wide variety of beautiful calls. Possible song a smooth, whistled, rippling trill on descending scale; loud and ringing "ti-ti-tong" (the "tong" much lower in pitch) may also be a song, the female responding with "twit-twit-twit". Call a nasal "ees", used as alarm; also as alarm gives a "whip whip whip whip whip" or "kerekerekerekeh", accompanied by bill-snapping. Several calls resemble those of *Euryceros prevostii*, but are finer and more modulated.

Habitat. Lowland evergreen humid forest in E and deciduous forest in W, in areas with open understorey and large trees; requires primary forest. Sea-level to c. 800 m.
Food and Feeding. Invertebrates, including beetles (Coleoptera), cockroaches (Blattodea), other insects, worms (Oligochaeta); also small vertebrates, e.g. lizards, chameleons (Chamaeleonidae) and geckos (Gekkonidae). A sit-and-wait predator, spends long periods perched on low branch, on lookout for potential prey; watches immediate surroundings and seizes prey on branches, trunks, sometimes among dead leaves on forest floor. Feeds on ground more than do other vangas; rarely forages on wing. Flies rarely, and then only for short distances. Main techniques are snatching, gleaning, sally-gleaning, hover-gleaning, less often hawking. Occurs in pairs or, more often, in family groups or in mixed-species flocks with Madagascar Cuckoo-shrike (*Coracina cinerea*), Common Jery (*Neomixis tenella*), Madagascar Paradise-flycatcher (*Terpsiphone mutata*), Common Newtonia (*Newtonia brunneicauda*), Common Tetraka (*Bernieria madagascariensis*), Madagascar Black Bulbul (*Hypsipetes madagascariensis*), and others.
Breeding. Season Oct–Jan in NW (Ampijoroa). Co-operative breeder; pair accompanied by helpers (yearling males and males aged two years and over). Territorial, pair or group maintains territory within which foraging and breeding take place; helpers participate in territorial defence. Nest built by both pair-members, infrequently assisted by helpers, cup-shaped, made from mosses and woven plant fibres and twigs, bound with spider webs, placed 4 m above ground and usually in fork of tree. Clutch 4 eggs, laid one per day, white with small, widely scattered chestnut and reddish spots, increasing in density at larger end; incubation by both pair-members, from first egg, period 14–19 days, generally c. 16 days; chicks brooded and fed by both partners, also by helpers, nestling period 12–17 days, usually c. 15 days.
Movements. Sedentary within territory; location of territories remains the same in successive years.
Status and Conservation. Not globally threatened. Locally common. Often very numerous in primary deciduous forest in W; less common and generally more patchy in distribution in evergreen humid forest in E. Reliant on undisturbed forest.
Bibliography. Genus *EURYCEROS* Lesson, 1831

13. **Helmet Vanga**

Euryceros prevostii

French: Eurycère de Prévost **German**: Helmvanga **Spanish**: Vanga de Casco
Other common names: Helmet Bird

Taxonomy. *Euryceros prevostii* Lesson, 1831, "East Indies"; error = Tintingue, east coast of Madagascar. Has in the past sometimes been placed in a separate, monotypic family, Eurycerotidae. Recent molecular-genetic analysis indicates that genus may be closest to *Calicalicus*, *Vanga*, *Cyanolanius* and *Schetba*. Monotypic.
Distribution. NE Madagascar (from Marojejy region S to Tsaratanana and Mantadia).

Descriptive notes. 28–31 cm; 84–114 g. Highly distinctive large vanga with massive hooked bill (51 mm long, 30 mm deep) and rather long, broad tail. Head, alula, primary coverts and remiges, rump and outer tail feathers are solid blue-black, mantle, scapulars, back, secondary coverts and central pair of tail feathers rufous; entire underside black, diffuse delicate light brown stripes on belly, flanks and undertail-coverts; iris pale cream; bill bright blue with black tip; legs black. Sexes similar. Juvenile has black areas of adult pale buff and rufous areas dark brown; bill initially pale horn-coloured. Voice. Song, given early in morning, often before sunrise, a series of c. 8 soft whistled "trec" notes decreasing in volume, often repeated a few times; territorial call described as a pleasant descending ripple, "pipipipewpewpew pew", like that of *Schetba rufa* but not so long or well-phrased, probably the same. Alarm call a harsh "treh treh treh…" or loud nasal "hink hink hink…", like alarm of *Schetba rufa*; contact call a short whistled "phu" and a higher "tseeah", latter like a high-pitched *Vanga curvirostris*.
Habitat. Evergreen humid forest in lowlands and lower middle altitudes; observed at 200–1800 m, but usually between 400 m and 900 m.
Food and Feeding. Insects, including cockroaches (Blattodea), butterflies and moths (Lepidoptera), crickets and katydids (Orthoptera) and beetles (Coleoptera), also other invertebrates; also frogs, geckos (Gekkonidae), chameleons (Chamaeleonidae), and lizards. Forages in middle level of forest; usually perches 3–10 m from ground, often remaining motionless for long periods, and is then difficult to locate. Feeds mostly by sally-gleaning large insects and other invertebrates from leaves and branches, or by seizing prey from ground; c. 80% of observed foraging motions involved snatching and 20% were gleaning. Found singly or in mixed-species flocks with other vangas, Madagascar Cuckoo-shrikes (*Coracina cinerea*) and other forest passerines.
Breeding. Season Oct–Jan in Masoala Peninsula. Monogamous. Cup-shaped nest 15 cm in diameter, made from mosses and woven plant fibres and twigs, placed 2–4 m above ground and usually in fork of tree or inside palm-leaf whorl. Clutch 2–3 eggs, pinkish-white and mottled with carmine-red, especially at larger end; male and female share equally in incubation of eggs and brooding and feeding of chicks; no information on duration of incubation period, nestling period c. 17 days.
Movements. Probably sedentary.
Status and Conservation. VULNERABLE. Restricted-range species: present in East Malagasy Wet Forests EBA. Uncommon, with patchy distribution; appears to be relatively common in Masoala Peninsula compared with rest of range. Has small global range in NE Madagascar, where confined to primary evergreen humid forest in lowlands. This habitat, on which this species is dependent, is being cleared at rapid rate for subsistence agriculture and timber; species' population is likely therefore to be seriously fragmented and declining. Masoala Peninsula contains Madagascar's largest intact area of low-elevation forest. Recorded in several protected areas, i.e. Mantadia, Marojejy, Masoala and Zahamena National Parks, Ambatovaky and Anjanaharibe-South Special Reserves, Betampona and Tsaratanana Strict Reserves, and Anjanaharibe, Bezavona and Haute Rantabe Classified Forests.

Genus *TYLAS* Hartlaub, 1862

14. **Tylas Vanga**

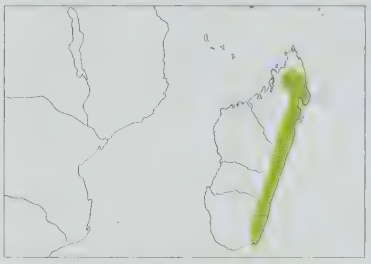
Tylas eduardi

French: Tylas à tête noire **German**: Bülbülvanga **Spanish**: Vanga Cabecinegro
Other common names: Tylas, Kinkimavo/Kinkimano; Western Tylas Vanga (*albigularis*)

Taxonomy. *Tylas eduardi* Hartlaub, 1862, Alanamasaotra, eastern Madagascar.
In the past, this species has been placed in bulbul family (Pycnonotidae) by some authors and with Old World orioles (Oriolidae), thrushes (Turdidae) or starlings (Sturnidae) by others. Recent molecular-genetic research indicates that it belongs in present family, although this treatment is not supported by cladistic analysis of vanga relationship based on morphological characters. W race *albigularis*, differing from nominate in plumage and voice, sometimes thought to represent a separate species, but a few individuals of each race exhibit characters typical of the other; moreover, in highlands, e.g. at Ambohitantely, both plumage types (white-throated and black-throated) occur. Two subspecies currently recognized.
Subspecies and Distribution.
T. e. albigularis Hartlaub, 1877 – very locally in W Madagascar.
T. e. eduardi Hartlaub, 1862 – E Madagascar (Andapa area S to Tôlanaro).

Descriptive notes. 20–21 cm; 35·5–54 g. A medium-sized vanga with rather slender silhouette. Nominate male has black head to nape and throat (rarely, only a black cap), green-grey upperparts; upperwing green-grey, primaries dark brown; tail green-brown; white band on side of neck and across upper chest, rest of underparts variable but usually notably tinged orangy; lesser underwing-coverts white; rarely has white throat and then usually with deep orange breast; iris typically dark brownish, occasionally pale; bill black; legs lead-grey to black. Sexes similar. Juvenile resembles adult, but has pale buffish fringes on wing feathers, usually slightly paler chin (and sometimes whitish forehead), pale orange base of bill. Race *albigularis* is similar to nominate, but almost always has ear-coverts, cheek, chin and throat whitish, leaving contrasting black cap (rarely, throat black), and breast typically pale or very pale pinkish-orange, variable (sometimes bright orange, sometimes almost white). Voice. Song "weeta weet yew ew". A highly characteristic series of "tu-too whirrit", including at least one whiplash-like note. Contact call a quiet "whit-whit-whit" or "quip-quip". In W range (race *albogularis*) "whitoo-whit, whitoo-whit" song heard, last note strongly upslurred; also a loud fluty whistle.
Habitat. In E range, nominate race frequents primary rainforest, occasionally adjacent second growth, from sea-level to 1800 m. In W, *albigularis* very poorly known and only few data available; recorded in deciduous, almost leafless dry forest, and a few times in mangroves, from sea-level to c. 900 m.
Food and Feeding. Invertebrates, including butterflies and caterpillars (Lepidoptera), dragonflies (Odonata), horseflies and other Diptera, grasshoppers (Acrididae), snails (Gastropoda), spiders (Araneae). Forages mainly in middle and upper levels of forest, in canopy and upper shrub layer. Catches prey by gleaning and hovering; hunts from ambush, often seizes prey on wing. Found in mixed-species flocks with other vangas, and Madagascar Cuckoo-shrike (*Coracina cinerea*), Common Tetraka (*Bernieria madagascariensis*), Madagascar Black Bulbul (*Hypsipetes madagascariensis*), Madagascar Crested Drongo (*Dicrurus forficatus*), Common Newtonia (*Newtonia brunneicauda*), and others.
Breeding. Season Oct–Jan in E of range (Ranomafana); possibly Aug–Sept in W. Monogamous; breeds as simple pair. Male defends territory. Cup-shaped nest 9·5 cm in diameter, built by both sexes, from dead leaves, spider webs and mosses, usually 4–7 m above ground in fork of tree. Clutch 2 eggs, green-blue with small, widely scattered chestnut and reddish-grey spots, increasing in density at larger end; incubation by both parents, mainly by female, period c. 16 days; chicks brooded predominantly by female, less by male, fed by both sexes, nestling period c. 15 days.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Nominate race is common to fairly common in most of range. Very poorly known race *albigularis* is rare and very local; recorded at a number of sites from Baty (near Mahajanga) S to R Mangoky region, with isolated record farther S, in forest near Ankazoabo (EC Toliara Province). Species is confined to native forest, where it occurs in a number of protected areas. Study required in order to determine distribution and population size of poorly known W race (*albigularis*).
Bibliography. Appert (1968a, 1970), Dee (1986), Delacour (1932), Dorst (1960c), Hartlaub (1877), Hawkins (1995), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Nakamura, Tateno & Rakotomanana (2008, 2009), Oberholser (1900), Schulenberg (2003), Sharpe (1870, 1871), Yamagishi & Eguchi (1996).

Genus *HYPOSITTA* A. Newton, 1881



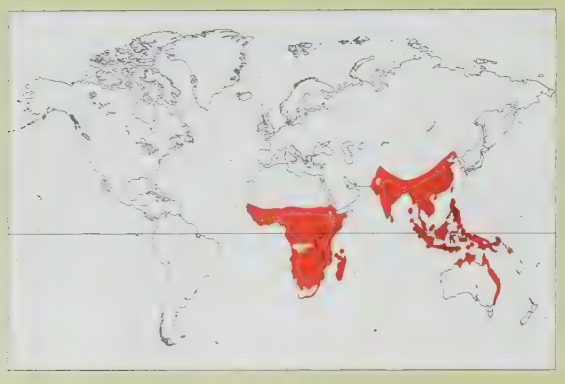
15. **Nuthatch Vanga**

Hypositta corallirostris

French: Hypositte malgache **German**: Korallenschnabelvanga **Spanish**: Vanga Trepador

Other common names: Coralbill, Coral-billed Nuthatch (Vanga), Madagascar Nuthatch; Bluntschli's Vanga (*"perdita"*)

Taxonomy. *Hypherpes corallirostris* A. Newton, 1863, Chasmanna, east Madagascar.
Has in the past sometimes been placed in a separate, monotypic family, Hypositttidae, or in tit family (Paridae), but certain morphological and anatomical features indicate that inclusion in present family more appropriate. Two juvenile specimens found in 1996 in museum drawer in Germany, and originating from primary forest near Eminiminy (N of Tôlanaro), in SE Madagascar, are plain olive-brown with blackish forehead, and similar to present species in size and loose plumage structure, but with much longer tarsus and significantly shorter toes; described as a new species, "*H. perdita*", but could be aberrant examples of present species or some other species, although no further individuals seen and impossible to assess whether they do represent a valid taxon (different species, or race). Monotypic.
Distribution. N & E Madagascar S to Tôlanaro.
Descriptive notes. 13–14 cm; 13·5–15·5 g. A small, highly distinctive vanga; claw of first toe elongated (20 mm). Male has black lower forehead, lores and chin; rest of plumage mid-blue, variably pale buff on vent; iris very dark brown; bill bright orange-red, slightly darker tip of culmen; legs dark grey. Female has brownish-green head lacking clear black eyestripe, buffy forecrown, blue hindcrown, mantle, scapulars, upperwing-coverts and tail, buffish rump, buffish chin, centre of breast and belly; bill duller red than male's. Juvenile is similar to female, but young male acquires increasing amount of blue on head and side of breast with age. Voice. A sequence of quiet hissing or squeaking notes, including "tsee see see", and quiet trill increasing in volume.
Habitat. Undisturbed evergreen humid forest; recorded from sea-level to 1800 m, mainly below 1000 m.
Food and Feeding. Small invertebrates, including beetles (Coleoptera), cockroaches (Blattodea), other insects, worms (Oligochaeta); also small vertebrates. Forages in middle and upper levels of forest. Climbs large and medium-sized tree trunks in manner of a nuthatch (*Sitta*), searching for food on bark; does not work from top downwards. Occasionally forages also on horizontal branches, and sometimes climbs narrow stems and even lianas. Most items captured by gleaning. Most often in groups of two or three individuals, almost always within mixed flocks with other vangas, Madagascar Cuckoo-shrike (*Coracina cinerea*), Madagascar Black Bulbul (*Hypsipetes madagascariensis*), Common Newtonia (*Newtonia brunneicauda*), Madagascar Paradise-flycatcher (*Terpsiphone mutata*), and other passerines.



Breeding. Nest found in Oct, and season probably from Aug–Sept. Nest a cup made from live and dead mosses, attached to main trunk of tree. No other information.
Movements. Probably sedentary.
Status and Conservation. Not globally threatened. Restricted-range species: present in East Malagasy Wet Forests EBA. Fairly common in N part of range; rather rare in S. Locally common in several protected areas, e.g. Marojejy, Mantadia and Masoala National Parks, and Perinet-Analamazaotra Special Reserve, among others. Dependent on rainforest. Mysterious form described as "*perdita*", sometimes treated as a genuine species, is almost unknown; when treated as valid, is considered a Data-deficient taxon. It is possible that since 1931, when the specimens were collected, it has become extinct, despite fact that good-quality forest habitat still exists at locality where originally found; in 1995 survey of fauna of Andohahela, including forest near this site, only present species was found.
Bibliography. Anon. (1999, 2008m), Butchart & Stattersfield (2004), Dee (1986), Delacour (1932), Dorst (1960c), Hawkins & Goodman (1999), Langrand (1990), Milon *et al.* (1973), Morris & Hawkins (1998), Peters (1996), Schulenberg (2003), Sharpe (1871), Stattersfield & Capper (2000), Yamagishi & Eguchi (1996), Yamagishi *et al.* (1997).

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family DICRURIDAE (DRONGOS)

- Medium-sized passerines with long tail generally deeply forked, some with terminal tail-racquets; plumage mostly shining or glossy black, sometimes with crest or elongated plumes on head.
- 18–70 cm (including extremely long tail of some species).

- Old World, mostly in tropical and subtropical regions.
- Forest and wooded areas.
- 2 genera, 26 species, 106 taxa.
- 2 species threatened; none extinct since 1600.

Systematics

In 1948, in their attempt to retrace the evolution of the Dicruridae, E. Mayr and C. Vaurie had pointed out the difficulty of determining the closest relatives of this family. Drongos have in the past been considered to be related to the crows (Corvidae), some authors having also suggested a relationship with the shrikes (Laniidae), the Old World flycatchers (Muscicapidae), the cuckoo-shrikes (Campephagidae), the birds-of-paradise (Paradisaeidae), and even the Old World orioles (Oriolidae) or starlings (Sturnidae), on the basis of morphological or behavioural similarities. Modern methods of DNA–DNA hybridization, developed in the 1980s by C. G. Sibley and J. E. Ahlquist, placed the drongos between the fantails (Rhipiduridae) and the monarch-flycatchers (Monarchidae) in the avian classification. More recent molecular-genetic studies have included drongos within the corvoid songbirds that probably radiated from Australasia, and this, together with comparative skeletal evidence, suggests that Australasian monarch-flycatchers are their closest relatives. Like the monarchs, they have a single pneumatized fossa in the head of the humerus and a strongly ossified nasal cavity.

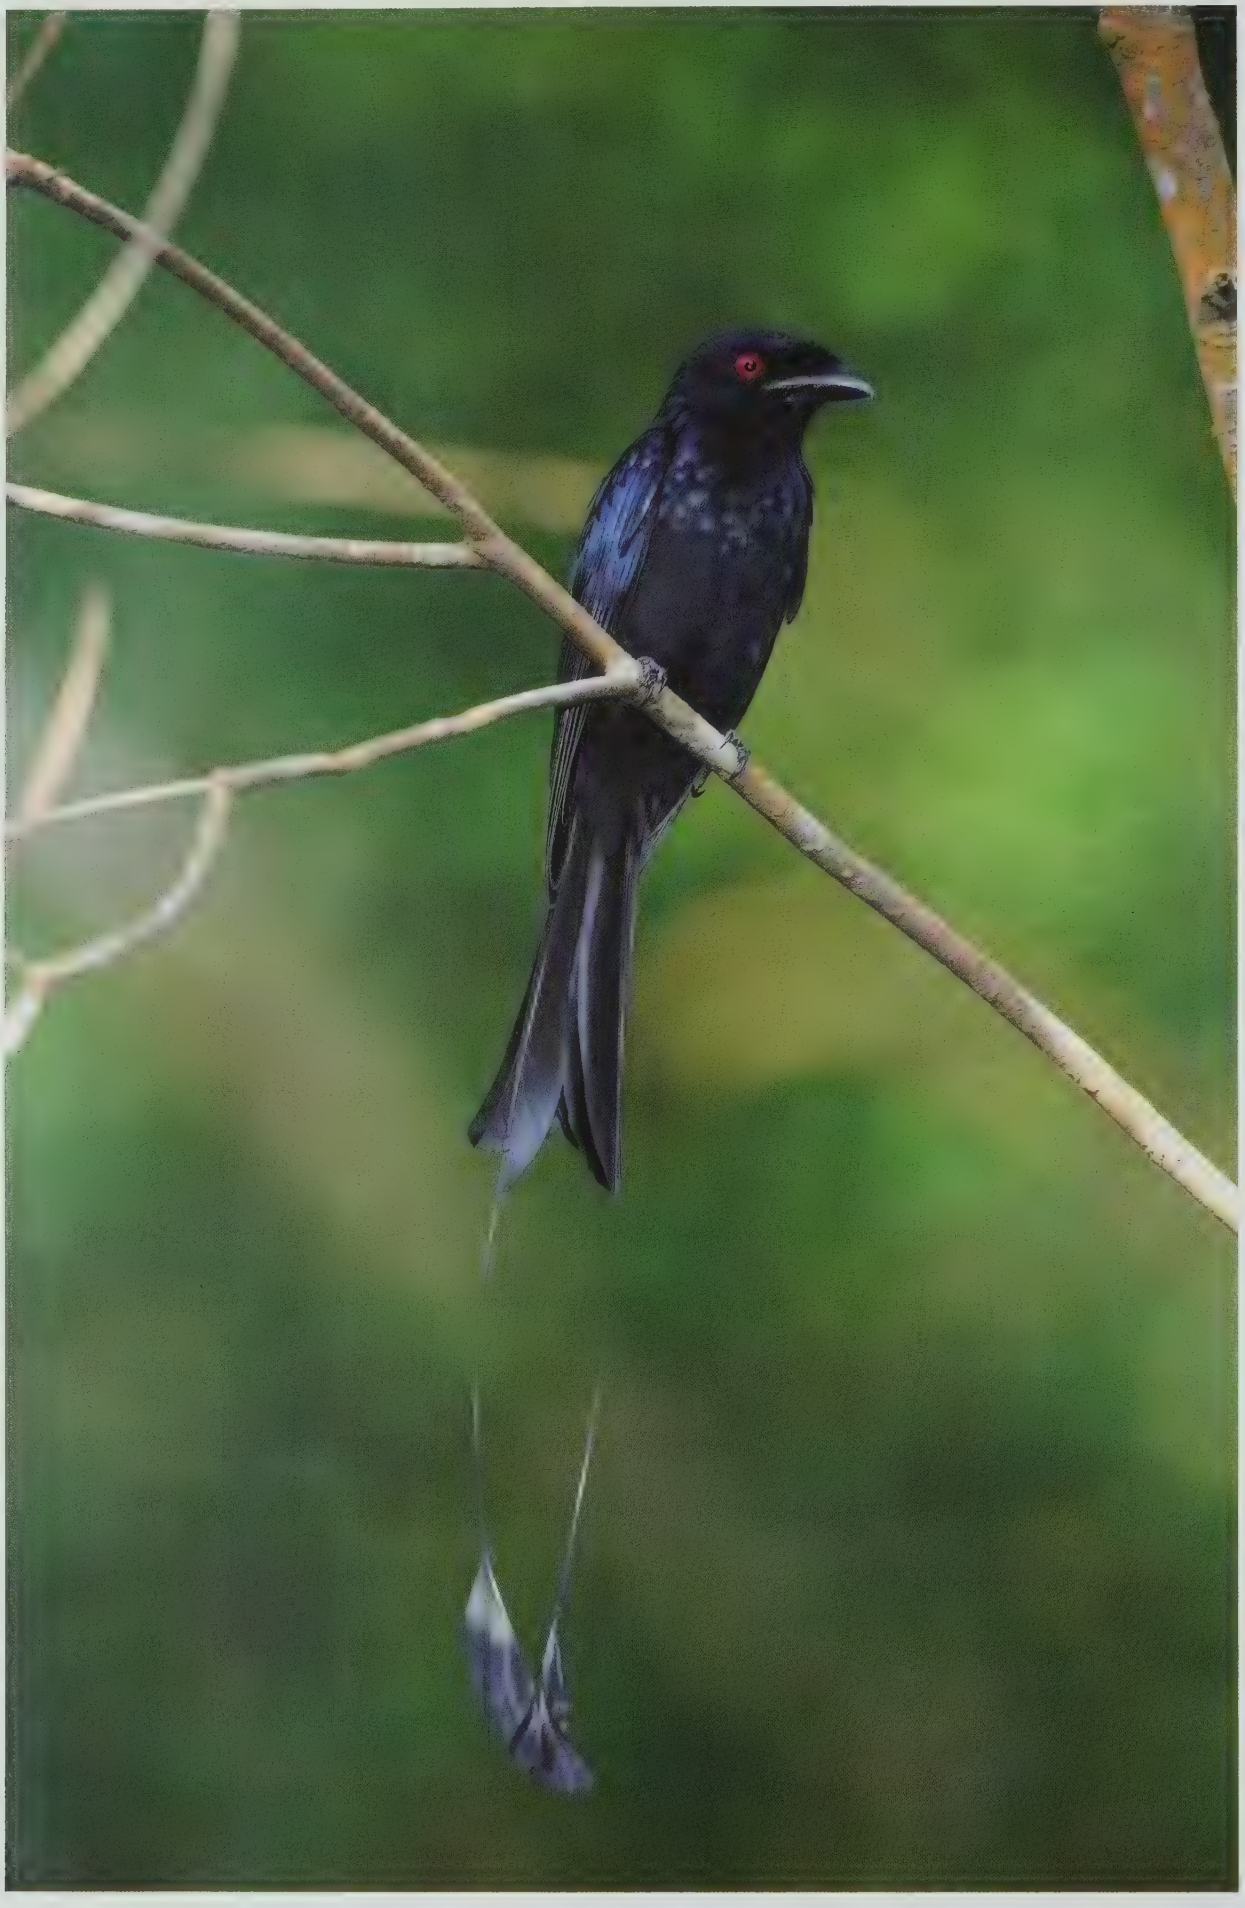
Six decades or more ago, Vaurie undertook a major taxonomic revision of the family and, in 1949, he produced a milestone publication of reference. The drongo family tree which Mayr and he had proposed was based mainly on biogeographical considerations and on morphological characters such as the distribution of gloss and the presence of modified feathers. This classification distinguished between the more primitive forms, with the gloss smooth and uniform, and specialized forms, having an irregular gloss. Primitive forms included the Pygmy Drongo (*Chaetorhynchus papuensis*), differentiated from other dicrurids by its possession of twelve rectrices, instead of ten, the White-bellied Drongo (*Dicrurus caerulescens*) and the Ashy Drongo (*Dicrurus leucophaeus*), along with a group containing all of the African and Indian Ocean drongos and a southern and south-eastern Asian species, the Black Drongo (*Dicrurus macrocercus*), this group being considered to form the "*Dicrurus adsimilis* superspecies". The results of molecular-genetic studies carried out by F. K. Barker and colleagues, published in 2004, indicate that the Pygmy Drongo really belongs with the fantails in the family Rhipiduridae. Specialized forms consisted of all other Asian and Australasian species: the Crow-billed Drongo (*Dicrurus annectans*), the Lesser Racquet-tailed Drongo (*Dicrurus remifer*), the Bronzed Drongo (*Dicrurus aeneus*), the Andaman Drongo (*Dicrurus andamanensis*), the Greater Racquet-tailed Drongo (*Dicrurus paradiseus*), the Balicassiao (*Dicrurus balicassius*), and the forms related to a very large "*Dicrurus hottentottus* superspecies complex" covering 32 taxa. In this family, subspecies are differentiated by body size, the shape and length of the bill and tail, including the depth of the tail fork, and plumage coloration, including the glossiness or velvetiness, and also by the presence and shape of modified feathers on the head, such as crests, hackles and spangles, and on the tail, such as very long outer rectrices that are fully webbed or partly denuded and forming racquets.

More recently, E. Pasquet and co-workers attempted to clarify the relationships within the Dicruridae by using DNA from sequences of two mitochondrial genes in order to reconstruct the phylogenetic tree, and discussed the resulting biogeographical and evolutionary implications. This major study, published in 2007, covered 18 of the 21 species then included in the Dicruridae,

Considered the most primitive drongo, and sole member of the genus Chaetorhynchus, *the* ***Pygmy Drongo*** *differs from all other drongos in having twelve, not ten, rectrices. Its slightly rounded tail recalls that of a fantail. Indeed, genetic studies indicate that* Chaetorhynchus *may actually belong in the fantail family, Rhipiduridae. Similar studies have included drongos within the corvoid songbirds, which probably radiated from Australasia. Comparative skeletal evidence suggests that Australasian monarch-flycatchers (Monarchidae) are their closest relatives.*

[*Chaetorhynchus papuensis*, Heroana, EC New Guinea. Photo: William S. Peckover]

A provisional taxonomic sequence based on DNA studies of 25 out of the 106 taxa currently recognized in the family Dicruridae assigns the ***Wallacean Drongo*** *to the "*hottentottus–balicassius–bracteatus *complex". The main taxonomic problem remaining for this complex is the treatment of the numerous island forms occurring in the Philippines–Wallacea–New Guinea region. Morphological, behavioural and vocal variations suggest that closer studies would probably result in the promotion to full species of several forms currently listed as subspecies.*



[*Dicrurus densus*, Sumba, Lesser Sundas. Photo: James Eaton]

but it comprised a maximum of only 25 out of the 106 taxa presently recognized in the family. This molecular study is therefore insufficient to answer all the taxonomic questions still pending regarding geographical variation among drongos. While its results confirmed many species arrangements made by Vaurie, it did, however, also reveal unexpected phylogenetic affinities between some species and, as a result, a completely different family tree, as well as the existence of a series of specific radiations and colonization events. On the basis of these results, a new taxonomic sequence is currently proposed, although it must be borne in mind that this is still provisional, as further studies are required on certain species groups.

In this new classification, the most ancient *Dicrurus* species is the Bronzed Drongo, a medium-sized Oriental drongo with a highly metallic gloss, instead of Vaurie's "primitive forms", namely the Square-tailed Drongo (*Dicrurus ludwigii*) and the Shining Drongo (*Dicrurus atripennis*) of the Afrotropics. The Bronzed Drongo seems to have evolved during the Miocene, about 18 million years ago, from a primitive *Dicrurus* ancestor that apparently separated from older avian groups, including the crows, the shrikes, the fantails and the flycatchers, around 35 million years ago, although this cannot be confirmed by the limited fossil record available.

Separation from the Asian drongos by those of Africa and the Indian Ocean islands occurred around 15 million years ago, and was followed by a large diversification in both continents. Within the Asian group, the Lesser Racquet-tailed Drongo is the first species to branch off from all other Australasian and Asian large drongos, of which all except the Balicassiao have an irregular gloss and modified head and/or tail feathers. The Greater Racquet-tailed Drongo and, curiously, the Crow-billed Drongo, which Pasquet and colleagues' molecular study now gives as the former's closest relative, would have diverged into two different species only relatively recently, within the last few million years. Validation of such close relatedness, however, requires sampling from more than one individual of the Crow-billed Drongo, especially as there is a strong suspicion about the species identity of the only specimen used in this study. To this group can be added the Sri Lanka Crested Drongo (*Dicrurus lophorinus*), still considered by some authors to be a subspecies of the Greater Racquet-tailed Drongo, its recent elevation to species rank by P. C. Rasmussen and J. C. Anderton meriting confirmation from DNA and other taxonomic studies. Morphological and possibly vocal distinctness of *lophorinus* from the *ceylonicus* race of the Greater Racquet-tailed Drongo, and the limited number of apparent intergrades, could be seen to favour recognition of *lophorinus* as a full species; indeed, in view of the recent absence of a contact zone, the few putative intergrades could be aberrant individuals, rather than hybrids. These two species, and possibly the Crow-billed Drongo, may have to be treated as a superspecies. The Andaman Drongo, identified by Vaurie as an ancient relative of the Greater Racquet-tailed Drongo, was not included in the recent phylogenetic study. It is provisionally retained in its early position in the classification.

Members of the former "*hottentottus* superspecies" as defined by Vaurie, namely the Hair-crested Drongo (*Dicrurus hottentottus*), the Spangled Drongo (*Dicrurus bracteatus*) and the Ribbon-tailed Drongo (*Dicrurus megarhynchus*), together with the Balicassiao, which Vaurie hesitated to include in the superspecies, form a distinct "*hottentottus–balicassius–bracteatus* complex"; this radiated about 6 million years ago, leading to dispersal across Wallace's Line and the colonization of Australasia by the Spangled and Ribbon-tailed Drongos. Four other forms from Vaurie's "*hottentottus* superspecies", provisionally retained as distinct species although not included in the DNA study, should also be part of this complex. These are the Sulawesi Drongo (*Dicrurus montanus*), already identified as a full species by Vaurie, the Sumatran Drongo (*Dicrurus sumatranus*) and the Wallacean Drongo (*Dicrurus densus*), proposed by C. M. N. White and M. D. Bruce in 1986 as two full species, and the Tablas Drongo (*Dicrurus menagei*), restricted to a very small island in the Philippines and suggested by D. Allen in 2006 as meriting elevation to species rank. Despite the insufficiency of published information for considering the treatment of the Sumatran and Wallacean Drongos as separate species, the fact that both were recognized as such by Sibley and B. L. Monroe in their landmark work *Distribution and Taxonomy of Birds of the World*, and were later integrated in various world bird lists, supports the current treatment. Sibley and Monroe grouped the Sulawesi, Sumatran and Wallacean Drongos within a "*balicassius* superspecies", along with the Balicassiao and the Spangled and the Ribbon-tailed Drongos. The rather large genetic distances between the Hair-crested Drongo, the Spangled Drongo and the Balicassiao found in Pasquet and colleagues' study suggests, however, that a superspecies treatment may not be appropriate. Although no formal proposal has yet been made to elevate the Tablas Drongo to species rank, this taxon's morphological distinctiveness, and its apparent differences in voice, behaviour and habitat preferences from other forms of the Hair-crested Drongo, would appear to justify its current provisional treatment, one that will require further corroboration.

When the racquet feathers are included, the total length of the ***Greater Racquet-tailed Drongo*** *may reach about 70 cm. The greatly elongated sections of the shafts of the outer tail feathers are completely denuded of barbs until, near the tip, the inner web or both webs reappear and form a racquet-like pendant. This may be a relatively unstable character, as specimens with fully webbed outer feathers have been reported for several races of the Greater Racquet-tailed Drongo, including the nominate race,* brachyphorus *and* platurus. *The outermost rectrices of the Sri Lanka Crested Drongo* (Dicrurus lophorinus), *still considered by some authors a race of the Greater Racquet-tailed Drongo, are always fully webbed. Drongos' heads are rather large and sometimes crested, with tufts of frontal feathers starting at the base of the bill and directed forwards and upwards, or sometimes curling backwards to form a large crest from just over the forehead to well beyond the nape. The greatest crest development is reached with the race* grandis *of the Greater Racquet-tailed Drongo, which has fully webbed feathers of up to 66 mm, although some other races of this species completely lack the crest and have only small bristly feathers curling forwards over the culmen. The race* platurus *of southern Peninsula Malaysia, shown here, has elongated frontal feathers mostly directed upwards, forming a bushy tuft, though more rarely this race has a short crest, sometimes curving backwards. Like the race* hypoballus *of northern Peninsular Malaysia,* platurus *has the glossy feathers of the breast arranged into well-defined spangles.*

[*Dicrurus paradiseus platurus*,
Sime Forest, Singapore.
Photo: Teo Nam Siang]

*In flight, the tail feathers of the **Greater Racquet-tailed Drongo** produce a characteristic humming noise, audible from some way off. The wings of drongos are rather long, and either rounded or somewhat pointed. The flight-feathers comprise ten primaries, including a well-developed outermost primary half as long as the next, nine secondaries, and a few tertials. Average wing lengths vary from about 107 mm in the smaller species to 180 mm or more in the largest forms.*

[*Dicrurus paradiseus otiosus*, Andaman Is. Photo: Konrad Wothe]

Information on all the existing types and a preliminary systematic review of the Asian Dicruridae, presently being compiled by E. C. Dickinson and colleagues, indicate, however, the uncertainty remaining in the taxonomy of the large conglomerate of 32 forms initially placed by Vaurie within the "*D. hottentottus* superspecies complex", described as an obvious candidate for subdivision into several species. A first major split was made by White and Bruce in 1986, with the distinction between *D. hottentottus*, renamed as the Hair-crested Drongo, and *D. bracteatus*, which kept the common name of Spangled Drongo; this involved the regrouping of eleven Australasian races of the initial complex. The main taxonomic problem remaining is the separation of the numerous island races described in the Philippines–Wallacea–New Guinea region. While the majority of these allopatric forms have been "lumped" in polytypic species such as the aforementioned Hair-crested and Spangled Drongos, there are important morphological and also behavioural or vocal variations among them, suggesting that closer studies would probably result in the identifying of new species. The separation of the Sumatran Drongo and the Wallacean Drongo, incorporating, respectively, two and six different subspecies, is a first step in that direction, and the Tablas Drongo's status as a species, if confirmed, would be another. Many other races exhibiting significant differentiation could likewise be strong candidates for species rank. This is the case, for instance, with the subspecies *buruensis* and *amboinensis* of the Spangled Drongo, currently containing ten island races, and of subspecies *striatus* and *samarensis* of the Hair-crested Drongo, which has twelve island races. The same could apply also to some insular subspecies of the Greater Racquet-tailed Drongo in the southern Oriental Region.

Following the colonization of Africa by drongos from Asia about 15 million years ago, the Square-tailed Drongo and Shining Drongo appear relatively rapidly and correspond to the most ancient species of the continent, occupying a basal position in the family tree of this group. Curiously, the Ashy Drongo, currently distributed widely over southern and eastern Asia, is the next species to branch off from the African group, providing evidence of a first colonization of Asia by a drongo species having originated in Africa around 10 million years ago. Next in the present classification is the White-bellied Drongo, which was not included in the molecular analysis but is, like the Ashy Drongo, another species from Vaurie's "primitive group". The remaining two African species, the Fork-tailed (*Dicrurus adsimilis*) and Velvet-mantled Drongos (*Dicrurus modestus*), along with the Indian Ocean species and the Black Drongo from Asia, all of which together form what Vaurie identified as the "*D. adsimilis* superspecies complex", correspond to a well-defined monophyletic group. Having originated about 5 million years ago, this group radiated and colonized all of Africa, Príncipe Island and the Indian Ocean islands, as well as, with the Black Drongo, Asia, thereby providing evidence of a second colonization event of Asia by an African species. Although genetic distances among members of this group are too great to support superspecies status, this taxonomic level should still apply to the two vicariant species, the Fork-tailed Drongo and the Black Drongo, present respectively in Africa and Asia. This superspecies may also englobe the continental forms of the Velvet-mantled Drongo, not represented in the molecular study by Pasquet and co-workers, but probably not its Príncipe form, the nominate race, which appears to be genetically well differentiated. The Black Drongo is still very closely related to the Fork-tailed Drongo, from which it probably became differentiated over the last million or so years; until the 1980s, it was systematically referred to by the name *D. adsimilis*, instead of *D. macrocercus*, in many Asian publications. The main morphological difference between the Black Drongo and the Fork-tailed and Velvet-mantled Drongos is that the tail length of the latter two is on average 86% of the wing length, whereas the Black Drongo's tail is longer than the wing, the average being 109%.

The phylogenetic DNA study undertaken by Pasquet and colleagues also revealed an early separation, about 4 million years ago, of the nominate form of the Velvet-mantled Drongo, confined to Príncipe, and the Fork-tailed Drongo. This supports the recognition of the Velvet-mantled Drongo as a distinct species, as proposed by Sibley and Monroe in 1990 and D. J. Pearson in *The Birds of Africa* in 2000, while other authors, including BirdLife International, still treat *modestus* as a subspecies of the Fork-tailed Drongo. Also, such a high level of differentiation does not support Pearson's hypothesis of a *D. adsimilis* superspecies encompassing both species. The validity of the Velvet-mantled Drongo species as currently constituted will not, however, be fully assessed until both continental forms from which the nominate race is likely to have originated, namely the central African subspecies *coracinus* and the West African *atactus*, can be included

It is calculated that around 15 million years ago the drongos of Africa and the Indian Ocean islands separated from the Asian forms. This was followed by a major diversification in both continents. Within the Asian group, the ***Lesser Racquet-tailed Drongo*** *was apparently the first species to branch off. Its outermost rectrices are greatly elongated, bare and wire-like, ending in the racquets, which differ in size and shape among the four subspecies. The female is similar to the male but smaller, with a shorter tail ending in similar racquets. Malformed or broken outer tail feathers can be used by ornithologists for individual recognition.*

[*Dicrurus remifer peracensis*, Fraser's Hill, Malaysia. Photo: Morten Strange]

in a full molecular-genetic analysis. It is possible that one or both of these races may actually prove to be closer to the Fork-tailed Drongo than to the Príncipe form of the Velvet-mantled Drongo, which would then require a redefinition of the subspecific composition of the *D. modestus* species, and possibly also of its English name.

Another important result from the 2007 molecular study is the fact that drongos from Indian Ocean islands do not form a monophyletic assemblage. The colonization of these islands by an ancestor of the "*D. adsimilis* group" seems to have occurred very early, shortly after its arrival in Africa, and to have followed a complex pattern. The most ancient species is the Comoro Drongo (*Dicrurus fuscipennis*), which originated about 5 million years ago and appears to be the closest relative of the Fork-tailed and Velvet-mantled Drongos. As the estimated age of Grand Comoro island, to which it is restricted, is only 0·5 million years, this species must have originated from another, older island in this volcanic archipelago, such as neighbouring Mohéli. Furthermore, it does not appear to be closely related to other drongo species from the Indian Ocean. The Mayotte Drongo (*Dicrurus waldenii*) appears at around the same time and is as old as Mayotte itself, branching off from the ancestor of the Madagascar Crested Drongo (*Dicrurus forficatus*) that colonized Madagascar. The recent colonizations by the latter of Aldabra and then the Comoro island of Anjouan, estimated to have occurred within the last 100,000 to 150,000 years, have led to the differentiation of a new species, the Aldabra Drongo (*Dicrurus aldabranus*), which lost the tufted crest, and, on Anjouan, of a new subspecies, named *potior*, of the Madagascar Crested Drongo. This confirms the little phylogenetic value of the crest, which can appear and disappear easily in the various lineages, in both ancient and recent forms of both Asian and African groups.

Further systematic studies based on molecular DNA analysis, but also on other parameters, including voice and ecology, should be conducted on all known drongo forms, in particular within the Philippines–Wallacea–New Guinea region and within the "*D. adsimilis–D. modestus* group", in order to clarify the taxonomic and geographical limits of neighbouring related species and to resolve taxonomic uncertainties. In the general context of a decline of tropical forests, it is essential to confirm or identify rapidly all species and subspecies. Only with this information will it be possible to provide effective protection of their habitats and to devise appropriate conservation programmes (see Status and Conservation).

Morphological Aspects

In the field, drongos appear generally as medium-sized glossy black woodland birds with a robust, slightly hooked bill, and a relatively long tail, which may be forked and have elongated decorative rectrices. Despite the high morphological homogeneity of this group, significant variations exist among species in terms of general size and wing length, details of plumage coloration, the intensity of gloss and velvetiness, the shape and length of the tail and bill, the modification of the outermost tail feathers, the presence or absence of a crest, the development of spangles and hackles, and the colour of the iris. Further, these characters may vary geographically within a single species and justify the naming of different races. The frontal feathers and the rectrices exhibit the greatest tendency for specific development or variation in the evolution of drongos, particularly in Asia, where it is most spectacular. Differentiation of such visual characters facilitating intraspecific recognition may be linked to the presence of many sympatric drongo species, especially since drongos are very similar in plumage coloration and their vocalizations are not always specifically distinctive. There are, for example, up to seven sympatric species in the region from peninsular India east to south-east China.

Body length varies from that of the Square-tailed Drongo, 18–19 cm, to that of the much larger Ribbon-tailed Drongo, which is 51–56 cm and sometimes up to 63 cm. These figures include the tail of all except the two racquet-tailed drongos, which have extremely long outer rectrices. Particularly small species include the Pygmy Drongo, at 20–22 cm, the Bronzed and White-bellied Drongos, 23–24 cm, and the Shining Drongo, which measures 21–24 cm. At the other extreme, the Wallacean Drongo subspecies *megalornis* and the Mayotte Drongo are among the longest dicrurids, both sometimes reaching as much as 38 cm. When racquet feathers are included, the total length may reach 70 cm

All drongos have black bills. These are almost always strong, and particularly broad and deep at the base, this being especially evident in the ***Crow-billed Drongo****. The base of the bill is covered by dense short feathers, with well-developed rictal bristles, possibly to protect the face and eyes during struggles with prey. The bill is hooked at the tip, compressed and well notched for seizing and holding prey. The nasal cavity is heavily ossified, and the palate reinforced by an extended bony plate to allow mastication of large insects with hard carapaces. Powerful jaw muscles are attached to a large depression in each temple. Bill length in the family ranges from about 20 mm to 35 mm.*

[*Dicrurus annectans*, S Peninsular Malaysia. Photo: Tony Tilford]

or more for the race *grandis* of the Greater Racquet-tailed Drongo, with outer rectrices of up to 50 cm. Data on weights are lacking for several species, but the Bronzed and Square-tailed Drongos, weighing 22–30 g and 25–35 g, respectively, appear significantly lighter than the other small, dumpier species. Heavier forms include the race *grandis* of the Greater Racquet-tailed Drongo, which weighs 100–124 g, and the Hair-crested Drongo, weighing 86–102 g.

Few significant morphological differences between the sexes are evident, except, perhaps, for size and weight. Females are generally, but not always, smaller and about 10–15% less heavy than males, and the lengths of the crest and bill tuft of female Madagascar Crested and Aldabra Drongos are shorter than those of the males. The amount of gloss is often higher in males, as demonstrated by the Square-tailed, Hair-crested and Shining Drongos, and the plumage of females of the Aldabra Drongo is greyer than that of the male. These small differences can sometimes allow the identification of the presumed male or female of a particular pair during nesting.

The head is rather large, and is sometimes crested, with tufts of frontal feathers starting at the base of the bill and directed forwards and upwards, or sometimes curling backwards to form a large crest from just over the forehead to well beyond the nape. Typical examples are the Madagascar Crested, Sri Lanka Crested, Hair-crested and Greater Racquet-tailed Drongos. The greatest crest development is reached with the subspecies *grandis* of the Greater Racquet-tailed Drongo, which has fully webbed feathers of up to 66 mm, although some other races of this species completely lack the crest and have only small bristly feathers curling forwards over the culmen. In the case of the Hair-crested Drongo, these frontal feathers are webless hair-like filaments, and these, too, may be absent in a certain percentage of specimens of some races. For example, they are lacking in 50% of *guillemardi* and *pectoralis* specimens, and are totally absent in the taxonomically problematic forms *striatus* and *samarensis*.

Drongo bills are black and are almost always strong, and particularly broad and deep at the base, this being especially evident with the Crow-billed Drongo; the exception is the Bronzed Drongo, which has a depressed, flat bill. The drongo bill has an arched culmen, and is hooked at the tip, compressed and well notched for seizing and holding prey; well-developed rictal bristles are present at its base, possibly to protect the face from captured prey, and concealing slit-like nostrils. Internally, the nasal cavity is heavily ossified, and the palate is reinforced by an extended bony plate to allow handling and mastication of large insects with hard carapaces; powerful jaw muscles are attached to a large depression present in each temple. Bill length ranges from about 20 mm for the Sulawesi Drongo and 21–23 mm for the Square-tailed and Bronzed Drongos, and the nominate race of the Balicassiao, to 30 mm for the Crow-billed and Madagascar Crested Drongos, 32 mm for the Comoro Drongo and race *longirostris* of the Hair-crested Drongo, and 35 mm for the Mayotte Drongo. The iris is usually red or brown, but it may vary from orange to dark brownish crimson-red, or from dark brown to reddish-brown. The three races *faberi*, *jentincki* and *leucops* of the Hair-crested Drongo have a white iris. All immature drongos have a brown iris.

The wings of drongos are rather long and either rounded or somewhat pointed, and are well adapted for the swift flight and aerial acrobatics that drongos perform with great ease to capture insects in the air and amidst vegetation. The flight-feathers comprise ten primaries, including a well-developed outermost primary that is half as long as the next, nine secondaries, and a few tertials, the Spangled Drongo, for example, possessing three; one remicle is also present. Average wing lengths vary from the 107 mm of the Square-tailed Drongo and the 120 mm or so of the Pygmy and Shining Drongos, these three being smaller species, to approximately 130–150 mm for medium-sized drongos, and up to 184 mm for the largest drongos; the three longest-winged are the subspecies *megalornis* of the Hair-crested Drongo, with an average wing length of 175 mm, the race *grandis* of the Greater Racquet-tailed Drongo, with a corresponding figure of 180 mm, and the largest of all, the Ribbon-tailed Drongo, which has an average wing length of 184 mm. Migratory species or subspecies appear not to have longer wing lengths compared with resident ones.

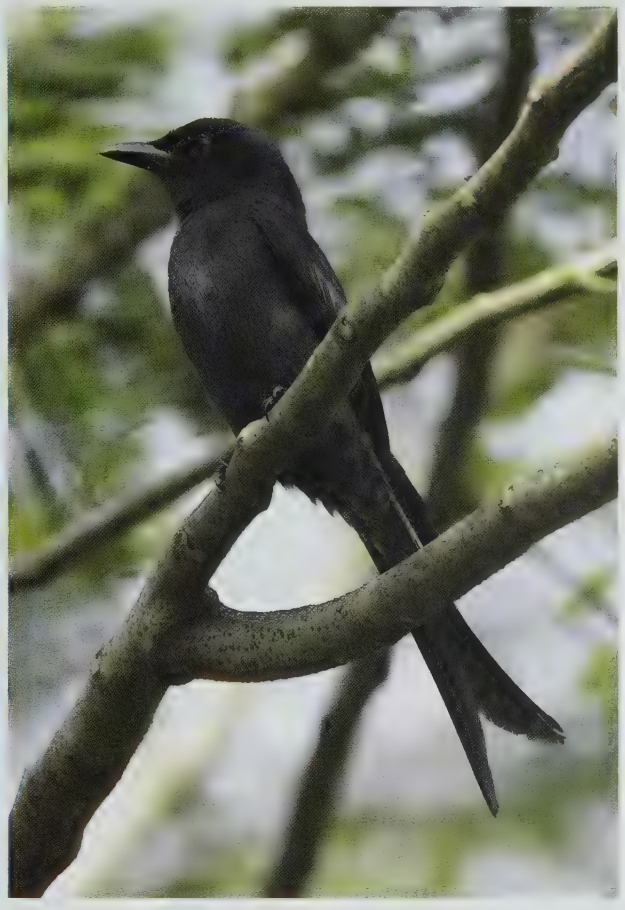
All *Dicrurus* drongos have only ten tail feathers. The more primitive Pygmy Drongo, the sole member of the genus *Chaetorhynchus*, has twelve rectrices and a slightly rounded tail reminiscent of that of a fantail (see Systematics). For the genus

*The first major split in the 32-taxon "*Dicrurus hottentottus *superspecies complex" was made in 1986, with the distinction between* D. hottentottus, *renamed the* **Hair-crested Drongo**, *and* D. bracteatus, *which kept the name Spangled Drongo. These two species, with six others, may constitute a superspecies. The nominate race of the Hair-crested Drongo has hair-like feathers around 80 mm long springing from its forehead, and extending over its hindcrown and upper back. Among the 14 subspecies recognized herein, some have shorter frontal filaments, others like* samarensis *and* palawanensis *lack frontal filaments, while in yet others the hairs are present in some individuals and lacking in others. The irides of most drongos are varying shades of orange, red or brown, but the races* faberi, jentincki *and* leucops *of the Hair-crested Drongo have a white iris.*

[*Dicrurus hottentottus*. Photo: Tom & Pam Gardner/FLPA]

Dicrurus, the tail is normally deeply forked or slightly notched, but that of the Square-tailed Drongo is square-ended, that of the Mayotte Drongo is lyre-shaped, and the tails of the Ribbon-tailed and Hair-crested Drongos are twisted. Some species or subspecies have long, decorative, racquet-shaped outer feathers. The lengthening of the tail is considered to be an evolutional character accompanied by the deepening of the fork. Vaurie found that the depth of the tail fork is proportionately greater for species or races with a long tail, ranging from 1% of the tail length in the race *samarensis* of the Hair-crested Drongo, and about 7% in the Sumatran and Square-tailed Drongos, to 38% and 44% in the Tablas and Mayotte Drongos, respectively, and 60% in the Ribbon-tailed Drongo. Tail lengths are generally of the same order of magnitude as wing lengths, measuring typically 90–100% of the latter, the average ratio between the two varying between 80% and 120% for most forms. Notable exceptions are those of the Ribbon-tailed Drongo and both racquet-tailed drongos, which have very long tail feathers over 200% the length of the wing, the Mayotte Drongo, for which the figure is 140%, and some comparatively shorter-tailed forms from Vaurie's "*D. hottentottus* superspecies complex" (see Systematics). Of the last, the tails of the Sumatran Drongo and of the race *samarensis* of the Hair-crested Drongo were calculated as being about 70% the length of the wing; and the tails of races *striatus* of the Hair-crested and *abraensis* of the Balicassiao as being about 77%. The most spectacular modification of the outermost tail feathers is that in which the greatly elongated sections of the shafts are completely denuded of barbs until, near the tip, the inner web or both webs reappear and form a racquet-like pendant. This may be a relatively unstable character, as specimens with fully webbed outer feathers have been reported for several subspecies of the Greater Racquet-tailed Drongo, including the nominate race, *brachyphorus* and *platurus*; indeed, the outermost rectrices of the Sri Lanka Crested Drongo and the Ribbon-tailed Drongo are always fully webbed. Curling of the outermost tail feathers appears at its maximum with the Ribbon-tailed Drongo, the Greater Racquet-tailed Drongo and several races of the Hair-crested Drongo. Asymmetrical outer tail feathers, either malformed or broken, are sometimes recorded, and can be used as a means for individual recognition.

Drongos have relatively short legs, with a fully feathered tibia, and a stout tarsus scutellated at the front but smooth at the back, with strong and long toes and claws, all black. Being almost exclusively arboreal, these birds can perch at will and jump with agility from branch to branch; they do not normally, however, walk on the ground, although some species can occasionally be seen to forage there. Some species are able also to cling to tree trunks in the manner of a woodpecker (Picidae).



Plumage coloration of adult drongos is for most species dominated by blackish tones, with variable proportions of shining metallic glossy areas contrasting with velvety deep black parts. Glossy feathers can be found mainly on the mantle, wing and tail, as well as on the breast and neck and around the head, and they vary from greenish to bluish or purple. Velvety areas are mostly restricted to parts of the head, such as the forehead, chin and lores, the mantle, as with, for example, the Hair-crested Drongo, and, more rarely, the underparts, as in the case of the subspecies *coracinus* of the Velvet-mantled Drongo. The intensity, distribution and colour of the gloss and the extent of velvety parts across the body are key morphological differences separating the various species or races of drongos. Some body parts can be brownish, such as the flight-feathers and tail of the Comoro Drongo, or greyish, the Ashy Drongo having an exceptional grey-dominated plumage that is, in some races, very light in colour. Spotting of the plumage does not normally occur on adult drongos, except for a few species that have restricted white patches: the Pygmy Drongo has white on the scapulars; the Black Drongo has white at the base of the bill; and some races of the Ashy Drongo have white feathering around the eyes. Other species present larger white areas, such as the White-bellied Drongo, which has more or less extensive white depending on subspecies, and the race *mirabilis* of the Balicassiao. In Kenya, instances of abnormal white coloration on the belly and wings, or fully albinistic specimens with a pale bill and legs, have been described for the Fork-tailed Drongo. In such cases in which the intense black coloration has been lost, the gloss also has disappeared. Evolutionary modification of the feathers includes concentration of gloss into certain parts of specific feathers. This leads to the

The plumage of adult drongos is dominated by black, with variable proportions of shining metallic glossy areas contrasting with velvety deep black parts. The gloss on the crown, throat and upper breast of the **Spangled Drongo** *is limited to the tips and outer margins of the feathers, forming sharply defined oval or pointed spangles. The glossy feathers on the side of the neck are elongated, forming lanceolate hackles. Spangles and hackles are more or less well developed among the eleven subspecies. Juvenile and immature drongos have less glossy, more brownish or greyish plumage, with features like spangles and hackles less developed or absent.*

[*Dicrurus bracteatus*, Daintree, Queensland, Australia. Photo: David Stowe]

*The **Ashy Drongo** is exceptional among drongos in having grey-dominated plumage that is, in some races, notably pale in tone. The white-faced race* leucogenis *and dark race* longicaudatus *were formerly treated as two separate species. The 14 subspecies currently recognized are distributed widely over southern Asia. The subspecific taxonomy of the Ashy Drongo is complicated. Many races are not clearly differentiated while some intergrade, and in most of the mainland, the races are highly migratory.*

formation of "spangles", when gloss accumulates at the tips of small, pointed breast feathers, as is typically the case with the Spangled Drongo, or to the formation of "hackles" in the long, narrow lanceolated plumes of the nape and hindneck, as with the Hair-crested and Wallacean Drongos and the Balicassiao.

Characters of individual species such as general size, pigmentation, body proportions and special structures, including crests and tail-racquets, vary geographically. It is interesting to note that these variations are not random, but are correlated with clinal environmental features such as temperature and humidity. As shown by Mayr and Vaurie in 1948, general size increases with latitude and altitude as a result of lower temperatures, as detailed in Bergmann's Rule, for six dicrurid species, including the Black, Ashy, Bronzed, White-bellied and Hair-crested Drongos; for the Greater Racquet-tailed Drongo, parallel decreases from north to south in general size, tail length and crest development are observed on both sides of the Bay of Bengal. Regarding intensity of pigmentation, which as a general rule tends to increase with humidity, at least four species, the Square-tailed, Fork-tailed and Hair-crested Drongos and the Balicassiao, have a denser, more bluish or purple gloss in the wettest parts of their ranges, and a less saturated, more greenish gloss in the drier areas. Similarly, White-bellied Drongos are darkest in the wet zone of Sri Lanka when compared with the races occurring in the dry zone of that island and in drier peninsular India. Island forms are frequently larger or smaller than the original continental forms, and the most distinctive forms are found at the periphery of the species' range or at very isolated locations.

Juvenile and immature dicrurids differ from adults mainly in having the plumage usually less glossy and less intensely coloured, more brownish or greyish, instead of black, with pale-barred or white-spotted underparts, and with whitish or buffy feather tips or fringes. In addition, they have a shorter and non-forked tail, and lack or have less well-developed ornamental feathers such as racquets and other modified outer tail feathers, crests, hackles and spangles. Particular immature plumages include that of the Pygmy Drongo, duller than the adult and with a white gape, that of the Black Drongo, which has a white rictal spot larger than the adult's, and that of the Shining Drongo, all sooty black with gloss only on the wing and tail. In the case of the White-bellied Drongo, the distinction between the browner throat and breast and the white belly is less visible on the immature than on the adult.

Drongos moult only once a year. Immatures may acquire adult plumage during their first year, after a first moult involving most or all feathers of the body, the Aldabra Drongo, for example, doing so before the start of the next breeding season. For some species, however, adult plumage is not acquired before the bird has entered its third year. Lesser Racquet-tailed Drongos in their first, juvenile, plumage have a slightly forked tail with no racquets, lack the frontal brush-like crest, have very restricted gloss, and have the axillaries broadly tipped with white. After their first moult, the outermost rectrices grow and have short shafts with traces of barbs and of terminal racquets, the frontal brush appears, and the plumage has more gloss and smaller white marks; this subadult plumage will be replaced after the second moult, when full adult plumage, with its longer outer rectrices and totally bare shafts, will appear. A similar succession of three plumages, those of juvenile, subadult and adult, is recorded for the Greater Racquet-tailed Drongo; the racquet feathers of the adult of this species are moulted asymmetrically. Adult drongos are known to moult every year, probably after breeding. This has been shown with the Spangled Drongo, the moult of which extends over a period of five months.

Habitat

The members of this family are found almost exclusively in tropical and subtropical ecosystems where trees are present. They occupy a large range of habitats, including primary, secondary and degraded broadleaf forests, both evergreen and deciduous, tree plantations, open woodland and savanna, forest edges, and such artificial habitats as urban gardens, residential areas and cultivated landscapes with isolated trees. Drongos are particularly fond of any openings in the vegetation, since all of these species need open areas in which to detect and hunt aerial insects. Some can

Molecular-genetic studies show that crests have little phylogenetic value, and can appear and disappear easily in the various lineages, in both ancient and recent forms of both Asian and African groups. The ***Madagascar Crested Drongo*** *has a tuft of elongated frontal feathers 20–40 mm long at the base of its bill, forming a slightly forward-curving crest. The crest is the main difference between this species and the otherwise almost identical Fork-tailed Drongo* (Dicrurus adsimilis), *which is widely distributed throughout the African mainland. Recent DNA studies indicate that the Madagascar Crested Drongo's closest relative is the Aldabra Drongo* (D. aldabranus), *which arose through colonization of Aldabra from Madagascar less than 125,000 years ago; this species has lost the tufted crest. A molecular study in 2007 indicates that the drongos on Indian Ocean islands do not form a monophyletic assemblage. The colonization of these islands by an ancestor of the "*D. adsimilis *group" seems to have occurred shortly after its arrival in Africa, and to have followed a complex pattern. The most ancient of these species is the Comoro Drongo* (D. fuscipennis), *which originated about five million years ago and appears to be the closest relative of the Fork-tailed and Velvet-mantled Drongos* (D. modestus). *As the estimated age of the island of Grand Comoro is only half a million years, this species must have originated from another, older island in this volcanic archipelago. It does not appear to be closely related to other drongo species from the Indian Ocean. The Mayotte Drongo* (D. waldenii) *appeared at around the same time and is as old as Mayotte itself, apparently having branched off from the ancestor of the Madagascar Crested Drongo. The race* potior *of the Madagascar Crested Drongo would have resulted from colonization of Anjouan in the Comoro Islands within the last 150,000 years.*

[*Dicrurus forficatus forficatus*, Mahajanga, Madagascar. Photo: Pete Morris]

live in very open habitats with only few isolated trees, whereas others are more typical woodland birds but have a preference for edges, gallery forest or trees overlooking roads or streams. Even those present in deep forest will still select clearings, created by falling trees or by small-scale human activities such as logging, forest houses or cultivation, possibly maintained by herbivores.

Comparative studies of habitat selection by the different drongo species are not available. Among the variety of ecological factors to which most species respond, however, the most important one seems to be the structure of the vegetation, and, more specifically, its degree of openness or artificialness, and sometimes the height of the trees. Accordingly, drongos can be classified in four main categories. These have been defined by positioning species along a gradient of vegetation openness and increased human influence, proceeding from primary to secondary forest, then degraded forest, open woodland, cultivated areas with scattered trees, and residential areas.

The first category consists of seven species that occupy almost exclusively deep mature primary or secondary forests. These are the Pygmy Drongo, Sulawesi Drongo, Sumatran Drongo and Ribbon-tailed Drongo, restricted to the respective islands of New Guinea, Sulawesi, Sumatra and New Ireland, the Tablas Drongo, confined to the relictual natural forests of the island of Tablas, in the Philippines, the Sri Lanka Crested Drongo, living in the dense humid forests of Sri Lanka, and the Shining Drongo, a denizen of the primary rainforests of West Africa and the Congo Basin.

Four species are combined in the second category, being found mainly, but not exclusively, in open wooded habitats with sparse trees. Two of them, the Fork-tailed Drongo and the Black Drongo, inhabit wooded savannas, plantations, cultivated landscapes and residential areas in Africa and Asia, respectively, while the White-bellied Drongo in India and Sri Lanka occupies a similar habitat but not agricultural land. The Endangered Comoro Drongo is localized in degraded woodland, plantations and agricultural areas at middle altitude on Grand Comoro, although its original habitat may have been different and could now have disappeared.

A third category is composed of eight typical forest species which, unlike those in the first category, are not restricted to mature dense forests. These eight exhibit a moderate niche extension with regard to open man-made habitats, being occasionally present in open degraded forest, although not normally in cultivated areas with sparse trees or in residential areas. They are the Mayotte, Square-tailed, Hair-crested, Crow-billed, Lesser Racquet-tailed and Bronzed Drongos, the Balicassiao and the Andaman Drongo. The ecology of the last two is still not well known.

Finally, the fourth category comprises six other species that have the largest amplitude of habitats, with an important niche extension with regard to man-made habitats. The habitats which they occupy range from primary and secondary forest to degraded woodland, plantations and open areas with scattered trees, including farmland. These are the Velvet-mantled and Wallacean Drongos, together with four species that are present also in residential areas and around villages, namely the Spangled Drongo, the Greater Racquet-tailed Drongo, the Madagascar Crested Drongo, and certain races of the Ashy Drongo.

The Aldabra Drongo represents a special case and cannot be placed into any of the above-mentioned four categories. Confined to the coralline atoll of Aldabra, in the Seychelles Group, it occupies the native shrubland, averaging 2–6 m tall and dominated by *Pemphis acidula*, which covers most of the atoll, and is found also in the coastal casuarina (*Casuarina equisetifolia*) open woodland and the mangroves that circle the lagoon.

Some drongos occupy particular breeding habitats. Examples are the deciduous forests of high-altitude subtropical climates present in China and along the Himalayan chain, which are utilized by the Crow-billed, Bronzed, Lesser Racquet-tailed, Ashy, White-bellied, Hair-crested and Black Drongos; the bamboo forests in China and South-east Asia, which host the Bronzed, Lesser Racquet-tailed, Hair-crested, Greater Racquet-tailed, Ashy and White-bellied Drongos; and mangroves, where the Aldabra, Spangled, Greater Racquet-tailed, Ashy, Crow-billed and Mayotte Drongos breed. Outside the breeding periods, some species may enlarge their habitat selection. This is the case, for example, with the Hair-crested and Crow-billed Drongos, which can be seen in parks and wooded gardens, tree plantations and mangroves during the non-breeding season and when making migratory or altitudinal movements.

Drongos can be found in a wide elevational range, from sea-level to approximately 4000 m. In general, they are common in

Drongos are highly territorial and generally live in breeding pairs. They are typically found alone, in pairs or in small family groups. However, occasional concentrations of up to 50 drongos can be found in suitable circumstances, such as at the mass emergences of ants, or at bush fires, which flush out insects. ***Black Drongos*** *are usually solitary, but will gather in numbers to feed on swarming winged termites or emerging mosquitoes. In the non-breeding season, some species, including Black Drongos, gather in large numbers at roosts.*

[*Dicrurus macrocercus albirictus*, Tal Chhapar Sanctuary, Rajasthan, India. Photo: Gaurav Bhatnagar]

*Drongos have been described by some authors as "little furies". They will attack animals much larger than themselves, such as monkeys or even humans. The **Fork-tailed Drongo**, here seen "bombing" a Tawny Eagle* (Aquila rapax), *can often be seen attacking and chasing crows or raptors, sometimes even pecking at them in flight while "riding" on their backs. Similar behaviour has been reported for the **Greater Racquet-tailed Drongo** when attacking a Great Hornbill* (Buceros bicornis).

Right: *Dicrurus paradiseus paradiseus*, Khao Yai National Park, Thailand. Photo: Morten Strange]

lowlands and in middle-altitude forests below 1000 m, but many species can ascend to much higher levels. A majority of dicrurids do, in fact, have large altitudinal ranges, in line with the distribution of their suitable habitats and local climatic conditions, from sea-level woodlands up to, sometimes, the upper tree-limit. The only drongo species with restricted altitudinal ranges are those found on small low-lying islands. The species with the widest elevational range is the Ashy Drongo, which is present from sea-level to 3000 m in the Sunda Islands, and from 600 m to 4000 m in south China. Other Asian and Australasian species occupying large altitudinal ranges of about 2000 m include the Bronzed and Black Drongos in the Indian Subcontinent, and the Spangled Drongo in the Moluccas, while others, such as the Greater Racquet-tailed, Wallacean and Sumatran Drongos, do not go much higher than 1500 m. A few species, such as the Sulawesi Drongo and the Pygmy Drongo, display a clear preference for middle altitudes, the former being found from 600 m to 1800 m, and the latter mainly at 600–1400 m although present at lower densities down to 200 m and up to 1600 m. Some members of the family exhibit different altitudinal preferences according to subspecies or even local populations. Taking the Asian Lesser Racquet-tailed Drongo as an example, the subspecies *tectirostris* is found from the lowlands to 2000 m along the Himalayan chain, but is present mostly between 450 m and 750 m, whereas in Indonesia it is more clearly a mountain bird, found only at 600–2500 m and mostly between 1200 m and 1800 m; in the Malay Peninsula, the race *peracensis* occurs only above 450 m.

Two African species are found from sea-level to 2000 m and above, the Fork-tailed Drongo occurring at up to 2200 m in Kenya and the Square-tailed Drongo to 2100 m in Sudan. The Madagascar Crested Drongo, in Madagascar, and the Velvet-mantled Drongo, in Africa, are recorded to lower altitudes, 1900 m and 1600 m, respectively. Two other species, the Shining Drongo in the Afrotropics and the Comoro Drongo, are not recorded above 1000 m. Species confined to small islands occur generally across the entire altitudinal range of wooded habitats available; this is the case with the Aldabra Drongo, restricted to a low-lying coralline atoll rising to less than 18 m, and the Mayotte Drongo, found in all natural forests up to the island summit, at 660 m.

There are multiple examples of various drongo species co-existing in the same geographical area. Large islands can harbour several species, Borneo and Sumatra for example holding, respectively, four and five, and south-east China is host to as many as seven species, including five on Hainan alone. Some of these may differ in altitude occupancy or in habitat preferences, but some can also occur together in the same forests. The extent of overlap in habitat use and competition between different sympatric species has not, however, been sufficiently studied. New Guinea has two dicrurid species which are separated to some degree by altitude: the Pygmy Drongo, known also as the "Mountain Drongo", lives mainly above 600 m, whereas the Spangled Drongo occurs chiefly in the lowlands. The same occurs with the

*Drongos tend to be more active during the morning and late afternoon, the hot hours of the day being devoted more to comfort activities such as resting and preening. Although drongos are essentially diurnal, they are often described as the birds which remain active for longest at dusk, and are among the earliest to become active. The **Hair-crested Drongo** is associated with forest, although it tends to prefer clearings and forest edge. Generally found from the lowlands up to above 2000 m, in Sulawesi it favours montane forest, while the Sulawesi Drongo* (Dicrurus montanus), *despite its scientific name, occupies lower elevations, although the two species do overlap to some extent.*

[*Dicrurus hottentottus*, China. Photo: Dong Lei]

Once the sun is up, and the immediate demands of foraging have been satisfied, many birds will spend some time sunbathing, as demonstrated by this ***Spangled Drongo****. This activity may serve several purposes, one of which is a general toning up of the feathers, in case some of them have been twisted out of shape during the morning's work. Feather care can involve a number of processes, all of which are designed to keep them in tip-top condition, as a bird's livelihood and even life ultimately depend on this.*

[*Dicrurus bracteatus baileyi*, Kakadu National Park, Northern Territory, Australia. Photo: Oriol Alamany]

Sulawesi Drongo and Hair-crested Drongo on Sulawesi. In each of these examples, however, the two species involved also overlap in altitudinal range.

Sri Lanka has two perfect examples of a clear bioclimatic separation. First, the subspecies *insularis* of the White-bellied Drongo is restricted to the lowland dry zone, whereas race *leucopygialis* of this species is confined to the lowland wet zone; secondly, the subspecies *ceylonicus* of the Greater Racquet-tailed Drongo and the newly recognized Sri Lanka Crested Drongo, the latter previously treated as a race of the Greater Racquet-tailed (see Systematics), are similarly distributed. Details of the methods by which the two pairs of taxa manage to co-exist in the forests of each bioclimatic region deserve investigation. The same applies to the Greater and Lesser Racquet-tailed Drongos, the distributions of which frequently overlap in the lowlands; they are often reported as foraging side by side in the same mixed-species associations in India, but they tend to exclude each other in Thailand and Myanmar.

In the Congo Basin of central Africa, the Square-tailed Drongo is found almost exclusively in the upper canopy of primary forests, while the Shining Drongo occupies mainly the lower strata below 20 m. In contrast, in secondary forests where the latter species is absent but where the Fork-tailed Drongo occupies the upper strata, the Square-tailed Drongo is then found mainly in the understorey, below 15 m. This example illustrates the important ecological plasticity of some drongos, a character probably common to the majority of species that have been able to adapt to a large range of man-modified habitats. The fact that some species are able to mould their own ecological niche in relation to the presence of other, competing drongos probably explains how three or more congeneric birds as aggressive and territorial as these can live together in the same habitat type.

General Habits

Drongos are medium-sized arboreal insectivores. Typically perched on a branch, or sometimes on a wire or pole, they are easily recognizable by their characteristic slim upright posture, the long tail hanging almost vertically, as they look out for insects from an exposed vantage point. Their aerial movements are remarkable, and may involve the birds hovering, springing up vertically, swooping down to the ground, and performing a slalom through the vegetation before looping back to the perch.

They are generally found alone, in pairs or in small family groups. Only one species, the Andaman Drongo, which forages in groups of up to 20 individuals, can be said to be regularly gregarious, although occasional concentrations of up to 50 birds of other species can be found in favourable circumstances, as at mass emergences of ants (Formicidae) or at bush fires, which flush out insects (see Food and Feeding). Most drongos readily associate with other animals, exploiting the prey they disturb.

The members of this family are very noisy and vocal birds, their loud voice, with typical harsh scratchy notes, making them easily detectable in the field. They are typically forest-dwellers, although many species have adapted to more open or semi-open wooded habitats created by man (see Habitat). A few of them are found in cultivated landscapes, where they may perch on the backs of domestic cattle, and some thrive even in suburban parks and gardens.

Although dicrurids are more or less exclusively diurnal, many hunt also during crepuscular hours, far into the dusk. Sometimes they are active several hours after dark, taking advantage of food in the form of insects attracted by artificial lights to the vicinity of houses and to suburban areas (see Food and Feeding). As with many other forest birds, however, drongos tend to be more active during the morning and the late afternoon, the hot hours of the day being devoted more to comfort activities such as resting and preening. They are often described as being the bird species which remain active for longer at dusk and as being among the earliest to become active in the morning, at or before dawn. Indeed, some dicrurids start to sing and display long before dawn, while it is still quite dark, or continue to sing into the night during moonlit nights. The parents and their young offspring will usually roost close to each other at night, especially when the young have only recently fledged. In the non-breeding season, some species, such as the Black Drongo, gather in large numbers at roosts.

Highly territorial, drongos generally live in breeding pairs, the members of which perform various displays (see Breeding). Some species, such as the Spangled Drongo, perform spectacular flight displays throughout the day, even when not breeding. Several members of the family offer a leaf to the mate during

While harsh elements are prominent in the songs of many drongos, a few species, such as the ***Balicassiao****, have songs and calls dominated by melodious warbling and high-pitched liquid twittering. The Balicassiao is one of 14 drongo species in which duets between partners have been recorded. They also sing collectively, in parties of three to four, as if in competition. Drongos usually sing from an exposed perch; they rarely do so in flight, except as part of an aerial display. They are often the earliest birds to begin singing. They sing during the day and with greater intensity at dusk, sometimes for several hours after sunset or during moonlit nights. They are well known for their ability to mimic other birds.*

[*Dicrurus balicassius*, Zambales, Luzon, Philippines. Photo: Doug Wechsler/ VIREO]

courtship (see Breeding), but some drongos will at times use leaves also in play, as was reported for two juvenile Black Drongos. One of the juveniles repeatedly picked up a leaf and dropped it deliberately, while the other juvenile would plunge to catch the leaf with its beak or claws before it touched the ground.

One of the most typical characteristics of drongos is their notorious aggressiveness, exemplified by their remarkable boldness in attacking other animals much larger than they themselves are. They will attack, among others, crows, birds of prey (Falconiformes) up to the size of large eagles, and monkeys and other mammals, including humans, and they seem, when defending the nest, not to be deterred by the size of any potential predator (see Breeding). Mobbing and aggressive behaviour, however, is not always linked with breeding. Recent research on the Black and Ashy Drongos in Indonesia has shown that the intensity of such behaviour does not differ significantly for the dangerous Indian Black Eagle (*Ictinaetus malayensis*) and the relatively harmless Javan Hawk-eagle (*Spizaetus bartelsi*), and increases during the breeding season only for the latter. This may be an adaptive strategy to ensure that dangerous predators do not use mobbing intensity as a clue to the presence of a drongo nest. The Black Drongo has also been reported mobbing and chasing Common Black-shouldered Kites (*Elanus caeruleus*), as well as House (*Corvus splendens*) and Large-billed Crows (*Corvus macrorhynchus*); and the Fork-tailed Drongo is known to mob raptors and other predators, including reptiles such as water snakes.

Amazingly, the African Fork-tailed Drongo and its closely related Asian counterpart the Black Drongo have been repeatedly observed to attack and chase crows, Short-toed Snake-eagles (*Circaetus gallicus*) and Black Kites (*Milvus migrans*), pecking at them in flight while "sitting" or "riding" on the back of the predator. The same behaviour has been reported also for the Greater Racquet-tailed Drongo when attacking a Great Hornbill (*Buceros bicornis*). Described by some authors as pugnacious "little furies", irascible and quarrelsome, dicrurids have been observed to mob and attack other large birds that are apparently harmless but are possibly identified by the drongo as potential egg predators, as, for example, when a Greater Racquet-tailed Drongo attacks a Great Hornbill or a Large Frogmouth (*Batrachostomus auritus*).

The flight of drongos is normally silent, and the wingbeats are often punctuated with very brief pauses when moving from one place to another. Exceptions to this are provided by certain long-tailed species, particularly those having two long tail-filaments with racquets flapping at the end like two small flags, which have a noisy flight, detectable by ear from a long distance. The sound produced by the Greater Racquet-tailed Drongo in flight is like humming, and the racquets give the impression that the bird is being pursued by two dark bees. The splendid tail possessed by many drongos represents a characteristic visual and sometimes acoustic signal for the human observer, and it must obviously play an important role in intraspecific or interspecific recognition.

Drongos do not have a strong association with water. They may be able, as are other forest birds, to drink rain from foliage or from pits or depressions in tree branches or trunks, but this behaviour has hitherto been reported only for the Spangled Drongo, which occasionally drinks from tanks or forest pools. As other highly aerial and short-legged birds do, drongos may occasionally drop or plunge-dive from a few metres into a pool of water or into a river to bathe for a brief moment. This behaviour has been reported for eight species: the Black, Hair-crested, Greater Racquet-tailed, Lesser Racquet-tailed and Bronzed Drongos in Asia, the Spangled Drongo in Australasia and New Guinea, the Fork-tailed Drongo in Africa and the Madagascar Crested Drongo in Madagascar. Other bathing techniques include rain-bathing, by perching with spread wings in the falling rain, and foliage-bathing, both recorded for the Crow-billed Drongo in Thailand.

Few ectoparasites have been reported on drongos. Feather mites such as *Calamicoptes zumpti* (Laminosioptidae) have been found on the Fork-tailed Drongo, and several species of philopterid lice (Mallophaga) have been identified on the Black Drongo. Internal parasites appear to be more frequent, and these include a variety of nematodes, such as *Viguiera majumdari* and *Viguiera adsimilisai*, and cestodal tapeworms, such as *Parutirena dicruri* and *Notopentorchis kherai*, found in Black Drongos,

Bronzed Drongos *are sometimes seen perching on roadside fences, electricity poles or wires, to take advantage of insects disturbed by passing cars or landing on the bare road surface. Drongos are very efficient hunters, and use a variety of techniques to capture their prey. The Bronzed Drongo hunts in the canopy, including the crowns of giant emergent trees, in clearings or at the forest edge, and also on the edges of cultivated areas. It hawks winged insects, making short sallies, and often swooping close to the ground, then looping back to the same perch. It also makes vertical sorties from treetops, diving back with the wings closed after a capture.*

[*Dicrurus aeneus aeneus*, Jiouliao, Yilan, China. Photo: Yung-Fu Chen]

Black Drongos *are often found accompanying livestock, the object being to capture insects displaced by them, or attracted by them. The same association has been reported in Pakistan for the Ashy Drongo* (Dicrurus leucophaeus). *These two drongo species will occasionally perch on the animals as they move, and in Sri Lanka, Black Drongos have been observed to eat ticks (Ixodoidea) directly from the backs of mammals. Black Drongos also join parties of Yellow-billed* (Turdoides affinis) *and Jungle Babblers* (T. striata), *and Jungle* (Acridotheres fuscus) *and Common Mynas* (A. tristis), *hawking insects flushed by these near-ground foragers, and in exchange, providing warning of predators. The Black Drongo is a bird of open country and farmland, rarely entering closed tree cover during the daytime, and often foraging far from any trees. It perches on wires, fence posts, bare treetops, earth banks or other vantage points, sallying to catch prey on the wing or among the leaves, or to snatch insects from the ground. Large items, such as locusts or cicadas, are held down with one foot and progressively torn to pieces with the bill. The wings are generally removed before the prey is swallowed. One Black Drongo, observed while eating a large locust, first made a small jump, while still holding its prey, in order to detach one leg, which it then tore up and swallowed. It repeated the operation with the other legs, and finally removed the head and, after some mastication, swallowed what remained of the body. Black Drongos will also follow human farm workers, pouncing on invertebrates disturbed or exposed by the plough. They are regularly reported pirating worms and other prey from Hoopoes* (Upupa epops), *mynas and wagtails* (Motacilla).

[*Dicrurus macrocercus macrocercus*, Tamil Nadu, India. Photo: Hanne & Jens Eriksen]

In Africa, the ***Fork-tailed Drongo*** *forages in close association with livestock, including dogs and chickens, and with large game, mainly African elephants* (Loxodonta africana), *but also African buffaloes* (Syncerus caffer), *giraffes* (Giraffa camelopardalis), *greater kudus* (Tragelaphus strepsiceros), *and chacma baboons* (Papio ursinus). *As well as using these large animals as beaters, the drongos may remove ticks and other ectoparasites from their hide, ears and nostrils. The* ***Black Drongo****, with which the Fork-tailed forms a superspecies, has also been observed to do this. This relationship, from which both bird and mammal benefit—the mammal by relief from discomfort and the removal of a potential disease vector—represents a limited but interesting form of symbiosis. Several drongo species, including Fork-tailed and Black Drongos, will accompany monkeys or squirrels (Sciuridae) in order to capture insects disturbed by them. A similar association has been noted for some species with a variety of other animals, ranging from tortoises to ants.*

Mayhewia in the Ashy Drongo, and trematodes of the family Dicrocoeliidae. In addition, the presence of Haematozoa has been reported in several drongos from Africa and Asia, and include *Haemoproteus dicruri* and *Haemoproteus khani* in the Madagascar Crested Drongo. The incidence of such parasites in drongo populations is not known.

Voice

Drongos are very vocal and noisy birds. The intrinsic muscles of the dicrurid syrinx are attached to the end of the bronchial semirings and they produce an astonishing variety of sounds, including mimicry of many other species. Generally speaking, drongos sing very well and have an extraordinary repertoire, some of the species seeming almost like true virtuosi. Few detailed studies have been made on drongo vocalizations. Some rather brief descriptions of song types and calls have appeared in the literature, and there are several unpublished recordings in the "Wildlife sounds" section of the British Library Sound Archive; more detailed account can be found in *Birds of South Asia*, by Rasmussen and Anderton, and in volume VI of *The Birds of Africa*, edited by C. H. Fry, S. Keith and E. K. Urban. Certain drongo forms, especially those recently elevated to species rank, have poorly known songs and calls which merit further investigation and description; this applies to, for instance, the Tablas, Sulawesi, Sumatran and Wallacean Drongos.

Calls given by this family consist generally of repeated short strophes of five or six syllables. They can be repeated a great number of times for up to five minutes, and even longer in particular circumstances; alarm calls, for example, are uttered persistently when drongos mob potential predators around the nest. The diversity of calls reported from drongos is huge, ranging from harsh scratchy notes, squeaks and shrill nasal buzzing, churrs and discordant sounds to loud ringing or twanging metallic notes, rolled gravelly sounds, and disyllabic or trisyllabic musical whistles with chopped notes, upslurs or downslurs. Examples of simple calls include the Tablas Drongo's typical rasping call, 2–3 seconds long and like the sound made by a cicada (Cicadidae); the long dry buzzes and sweet short whistles uttered by the White-bellied Drongo; and the whistles of several similar notes, or rolling sounds dropping into low deep twangy notes, given by the Ribbon-tailed Drongo. More complex calls include the rapidly repeated identical short whistles, or a creaky note followed by a double fluty one, given by the Greater Racquet-tailed Drongo; and harsh and metallic sounds alternating with whistles, or short fluty calls and long descending churrs, emitted by the Spangled Drongo. Some calls made by members of the family are quite amazing, examples being the sounds like that of tearing paper or the grinding of unoiled wooden wagon wheels, reported for the Fork-tailed Drongo. The latter also gives specific scratchy calls of several syllables before attacking raptors. Many drongo species flare the tail when calling.

Drongo songs are sometimes described as being a jumble of melodious whistles, squeaks and harsh notes. As with calls, songs can be composed of different sound elements of all kinds, sometimes juxtaposed in strophes of varying lengths, in which calls elements are often recognizable. Song types of particular species are generally varied, and may include, for example, low-pitched melodious sounds, sharp fluty or metallic whistles, rising or descending tones, rapid cascades of clipped notes, jumbled outbursts, and rasping or discordant sounds, often given in repetitive phrases. Such varied and contrasted vocalizations are probably one of the most important characteristics of drongo songs. While harsh elements appear to be prominent in the songs of many species, such as the Spangled and Mayotte Drongos or, to a lesser extent, the Greater Racquet-tailed, Fork-tailed, Black and Madagascar Crested Drongos, a few others, such as the Balicassiao and the Wallacean, Bronzed and White-bellied Drongos, appear to have much softer songs and calls dominated by melodious warbling and high-pitched liquid twittering reminiscent of the sounds made by small passerines, such as some finches (Fringillidae), Old World warblers (Sylviidae), thrushes (Turdidae) or larks (Alaudidae). Compared with other drongos, the Balicassiao and the Lesser Racquet-tailed Drongo, which have remarkably extensive repertoires, together with the White-bellied Drongo, which has the sweetest song, may be considered to be the most pleasing singers to the human ear. The songs of some other dicrurids, such as the Fork-tailed, Black, Crow-billed and Ashy Drongos, are sometimes described as being quite pleasant.

Duets have been recorded for at least 14 species of drongo, nine of these in Asia and Australasia and five in Africa and the

Drongos have relatively short legs, and do not normally walk on the ground. However, the habit of feeding on ground-dwelling prey has been reported for several species, among them Fork-tailed (Dicrurus adsimilis), *Spangled* (D. bracteatus) *and* ***Black Drongos****, especially young birds with limited aerial-hunting skills. The only invertebrates other than insects taken in significant quantities are spiders (Araneae), millipedes (Diplopoda) and earthworms (Oligochaeta). Occasionally, mainly in the Indian Subcontinent, the Black Drongo's diet may include lizards, small bats, and nestlings and even small birds. A Black Drongo has even been reported feeding on dead fish floating on muddy water.*

[*Dicrurus macrocercus albirictus*, Chitwan, Nepal. Photo: Neil Bowman/FLPA]

*Drongos feed mostly on large flying insects, but as this **Bronzed Drongo** shows, smaller winged insects, such as termites (Isoptera), dipteran flies and ants, wasps and bees (Hymenoptera), may also feature in the diet. They may capture these smaller insects by hovering in the manner of a muscicapid flycatcher. After a catch, carrying the prey in the bill or, in the case of large items, in the claws, drongos invariably move to a perch. Small food items are generally swallowed immediately. When dealing with bees or wasps, some drongos wipe the item against a branch to remove the sting, or, after returning to the perch, peck off the sting while holding the prey in the claws.*

[*Dicrurus aeneus aeneus*, Jiouliao, Yilan, China. Photo: Yung-Fu Chen]

Indian Ocean islands. Pair-members of the Fork-tailed Drongo, for example, give performances lasting 4–5 minutes and consisting of brief duets of 12–20 rapidly alternating elements of 25 to 300 milliseconds each. These elements are sung by each partner in a non-random sequence involving a complex correlation between the two birds, although one individual appears to dominate the duet with its own programme; the answering time of the partner is about 200 milliseconds. In Gabon, Square-tailed Drongo pairs perform quiet but rapidly delivered territorial duets, combining short whistles and continued chattering of liquid notes, including clicking sounds such as "tec-why-tyee" or "piu-took-why-tyee", from the male, to which the female gives harsh nasal replies. Mayotte Drongos sing remarkable duets throughout the breeding season at different points in the territory, especially in the vicinity of the nest. This species' song is a harsh repetitive jumble of chirps and squeaks, with syncopated loud whistles and harsh nasal notes rapidly alternated with creaky squawks and grinding sounds, but a low, soft and continuous whistling chatter is sometimes audible at close range. The male calls "chu-chi", the female responds with "chu" and the male ends with "chit", all of which is repeated rhythmically by both birds, each bobbing its head and body vigorously up and down in rapidly alternating turn, the two facing and almost touching each other, in a powerful vocal and dancing display. Spangled Drongo pairs are known to duet or jangle in unison. On Buru, in the Moluccas, one partner gives soft low whistles at long intervals, and when duetting utters longer crescending rolling "rurrrrrru" calls and high-pitched trills, answered with three or four slightly rising short whistles. In Australia, during its flight display, this species' distinctive song consists of five or six single notes given in series during the aerial descent and ceasing when the bird reaches about 3 m above the ground; the drongo may also produce a discordant jangle before the display and during the ascent phase, followed by a flow of rapid sharp twittering during the descent. Greater Racquet-tailed Drongos likewise perform duets; in Kerala, in southern India, one partner starts with a sharp double rising note, the other answering with a low-pitched whistle, and so on. Duets have been recorded also for the Shining Drongo in tropical Africa, for the Comoro Drongo on Grand Comoro, and, in Asia and Australasia, for the Balicassiao and the Sulawesi, Bronzed, Tablas, Crow-billed, Ashy and Black Drongos.

Collective singing, involving more than two individuals, has been reported for several species, including, occasionally, the Black, Bronzed and Ashy Drongos. On Luzon, in the Philippines, Balicassiaos will sing in parties of three or four individuals for long periods, as if engaged in a competition of vocalizing performances, producing an extraordinary variety of repeated short phrases, including melodious whistles sometimes reminiscent of those of a thrush or a sylviid warbler, repeated nasal notes, chuckling and rolling sounds, plaintive calls, and twangy or grinding notes, but with no harsh squeaks, jumbles or grating tones. Spangled Drongos, too, are known to sing in chorus, at times of up to 20 birds.

Within a single species, the vocal repertoire may vary considerably according to race or geographical area, as is the case with, for example, the Greater Racquet-tailed Drongo, and in particular with forms related to the "*D. hottentottus* Hair-crested Drongo complex", for which voice may be used also to investigate taxonomy (see Systematics). For the Square-tailed Drongo, differences exist between West Africa and East Africa, individuals being more silent in the former region. Cases of island differentiation include, for example, the Tablas Drongo, which has significantly different vocalizations from those of neighbouring related forms. Similarly, the typical vocalizations of the drongo present on the island of Príncipe include a loud and hoarse call, unmusical and dissonant, lacking in related forms on the African mainland.

Usually, drongos sing from a well visible perch, often a branch, but some species living in artificial habitats, such as the Black Drongo, will make use also of fences, electric wires and buildings. Drongos rarely sing in flight, except when this is part of an aerial display, as is the case with the Spangled Drongo. One Fork-tailed Drongo was reported singing while bathing. Drongos start to sing before dawn (see General Habits), sometimes up to two hours before, as is the case of the Black Drongo; they will sing during the day and with additional intensity at dusk, sometimes continuing for several hours after sunset or during moonlit nights, as do the Fork-tailed and Bronzed Drongos. Indeed, these birds are often said to be among the first to rise and the last to go to roost. They are very noisy and demonstrative throughout the breeding season, but much less so at other times. During the winter months, some members of the family, such as the Spangled Drongo, continue to give short subsongs.

Drongos are well known for their excellent ability to mimic other bird species. They have been noted as imitating members of numerous passerine families, including: pittas (Pittidae); larks; cuckoo-shrikes (Campephagidae); bulbuls (Pycnonotidae); fairy-bluebirds (Irenidae); ioras (Aegithinidae); thrushes, including chats and relatives in the subfamily Saxicolinae; Old World flycatchers; Old World warblers; babblers (Timaliidae); honeyeaters (Meliphagidae); Old World orioles; bush-shrikes (Malaconotidae); helmet-shrikes (Prionopidae); vangas (Vangidae); butcherbirds (Cracticidae); starlings; and cardueline finches. In addition, they have been reported to imitate woodpeckers (Picidae) and hornbills (Bucerotidae) in Asia; two species of cuckoo (Cuculidae), one in India and the other in Madagascar; various raptors in both their Asian and African ranges; and at least one species of owl (Strigidae). They use this talent to integrate themselves into mixed-species flocks, learning specific alarm calls from other species in order to get closer to them for foraging, and notifying the presence of predators. During these feeding parties, drongos occasionally give false alarms in order to distract other flock-members and steal their prey (see Food and Feeding). They also imitate introduced bird species, as well as domestic animals such as cats and even short tunes whistled by human beings.

Food and Feeding

Drongos are mainly insectivorous, but some species will also take small vertebrates and certain vegetable items. They feed on

Three different drongo taxa are known to perch vertically on tree trunks in the manner of a woodpecker (Picidae), with the head upwards and the tail against the bark, when capturing ants and other insects. The three are the race leucops *of the* ***Hair-crested Drongo****, the Andaman Drongo* (Dicrurus andamanensis)*, and the subspecies* viridinitens *of the Sumatran Drongo* (D. sumatranus)*. In fact, this behaviour may be more widespread, as suggested by this Hair-crested Drongo of the race* brevirostris*, which breeds in central and southern China. On the island of Siberut, the Sumatran Drongo has been recorded feeding in this way for up to 30 seconds. Woodpeckers are absent on Siberut, and Sulawesi and the Andamans have only two woodpecker species. Drongos may therefore be able to occupy part of the woodpecker niche.*

[*Dicrurus hottentottus brevirostris*, Dongzai National Nature Reserve, Henan, China. Photo: Dong Lei]

Nine drongo species are known to be regular consumers of nectar or pollen. The ***Ashy Drongo*** *regularly visits the silk cotton or cotton tree* (Bombax ceiba)*, as here; it also uses* Erythrina *blossom, as well as introduced* Grevillea *and* Eucalyptus. *Nectar, and sometimes pollen, appears to represent an important part of the diet of the Hair-crested Drongo* (Dicrurus hottentottus) *throughout continental Asia, although nectar consumption has not been reported for any of its island races. Some drongos may also visit nectar-rich flowers because of the insects they attract. Drongos may act as pollinators of certain flowering trees. When they have fed on nectar, the forehead and throat feathers may become covered with pollen.*

[*Dicrurus leucophaeus longicaudatus*, Goa, India. Photo: Jussi Vakkala]

a remarkable variety of prey, mostly large flying insects such as grasshoppers (Acrididae), cicadas, beetles (Coleoptera), hornets (*Vespa*), mantises (Mantodea), dragonflies (Odonata), and moths and butterflies (Lepidoptera). Smaller winged insects, such as termites (Isoptera) and ants, wasps and bees (Hymenoptera), mosquitoes (Culicidae) and other dipteran flies, and large homopteran or heteropteran bugs have also been found in stomach contents, as have caterpillars, pupae and other larvae. Some unwinged insects, including crickets (Gryllidae), stick-insects (Phasmida) and water-beetles, are also captured. The only invertebrates other than insects taken in significant quantities are spiders (Araneae), millipedes (Diplopoda) and earthworms (Oligochaeta).

Occasionally, dicrurids capture and feed on small vertebrates, and this has been reported for at least eight drongo species. Examples include Hair-crested, Black and Aldabra Drongos being seen to take skinks (Scincidae) or geckos (Gekkonidae); the Madagascar Crested Drongo preying on chameleons (Chamaeleonidae); Greater Racquet-tailed Drongos preying on frogs; Ashy, Spangled, Fork-tailed and Black Drongos feeding on small birds, including nestlings; and Black and Spangled Drongos killing and eating small bats. In addition, the Black Drongo has been seen to take dead fishes, and the Fork-tailed Drongo sometimes catches small living fishes by swooping from a perch, hovering low over the water and dipping its bill beneath the surface.

Nine species are known to be regular consumers of flower nectar or pollen. These are the Hair-crested, Ashy, White-bellied, Greater Racquet-tailed, Bronzed, Spangled, Fork-tailed, Square-tailed and Black Drongos. At least five members of the family occasionally take other vegetable items. Spangled, Comoro and Madagascar Crested Drongos will at times feed on fruits, Black Drongos on sorghum grains, and Velvet-mantled Drongos on bits of bark.

Large insects, up to 40–60 mm in length, can represent a predominant part of the diet. In observations in humid natural forests on Mayotte, in 2002, cicadas represented up to 47% of the food items brought to the nest by adult Mayotte Drongos, the remainder consisting of spiders, butterflies, wasps, grasshoppers and caterpillars in smaller proportions. Flies, beetles and millipedes were found in stomach contents of this species during previous studies. An analysis of the stomach contents of 19 Black Drongos, carried out in 1992 by the Bangladesh Rice Research Institute, revealed a diet composed of 49% phytophagous insects, along with 35% predaceous insects and 16% others; of the total, 22% were grasshoppers and 20% dragonflies. Invertebrate groups recorded in the diet of the Spangled Drongo, one of the most well-studied dicrurids, include earthworms and a wide variety of insects, among them termites, Orthoptera, cicadas, Neuroptera, beetles of the families Cerambycidae, Chrysomelidae, Scarabaeidae and Tenebrionidae, bees (Apidae) ants and vespid wasps, nymphalid butterflies, noctuid moths, dragonflies and stick-insects. On the island of Siberut, the Sumatran Drongo has been observed to take ants of the genus *Iridomyrmex* from the trunks of trees.

In India, Black Drongos occasionally capture small birds, in the region of about 10 g in weight. These include Oriental White-eyes (*Zosterops palpebrosus*), ioras, *Muscicapa* flycatchers, Streak-throated Swallows (*Petrochelidon fluvicola*) and prinias (*Prinia*), the last also reported as taken by this drongo in Hong Kong. Most of these incidents of preying on small birds occurred during the cold season, at a time when insects are scarce and drongos may be driven more to find other food sources with a higher energy value. The capture of small birds, in this case ioras and sylviid warblers, has been reported for the Ashy Drongo, too. In Australia, Spangled Drongos occasionally feed on the young or the adults of honeyeaters, including the Graceful Honeyeater (*Meliphaga gracilis*), the Yellow-faced Honeyeater (*Lichenostomus chrysops*) and the Dusky Myzomela (*Myzomela obscura*); in addition, they have been recorded as taking Scaly-breasted Munias (*Lonchura punctulata*), House Sparrows (*Passer domesticus*), Zebra Finches (*Taeniopygia guttata*), thornbills (*Acanthiza*) and pardalotes (*Pardalotus*). In Africa, similar predatory behaviour involving small birds has been reported only for the Fork-tailed Drongo. This species has been seen to prey on Bronze Mannikins (*Lonchura cucullata*), Yellow-fronted Canaries (*Serinus mozambicanus*) and white-eyes in various parts of its range in that continent.

In west Madagascar, the Madagascar Crested Drongo is observed occasionally to feed on the fruits of the arofy tree (*Commiphora guillaumini*), and has been identified as being a

seed-disperser for this tree. In Malaysia, the Greater Racquet-tailed Drongo occasionally takes figs from fruiting banyans (*Ficus*). Nectar and, sometimes, pollen appear to represent an important part of the diet of the Hair-crested Drongo in the whole of its distribution in continental Asia, although such consumption has not been reported for any of this species' insular races. At Dehra Dun, in north India, this drongo has been recorded feeding on the nectar of 22 different species of tree, especially *Erythrina indica*, *Delonix regia*, *Butea monosperma* and *Bombax ceiba*, and recommendations have been made to keep a significant proportion of flowering trees for nectar-feeding birds in tree plantations, managed forests and recreational areas. Spangled Drongos in Australia sometimes feed on fruits, as well as on the nectar from at least six different tree species, including the genera *Erythrina*, *Eucalyptus*, *Grevillea* and *Banksia*. Classed as omnivorous, this species has been seen to take household foods such as cheese, bread, raw sugar and meat, including animal fat and bone.

Drongos are very efficient hunters, and use a variety of techniques in order to capture their prey. They watch from a prominent perch, and sally or dart out to seize large flying insects such as locusts, cicadas or beetles in the air, before diving back on closed wings to the perch. They will also glide down and sometimes pursue prey, even slaloming between vegetation, as well as hovering to catch smaller insects, such as flies or bees, in the manner of a muscicapid flycatcher or swooping close to the ground for emergent ones, such as flying ants or termite alates. They normally use the bill as a means of capturing aerial insects, although the claws are sometimes utilized in the manner of an *Accipiter* hawk.

Non-aerial feeding is also very important for several species, the Hair-crested and Ribbon-tailed Drongos being two examples, and it can sometimes represent the most frequent method of capturing prey, as is the case with the Spangled and Mayotte Drongos. This last species obtains food items by pecking at the surface of trunks, branches, leaves or flowers, or catches items with its claws by pouncing on trunks and branches, as when seizing cicadas, or by pouncing on items on the ground. The Tablas Drongo has been described as foraging in vine tangles in the manner of coucals (Cuculidae); during this exercise, the drongo hung by one of its feet to the vine, held a dead leaf with the other foot, and used its bill to strip out insects. The habit of feeding on ground-dwelling prey has been reported for several species, among them the Fork-tailed, Black and Spangled Drongos, and especially for young birds with limited skills in flying and aerial hunting, as exemplified by the Aldabra Drongo.

Three different drongo taxa, namely the Andaman Drongo, the subspecies *viridinitens* of the Sumatran Drongo and the race *leucops* of the Hair-crested Drongo, are known to perch on vertical trunks in the manner of a woodpecker, with the head upwards and the tail against the substrate, when capturing ants and other insects; on the island of Siberut, the Sumatran species has been recorded feeding in this way for up to 30 seconds. Such behaviour has been reported for drongos living on islands where woodpeckers are either absent or uncommon, and where drongos may, therefore, be able to occupy part of the woodpecker niche. Woodpeckers are absent on Siberut, and north Sulawesi and the Andamans have only one and two woodpecker species, respectively.

Drongos hunt from a wide variety of trees, creepers and dead wood and utilize all vegetation strata, from low shrubs up to the top of tall trees at 30 m, and probably above. Some members of the family hunt more frequently in lower and middle levels, whereas others seem to prefer the higher canopy. As examples, the Shining Drongo hunts at 5–20 m in Gabon and the Mayotte Drongo even lower, at 2–6 m; in contrast, the Velvet-mantled Drongo prefers to forage above 25 m in Liberia and at 15–30 m in Gabon, and the Spangled Drongo at 10–25 m in Australia. Most drongo species appear not to have any particular preferences for trees rich in invertebrates; rather, trees and bushes used for foraging seem to reflect the actual vegetation composition of the habitat. This is the case especially for those species well adapted to degraded wooded habitats and man-made cultivated landscapes, such as the Fork-tailed, Velvet-mantled, Black, Madagascar Crested and Spangled Drongos. For the Mayotte Drongo, a forest species showing only limited adaptation to man-altered habitats, the huge diversity of vegetation used for foraging includes many introduced or cultivated trees, among them the invasive *Litzia glutinosa* and the mango tree (*Mangifera indica*). Blossoming trees certainly attract nectar-feeding species, as *Bombax ceiba* does with the Hair-crested Drongo, but also species that are not particularly nectarivorous, such as the Mayotte Drongo, as the

Like other forest birds, drongos may be able to drink rain from foliage or from pits or depressions in tree branches or trunks, but this has hitherto been reported only for the ***Spangled Drongo****, which in New Guinea has been observed drinking water from a forest pool during the dry season, as in this picture. Drongos may be attracted to water to hunt flying insects, in the manner of swallows (Hirundinidae). The Fork-tailed Drongo* (Dicrurus adsimilis) *sometimes catches small fish by swooping from a perch, hovering low over the water and dipping its bill beneath the surface.*

[*Dicrurus bracteatus carbonarius*, near Brown River, SE New Guinea. Photo: Brian J. Coates]

flowers attract large numbers of insect pollinators, on which drongos can feed. The role of dicrurids as cross-pollinators has been mentioned for the Hair-crested, White-bellied and Black Drongos, and this probably applies to all the other nectarivorous species, at least.

Usually, drongos hunt from an elevated position, generally a horizontal tree branch over a clearing or at a forest edge, or a creeper hanging in the open, as typified by the Shining Drongo, for example. They scan the surroundings also from fence posts, wires, earthbanks and any type of vantage point, as is the case with the Black Drongo and, to a lesser extent, the Fork-tailed Drongo. When stalking prey, drongos often loop back and return to the same perch, and they will always perch after a catch, carrying the prey item in the bill or, in the case of large items, in the claws. Small food items are generally swallowed immediately. When dealing with bees or wasps, some drongos, such as the Spangled Drongo, first wipe the item against a branch to remove the sting, or, after returning to a perch, peck off the sting while holding the prey in their claws. Large items, such as locusts or cicadas, are held down with one foot and progressively torn into pieces with the bill, the victim's wings generally being removed before the prey is swallowed. A Black Drongo, observed eating a large locust, first made a small jump, while still holding its prey, in order to detach one leg, which it tore up and swallowed; it then repeated the operation with the other legs, and finally removed the head and, after some mastication, swallowed what remained of the body. Spangled Drongos, when dealing with food held in the feet, generally toss it into the air before swallowing it. When the drongo has captured a small bird for food, it brings this in the bill or claws to a branch, holds it down with one foot, and pecks at the prey until it is dead; it then tears it into small pieces and swallows them, apparently feathers and all, starting at the neck and continuing until only the legs remain. The entire process may take about 13 to 50 minutes.

Particular and opportunistic foraging techniques include fire-driven hunting by several species, the Fork-tailed, Black, Ashy and Spangled Drongos, which congregate at bush and grass fires and capture insects flushed by the flames, heat and smoke. In the Chitwan National Park, in Nepal, a concentration of about 50 Black Drongos and four Ashy Drongos was in attendance together with more than 30 Ashy Woodswallows (*Artamus fuscus*) and three Common Black-shouldered Kites during permitted burning and harvesting of *Saccharum* cane. Fork-tailed Drongos in Africa and, to a lesser extent, Bronzed Drongos in Asia are often seen perched on roadside fences, electricity poles or wires, from where they can take advantage of insects disturbed by passing cars or those landing on the clear road surface, where they can be immediately spotted and captured. The habit of hunting at dusk or at night around artificial lights has been reported for at least five dicrurids. In Africa, the Fork-tailed Drongo is known to hunt occasionally up to 90 minutes after sunset and 40 minutes before sunrise, hawking moths and other nocturnal insects, and the Velvet-mantled Drongo, too, sometimes seeks prey at dusk or dawn. The Aldabra Drongo hunts regularly at dusk, including from trees above beaches, where insects falling on the sand can be easily detected. In India, the Black Drongo is known to feed at night around streetlamps for up to 2–4 hours after sunset. This unusual behaviour of crepuscular or nocturnal hunting has been observed too for the White-bellied Drongo, a forest bird that avoids human habitations; in this instance, it may result from the gradual reduction of food resources in the periphery of expanding cities following woodland destruction and the huge numbers of insects attracted by city lights.

An interesting example of co-operative hunting has been reported for two Black Drongos around a bee hive suspended beneath the roof of a building. One individual made a quick pass and hit the hive, while the second followed behind and captured some of the disturbed bees as they came out.

Being territorial birds, drongos generally forage alone, in pairs or in small family parties of three to five individuals. Although several species, including the Fork-tailed Drongo, are known to gather occasionally at fires and other sites of food concentration, such as the mass emergences of flying ants and termites, the Andaman Drongo is the only member of the family that is truly gregarious, as it can frequently be found in single-species groups of 10–20 individuals foraging through the forest. At least 18 drongo species are known to associate, when foraging, with a variety of other animals, ranging from ants to Aldabra giant

Monogamous and in most cases highly territorial, drongos live in pairs in which the bond is very strong. More than half the drongo species, including the ***Bronzed Drongo****, are known to perform duets, which are performed at different points of the territory, helping to delimit its boundaries while at the same time maintaining a close bond between the partners. Territory size has been calculated for a relatively small number of species to date, the averages ranging from about 0·6 ha to about 3 ha.*

[*Dicrurus aeneus aeneus*, Jiouliao, Yilan, China. Photo: Yung-Fu Chen]

tortoises (*Dypsochelis dussumieri*), to other birds, and to mammals, including livestock. The most frequent associations, however, are mixed-species bird parties, and these are exploited by 15 dicrurids: the Pygmy, Spangled, Sumatran, Wallacean, Greater Racquet-tailed, Sri Lanka Crested, Lesser Racquet-tailed, Crow-billed, Bronzed, Black, Madagascar Crested, Fork-tailed, Velvet-mantled, Square-tailed and Shining Drongos. By being members of such feeding parties, which contain anything from a few individuals to dozens of birds, drongos benefit from a "beater effect" and capture prey flushed by other participants. In return, the drongos act as "sentinels" and contribute to the success of mixed flocks by giving alarm calls informing all participants of the presence of a predator. Several studies conducted in Asia, Africa and Madagascar have shown that the feeding success of drongos, in these cases the Greater Racquet-tailed, Fork-tailed, Black and Madagascar Crested Drongos, increased when they were following other species in mixed flocks compared with when foraging alone. In New Guinea, a study found that 64% of mixed flocks contained at least one individual of either the Pygmy Drongo or the Spangled Drongo, but never both species in the same flock. In Sri Lanka, Greater Racquet-tailed Drongos are frequently associated with the highly gregarious Orange-billed Babbler (*Turdoides rufescens*) in mixed feeding parties. Both are considered "nuclear" species, having a key role in the formation and coherence of mixed feeding flocks, which contain an average of about ten species and 40 individuals. Their combined presence is highly attractive to other gregarious insectivorous birds, the drongo serving as a more sensitive and reliable alarm-caller. The Greater Racquet-tailed Drongo associates also with the Ashy-headed Laughingthrush (*Garrulax cinereifrons*) and the Jungle Babbler (*Turdoides striata*), adjusting its perching height to those species' hunting habits, and using vocal mimicry of their songs and contact calls in order to increase its proximity to them, normally to within 5–10 m. Black Drongos in Tamil Nadu, in southern India, have a mutually beneficial association with the Yellow-billed Babbler (*Turdoides affinis*), the former capturing insects flushed by the latter and giving the alarm against predators. A study conducted nearby, in Bangalore, indicates clear gains for the Black Drongo when associated with Common Mynas (*Acridotheres tristis*) and Jungle Mynas (*Acridotheres fuscus*) in terms of increased frequency of foraging and greater probability of capturing insects in each foraging trip; the association has neither benefits nor costs for the mynas. In Madagascar, the endemic drongo associates in mixed flocks with such species as the Common Newtonia (*Newtonia brunneicauda*), the Common Tetraka (*Bernieria madagascariensis*) or the Rufous Vanga (*Schetba rufa*).

Certain drongos associate with individual bird species in a commensal relationship which benefits generally only the drongo and may occasionally involve some form of parasitism. Observations in Peninsular Malaysia suggest that the Greater Racquet-tailed Drongo associates with woodpeckers during the majority of its foraging time. The Aldabra Drongo often accompanies on that island the Madagascar Coucal (*Centropus toulou*), capturing insects displaced by this larger bird and which the coucal itself is unable to catch, a relationship that may involve some form of parasitism. During a study in Botswana, the Fork-tailed Drongo was recorded as foraging in association with 37 different wildlife species, which it used as prey-flushers. These included 21 terrestrially foraging bird species, 15 of which were insectivores/omnivores, mainly the Red-billed Buffalo-weaver (*Bubalornis niger*) and Cape Glossy Starling (*Lamprotornis nitens*), along with other *Lamprotornis* starlings, *Tockus* hornbills and the Hoopoe (*Upupa epops*), and six gregarious granivores, mainly the Southern Masked-weaver (*Ploceus velatus*) and Southern Grey-headed Sparrow (*Passer diffusus*), together with the Scaly-fronted Weaver (*Sporopipes squamifrons*) and queleas (*Quelea*). In addition, the drongo exploited eight gleaning, pouncing or hawking insectivore species, such as rollers (*Coracias*), helmet-shrikes and bee-eaters (*Merops*), and four large terrestrial birds, mainly the Ostrich (*Struthio camelus*) and the Helmeted Guineafowl (*Numida meleagris*).

Several dicrurid species will accompany wild mammals such as monkeys or squirrels (Sciuridae) in order to capture insects disturbed by the mammals. This has been recorded for the Black, Fork-tailed, Hair-crested, Sumatran, Greater Racquet-tailed, Ashy and Andaman Drongos, and it is possible that other drongo species behave in a similar manner. In Africa, the Fork-tailed Drongo

Although it occurs in somewhat varied environments, from at least 2000 m in the Himalayas south to Sri Lanka, the ***White-bellied Drongo*** *has a fairly well-delimited breeding season, with little variation between north and south. Birds begin displaying around February or March, depending on the locality, with the bulk of the breeding activity taking place from March to June. This coincides fairly well with the period just before the onset of the south-west monsoon, which does so much to shape the Subcontinent's climate. At the start of the breeding season, the drongos will search for a suitable nest-site, normally 3–9 m above ground level, in a small or medium-sized tree.*

[*Dicrurus caerulescens caerulescens*, Goa, India. Photo: Jussi Vakkala]

is known to forage in close association with livestock, including cattle, goats, sheep, donkeys and also domestic dogs and chickens, these being involved in 61% of all associations observed in Botswana, and with large wildlife game, mainly African elephants (*Loxodonta africana*) but also such others as giraffes (*Giraffa camelopardalis*), greater kudus (*Tragelaphus strepsiceros*), African buffaloes (*Syncerus caffer*) and chacma baboons (*Papio ursinus*), which accounted for 7% of all observed associations in Botswana. Similarly, in Asia, the Black Drongo is often found with livestock, including cattle, water buffaloes (*Bubalus arnee*) and goats, when foraging, and the same association has been reported in Pakistan for the Ashy Drongo. Perching on nearby trees and bushes, these birds follow individual animals or herds and capture insects displaced by the mammals, or in some cases attracted to or living on them; these two drongo species will occasionally perch on the animals as they move, and in Sri Lanka the Black Drongo has been observed to eat ticks (Ixodoidea) directly from the back of mammals. Such consumption of external parasites or potential disease-vectors illustrates a limited but interesting form of symbiosis between, on the one hand, certain drongos and, on the other, cattle or wild herbivores.

On Aldabra, a remarkable association was discovered between the Aldabra Drongo and the giant tortoise: the former perched close to herds of tortoises resting under the shade during the hot hours of the day, and regularly swooped down to snap up various flies or other insects attracted by the tortoises and their dung, or followed these large animals as they moved around and displaced insects. The drongo's mandibles produced a characteristic "clap" sound as the bird seized an insect. Another interesting association concerns the Shining Drongo, a bird of the African equatorial rainforests, which follows swarms of the carnivorous driver ant *Dorylus wilverthi* for hours, sallying rapidly for disturbed insects in trees or plunging after falling prey, competing with and sometimes aggressive towards other large ant-followers such as bulbuls, hornbills and small raptors. Similarly, Fork-tailed Drongos have been reported following ants in Tanzania.

Kleptoparasitism on a variety of other bird species is practised by at least eight members of the Dicruridae. These are the Greater Racquet-tailed, Spangled, Pygmy, White-bellied, Black, Ashy, Fork-tailed and Madagascar Crested Drongos. The Black Drongo has been seen stealing food from Hoopoes, Common Mynas and wagtails (*Motacilla*). The Fork-tailed Drongo occasionally robs birds bringing insects back to their own nests, for example Cardinal Woodpeckers (*Dendropicos fuscescens*); other victims are the Cape Longclaw (*Macronyx capensis*), various pipits (*Anthus*), wagtails, and Hoopoes, which appear particularly vulnerable to such piratical attacks. When in mixed-species feeding parties, Fork-tailed Drongos may also steal food from other party-members such as the Kurrichane Thrush (*Turdus libonyanus*) or the Southern Pied Babbler (*Turdoides bicolor*), which have a complex association with the drongos; this may happen only in a very small minority of cases, less than 1%, for instance during difficult climatic conditions when the abundance of flying insects is low, as shown in studies in Botswana. When foraging in these parties, drongos act as sentinels, warning of the proximity of predators, but they occasionally give false alarm calls in order to distract other members and steal their food, typically mimicking the specific predator-calls of the other species to make them drop their food. This has also been reported for a Spangled Drongo which was chasing a food-carrying Magpie-lark (*Grallina cyanoleuca*) that was not in a feeding party, after an initial, unsuccessful attempt using its own drongo alarm cry. When their group contains enough members to keep watch efficiently themselves, Southern Pied Babblers respond by chasing the drongos away aggressively, whereas small babbler groups prefer to tolerate the presence of drongos and pay the price of occasional piracy. Cases of piracy by the Greater Racquet-tailed Drongo when in mixed feeding parties have been reported, the victims being the Orange-billed Babbler, Ashy-headed Laughing-thrush, Malabar Trogon (*Harpactes fasciatus*) and Indian Scimitar-babbler (*Pomatorhinus horsfieldii*). A study in Sri Lanka, however, found that such kleptoparasitism represented a minority of cases, just 3% of drongo feeding attempts, compared with captures of insects displaced by other birds, which accounted for 41%. In conclusion, drongos are better classified as commensalists or mutualists, rather than as parasites, since they exact only a small cost on other species in flocks.

Breeding

While the breeding biology of a few dicrurids, mainly the Fork-tailed, Aldabra, Mayotte and Black Drongos, is very well known, relatively limited information is available for many others, despite the fact that most of the species are very common birds.

Generally, drongos have an established breeding season, the period and length of which vary geographically across the different tropical biomes, and which usually coincides with the wettest season, or the period when large insects, on which the chicks are raised, are most likely to be abundant. A few species, however, appear able to breed in all months of the year in the rainforests or secondary evergreen forests of equatorial Africa and Asia; the Shining Drongo and the Velvet-mantled Drongo exhibit no clearly defined nesting season in part of their African equatorial range, and this applies also to the Balicassiao in the Philippines and the Spangled Drongo in New Guinea. The Fork-tailed Drongo, which occupies seasonal savanna ecosystems on both sides of the equator, has breeding seasons in line with the differences between the two hemispheres in the timing of the rainy seasons, roughly March–September in the north and September–January in the south, the same applying to the Square-tailed Drongo. All four drongos of the Indian Ocean islands have a clearly defined breeding season, between October and February, coinciding with the rainy season. In Asia and Australasia, some species appear to have short nesting seasons lasting for just a few months, an example being the Wallacean Drongo, which nests in October–December in the Lesser Sunda Islands. In contrast, some others have been recorded as breeding for up to eight or nine months of the year; examples are the Spangled Drongo, nesting from September to early May in Australia and in July–March in New Guinea, and the Black Drongo, breeding from April to December in Java and Bali. Generally speaking, species with a limited geographical distribution tend to have a shorter nesting season, in contrast with those that are widely distributed, especially from north to south. In tropical monsoon climates, drongos will normally start to lay their eggs soon after the first rains, although nests are sometimes built several weeks earlier in the season, as observed for the Aldabra Drongo. In a study conducted on 65 nests of Black Drongos in Calicut, in south-west India, the egg-

In the eleven drongo species for which information is available, both sexes take part in nest building. In the ***Ashy Drongo****, the female does most of the construction work, while the male brings materials, although in the early stages, he may occasionally help with placing them. The work takes five to ten days. A longer period of up to 20 days is sometimes required in some species. Some species build the nest with remarkable delicacy and precision, intertwining each piece of material as if using a needle and thread, and sitting in the cup and hollowing it out with wriggling movements of the breast.*

[*Dicrurus leucophaeus leucogenis*, Nanjing, Jiangsu, China. Photo: Li Hang]

All four drongos of the Indian Ocean islands have a clearly defined breeding season coinciding with the rainy season. Nesting of ***Mayotte Drongo*** *has been observed between September, with the first eggs, and February, with the last fledglings. In a study of Black Drongos* (Dicrurus macrocercus) *in south-west India, egg-laying was synchronized with the incoming monsoon, so that nestling and fledging periods coincided with the highest insect abundance. Fork-tailed Drongos* (D. adsimilis), *which occupy seasonal savanna on both sides of the equator, have breeding seasons in line with the differences in the timing of the rainy seasons. In the equatorial forests of Africa and Asia, however, most species appear able to breed in all months of the year.*

[*Dicrurus waldenii*, Mayotte, Comoro Is. Photo: Pete Morris]

laying period was synchronized with the incoming monsoon, and two-thirds of the eggs were laid within two weeks after the first rainfall, so that the nestling and fledging periods coincided with the time when insect abundance was very high.

Monogamous and in most cases highly territorial, drongos live in pairs in which the bond is very strong. They are extremely aggressive, and will defend a certain area around the nest from other drongos and potential predators. For example, the Black Drongo in India defends the habitat within an average radius around the nest of about 45 m, corresponding to an area of about 0·6 ha. Whenever another drongo penetrates inside what the pair considers to be its territory, the owners will fiercely chase the intruder. A territory size of about 3 ha has been estimated for the Spangled Drongo in New Guinea, and an average size of 2·4 ha has been calculated for the Mayotte Drongo on the basis of nest distribution in a densely occupied forest. Territorial fighting between neighbouring pairs is frequent and has been documented for several species, among them the Black and Mayotte Drongos.

At the approach of the breeding season, drongos will resume their territorial songs and displays, or increase the frequency of them when this season is not so neatly delimited within the year. Of eight species in the African and western Indian Ocean region, six are known to perform territorial displays; these are the Fork-tailed, Shining, Velvet-mantled, Mayotte, Comoro and Aldabra Drongos. These displays include duets between the male and the female, although these are less frequent and less clearly defined for the Aldabra Drongo, and they correspond also to a courtship activity. They are performed mainly at different points of the territory, helping to delimit its boundaries while at the same time maintaining a close bond between the partners.

Displays of the Fork-tailed Drongo include bowing and bobbing of the head while the male sings or during duets, with aerial stunts at dusk when the birds rise vertically for several metres and dive steeply back to the same perch. In the displays of the Velvet-mantled Drongo, the male bows from side to side while the female flutters her wings. Aldabra Drongo partners face each other, each with the bill held slightly above the horizontal, and shaking the wings vigorously and wagging the tail from side to side while uttering high-pitched soft squeaky sounds. Pairs of the Mayotte Drongo have been observed performing spectacular duetting displays; these were more frequent during the early morning and late afternoon, but they were heard also during the rest of the daytime. The two partners perched next to or facing each other, almost touching, while singing loud harsh and grinding notes, the male and female responding to one another in rapid alternation, giving the impression of a repetitive jumble of chirps and squeaks, while vigorously raising and lowering the head and body in a rhythmic and perfectly synchronized way, almost as a kind of dance, at the end of which copulation sometimes took place. The two members of a Mayotte Drongo pair were once observed to play together with a leaf, which one partner, presumably the male, offered to the other (see also General Habits). Similar courtship behaviour has been reported also for the Madagascar Crested Drongo and for the Greater Racquet-tailed Drongo, and it may be practised by other drongo species, too.

Little is known about the courtship and displays of the Asian and Australasian drongos. These have been recorded only for five species, the Black, Greater Racquet-tailed, Lesser Racquet-tailed, Spangled and Tablas Drongos, duets being mentioned for the last two species. The courtship displays and duets in India of the Black Drongo, a species closely related to the Fork-tailed Drongo of Africa, were described as follows: "two birds, frequently a trio, will sit together face to face and will talk loudly at one another (argue?), in harsh scolding notes, raising heads, and foreparts of body, and up and down like hammering with the bill and fluttering the wings from time to time". The two sexes chase each other in flight, bringing their bills into contact and interlocking their wings, which can cause them to fall to the ground; during copulation, the female lowers the fore part of her body slightly and raises her tail, while the male mounts her, tilts his tail, and brings his cloaca into contact with hers. Displays and duets by Spangled Drongos have been observed in Australia. The two partners first sit side by side, facing away from each other and calling, flicking the tail and shaking their partly extended wings; they

*The nest of the **Fork-tailed Drongo** is generally built 5–7 m above the ground, and usually slung across the fork of a horizontal branch, to which it is firmly fastened by cobwebs or leaf petioles. Occasionally the Fork-tailed will build a larger bowl on top of a fork or horizontal branch. Drongo nests are relatively small, with a shallow rounded cup, sometimes giving the impression that the bird barely fits inside. Materials can include rootlets, fine creepers and grass stems, coconut fibres and casuarina needles, all bound together with cobweb, and with a rim of leaf petioles, cobweb or lichens. Most nests are relatively coarsely built, with a thin floor, so that the contents can often be seen from below.*

[*Dicrurus adsimilis*, Modimolle, Limpopo, South Africa. Photo: Warwick Tarboton]

then turn and face each other, calling in unison, one bobbing and bowing. During the magnificent flight displays by this species, a singing individual flies upwards, with its wings raised at 45 degrees above the body, the latter almost vertical; as its momentum decreases, it drops forward rapidly, its tail held arched over the body and its head pointing downwards, until, when about 3 m above the ground, it stops calling, spreads its wings and flies off. A pre-copulatory display by the Spangled Drongo has also been described. In this, which was performed around the nest, the male, having wiped his bill on each side of a branch, pecked repeatedly at the female's feet and at her body, leaping over her several times from side to side, while she held her feathers puffed up and was rapidly quivering her wings; the wingbeats of both birds were very audible during the ensuing copulation.

Drongos normally build their nests in trees, and in a great variety of locations, depending on the type of habitat which they occupy. Nests can be found in deep forest, in forest clearings and openings, at forest edges, above streams or rivers, including in gallery forest, or in isolated trees. They are normally located close to open places, often overhanging an area of several metres without vegetation, those of the Mayotte Drongo, for example, being on average 7·4 m above vegetation. Most often, the nest is built at the extremity of a horizontal branch, although it is sometimes sited at the base of leaf stalks in a palm, as with the Hair-crested, Ashy and Sri Lanka Crested Drongos, among upright twigs from a node in a bamboo, as with the Bronzed and Black Drongos, or next to a tree trunk, a site often chosen by Black, Sri Lanka Crested, Fork-tailed and Madagascar Crested Drongos. Nests of Andaman and Ashy Drongos have been reported in conspicuously open sites, such as in dead or leafless trees. The height above ground at which drongo nests are built varies from 2 m, when nests are located in lower branches, to over 30 m for species present in deep primary forests, as in the Square-tailed and Shining Drongos, although recorded nests of most dicrurids have generally been between 4 m and 15 m. In Bali and Java, exceptionally low nests, described as "close to ground", have been reported for the Black Drongo. A study of 47 nests of Hair-crested Drongos, conducted in China, recorded heights of 2–14 m, distances of nest to main branch of 1–8 m, and branch lengths of 1·5–9 m; it identified the distance to the mountain ridge and to water, the average height of the tree, and the shrub density as the main factors related to nest-site selection.

Generally speaking, the choice of tree species in the selection of the nest-site location does not seem very important, as most drongo species build their nests in a very wide variety of trees, including mango and rubber (*Hevea*), mangrove trees, bamboos, oaks (*Quercus*), pines (*Pinus*), acacias (*Acacia*), *Albizzia*, tamarinds (*Tamarindus*), eucalypts (*Eucalyptus*), figs (*Ficus*), casuarinas and others, many of them being introduced or invasive species. In the Indian Ocean, 26 nests of Mayotte Drongos, located 5–18 m above the ground, were in 16 different trees species, of which four, the mango, the mbarabai (*Grisollea myrianthea*), the African tuliptree (*Spathodea campanulata*) and the sang dragon (*Pterocarpus indicus*), all except one introduced, represented half of the sites; for the Aldabra Drongo, a total of 24 nests was found at between 2 m and 13 m, built preferentially in taller casuarina species or mangrove trees, but also on smaller terrestrial native trees such as figs or *Euphorbia*. The Black Drongo, which lives mainly in open artificial habitats, appears to be the least rigorous member of the family in terms of its nest-site selection, using a large variety of tree species and nesting sites, including atypical nests on electricity poles in India. In a study of this drongo conducted on a university campus at Calicut, in southern India, 65 nests were found at heights of between 2 m and 13 m, and the species showed a strong preference for jackfruit (*Artocarpus integrifolia*), 48 of the 60 available trees holding nests. This was possibly due to the jackfruit's more open type of leaf arrangement, offering a better view of the territory compared with cashew (*Anacardium occidentale*), of which only eight of the hundred trees were utilized, mango, fig, *Macaranga* or *Alstonia*.

Both sexes seem to participate in the constructing of the nest, as reported for all of the eleven species for which information on nest-building is available. In the case of the Ashy Drongo, the female apparently does most of the building work while the male brings the material. The work of construction may take between four and ten days for the Spangled, Ashy, Black and Mayotte Drongos, but a longer period is sometimes required, up to 20 days for the Aldabra Drongo. Drongo nests are generally located in a small fork of a horizontal branch, firmly bound to the twigs of the fork by a rim of leaf petioles or other fibres, and are rela-

*Even for one of the smallest drongos, the nest of the **Square-tailed Drongo** is relatively very small indeed, with an inner cup just 5 cm wide and 2·5 cm deep. Incubation of the clutch of two or three eggs is shared by the parents, and they will also rear the brood together. This species has the largest average clutch size, of 2·7 eggs. There is no information on its incubation and nestling periods. Indeed, details of incubation are documented for only seven of the 26 species, ranging from 13 days to 19–20 days. During nesting, the forest floor below the Square-tailed Drongo's nest becomes covered with accumulated white droppings.*

[*Dicrurus ludwigii*, Seldomseen Ringing Station, Bvumba, Zimbabwe. Photo: Peter J. Ginn]

tively coarsely built, with a thin floor, and sometimes thin walls, so that the contents can often be seen from below. Those of Asian and Australasian drongos normally appear suspended from the fork in the manner of a cradle or hammock, whereas nests of African and Indian Ocean drongos, namely the Mayotte, Aldabra, Madagascar Crested, Comoro and Fork-tailed Drongos, can sometimes look as if they are placed on top of the fork, like that of the related Black Drongo in Asia.

Dicrurid nests are relatively small and with a shallow rounded cup, sometimes giving the impression that the drongo barely fits inside, for instance the nests built by Bronzed and Square-tailed Drongos. The diameter of the nest is roughly twice as great as the depth. For the majority of Asian drongos, the dimensions vary from 9 cm to 15 cm in external diameter, 6 cm to 10 cm in internal diameter, 4 cm to 7·5 cm in external depth and 2 cm to 5 cm in internal depth. A notable exception is that of the Hair-crested Drongo, which builds much larger nests: externally, the nest diameter is about 22 cm and the depth 11 cm, the corresponding internal measurements being 10 cm and 4 cm. Nests of drongos of Africa and the Indian Ocean have a thicker wall but a similar egg-chamber, with external diameter in the range 11·5–17 cm and depth in the range 5–8 cm, and internally 7·5–9 cm in diameter and 2·5–4 cm in depth; the Square-tailed Drongo represents an exception, its nest, the smallest of all drongo nests, measuring 7·5 cm across externally and having an internal diameter of 5·5 cm and an internal depth of just 2·5 cm. Building materials utilized are rootlets, fine creepers and grass stems, including khus-khus grass (*Vetiveria zizanioides*) in the Indian Subcontinent, and coconut fibres and, on Aldabra, casuarina needles, all bound together with cobweb, and with a rim of leaf petioles, cobweb or lichens; the lining consists of grasses, coarse fibres, horsehair, lichens, pieces of bark and, more rarely, leaves or sheep wool. The structure is woven to the tree fork by its margins. Some species, such as the Bronzed Drongo, build the nest with a remarkable delicacy and precision, intertwining each piece of material as if using a needle and thread, and sitting in the cup and hollowing it out with wriggling movements of the breast. Occasionally, an old nest is destroyed and its materials reused to build a new one, as has been reported for the Square-tailed Drongo and others.

Drongos lay from one to five eggs per clutch, normally at the rate of one per day. In the African and Indian Ocean region, the clutch size is between one and four eggs, although average clutches measured for individual species normally comprise 2–3 eggs. The Fork-tailed Drongo and the Square-tailed Drongo have the largest average clutch sizes, with, respectively, 2·7 and 2·6 eggs; the Comoro Drongo, with an average clutch size of 1·3 eggs, and the Shining Drongo, with an average of 2·0, apparently lay the fewest eggs. In Asia and Australasia, the clutch varies between two and five eggs, but is more frequently of three or four: the average clutch size of the Spangled Drongo in Australia is 3·4 eggs and that of the Black Drongo in south-west India is 3·0 eggs, whereas the Hair-crested Drongo sometimes lays up to five eggs; the Andaman, Ashy and White-bellied Drongos, on the other hand, normally lay only two or three eggs. Egg weights are documented with only a few examples, such as 4·8–5·8 g for the Black Drongo and an average of 2·3 g for the Square-tailed Drongo.

Dicrurid eggs can be broad to elongated oval or pyriform in shape, with substantial variation within one and the same species. Their measurements are 20–30 × 15–21 mm, depending on the species; the Square-tailed Drongo and two races of the Bronzed Drongo have the smallest eggs, 21–22 × 16 mm, the largest being the eggs of the Greater Racquet-tailed Drongo, measuring 28–30 × 20–22 mm, and those of the Hair-crested Drongo, 29 × 21 mm. Drongo eggs vary also in colour, from pinkish-white or creamy, rarely pure white, to deep salmon-pink, more or less spotted or blotched, mainly at the larger end, with rufous or brownish-red on underlying purplish lavender-grey and sometimes with tiny dark brown specks, depending on species and race; individual variability also is very high. Particularities include longitudinal streaks, typical of the eggs of the Crow-billed Drongo, and glossiness, reported for eggs of the Andaman and Spangled Drongos. Eggs from the same clutch are always similar to one another, with very few exceptions in size and colour reported.

Incubation periods are poorly known for this family. Details are documented for only seven of the 26 species. The period ranges from 13 days, for the Bronzed and Ashy Drongos, to 19–20 days, as recorded for the Spangled and Mayotte Drongos. The remaining three species for which data are available are the Black, Aldabra and Fork-tailed Drongos.

The chicks remain in the nest for 15–22 days, but the duration of this stage of the breeding cycle is much more variable than that of incubation and has been measured for only five species. These are, in order of increasing length of nestling period, the Fork-tailed, Black, Aldabra, Mayotte and Spangled Drongos. The parents will feed hatchlings with small and soft insects, described as a process of "regurgitation" for Black Drongos in Myanmar, for the first 2–3 days, during which one parent will remain to brood the young, as observed with several species. The adults also remove faecal sacs and, as the chicks grow, feed them with progressively larger prey items, transferring the whole food directly into the nestling's mouth; when presenting very large prey, such as locusts, the parents first remove the wings and sometimes the head, and carry out some initial mastication of the food. Hatchlings of the Black Drongo have a yellowish-red mouth-lining, a flesh-coloured bill, and dark greyish tarsi that will gradually turn black. Young drongos develop very rapidly, and their weights increase steadily, the remiges and rectrices protruding at about seven days of age. For the first few days after leaving the nest, the fledglings are weak fliers and are, therefore, very vulnerable to predation during this period. For the first two to three weeks, they are still easily recognizable by the short tail and the relictual gape-flanges, the latter being white or yellowish in some species. Fledglings normally never return to the nest after they have left it, although young Spangled Drongos perhaps do so occasionally. They remain dependent on their parents and are fed for at least 4–7 weeks, as observed for the Black, Spangled, Aldabra and Mayotte Drongos.

Parental care, including the incubation of the eggs and the feeding of the chicks, is undertaken by both parents, at least in the nine species for which such information is available, but how this task is shared between the sexes remains to be elucidated.

*Nests of the **Lesser Racquet-tailed Drongo** seem mainly to be built close to open places, where ample light and sunshine encourage an abundance of flying insects. Both parents incubate the eggs and tend the brood. Drongo chicks remain in the nest for 15–22 days. The parents feed their chicks with small and soft insects for the first two to three days, during which one adult always remains to brood the young. The adults also remove faecal sacs. As the chicks grow, the adults feed them with progressively larger prey. They will remove the wings and sometimes the heads of very large prey items, such as locusts, and carry out some initial mastication.*

[*Dicrurus remifer peracensis*, Fraser's Hill, Malaysia. Photo: Ong Kiem Sian]

The female of the Hair-crested Drongo, for example, has been reported as doing most of the incubation. Interestingly, observations have been made of one of the two nesting adults, presumably the male, feeding its incubating partner with an insect; this has been recorded for the Mayotte, Fork-tailed and Madagascar Crested Drongos.

Although no drongo species is known to indulge in co-operative breeding, two instances of pairs with helpers have been described, both involving the Black Drongo in India. In one case four adult drongos, presumably two parents and two helpers, the latter probably young from an earlier brood, simultaneously fed three drongos fledglings. In another, rather remarkable case, an adult Red-vented Bulbul (*Pycnonotus cafer*) was reportedly feeding two young drongos, both at the nest and after they had fledged; the bulbul was finally accepted by the drongo parents, which had initially chased it.

Despite the legendary aggressiveness of drongos and their highly evolved defence behaviour, some of these species appear to suffer surprisingly high rates of nest predation. Little information is available on the breeding success of drongos, but recent investigations have shed some light on this aspects for two Indian Ocean species. Artificial nest experiments and observations revealed that, in certain years, more than 70% of the nests of the Aldabra Drongo were preyed on at the egg stage by rats (*Rattus*), Pied Crows (*Corvus albus*) and probably other large birds, such as coucals, herons (Ardeidae) and bulbuls. The overall rate of nest failure calculated over two years for the Mayotte Drongo was 75%, the principal cause being predation at both the egg and the nestling stages; the other factors affecting nesting success were falling branches as a result of adverse weather, and human disturbance. Despite the fact that pairs can make new nests and lay replacement clutches, in some years on Aldabra only 20% of them succeed in producing fledglings, with annual productivity of 0·4–0·6 fledglings per breeding pair, a hatching success for 31 eggs of 29%, and a fledging success for ten nestlings of 80%. On Mayotte, based on 20 nests, about 70% of pairs were successful in producing an average of 1·4 fledglings per year, with a hatching success of 53% and a fledging success of 46%.

Yearly productivity rates are not available for Asian drongos, and the few existing data cannot always be compared between species. For Spangled Drongos, 70% of 29 nests monitored in Australia in the 1990s succeeded in producing fledglings, and 45% of eggs laid produced hatchlings. During a study of 57 Black Drongo clutches in India, the hatching success was 63% and the fledging success 71%. The number of fledglings produced per nest in which eggs were laid was 1·3 for both the Spangled Drongo and the Black Drongo, which compares with values of 1·3 for the Mayotte Drongo and 0·4 for the Aldabra Drongo, although the sample sizes for the Spangled and Mayotte Drongos were very small. Breeding success in terms of number of fledglings produced per egg laid varies from 23% and 25% respectively for the Aldabra and Mayotte Drongos to 39% for the Spangled Drongo, and 44% for the Black Drongo.

After experiencing failure at the laying stage or during incubation, drongos will generally build a new nest and lay a replacement clutch, which tends to be smaller than the first one. They do not normally reuse the nest for a replacement or second brood, but this has been documented once for the Aldabra Drongo. In the event of a second failure, certain species will lay yet again, and one pair of Aldabra Drongos is known to have built a new nest and re-laid up to four successive times during the same season. Some dicrurids, however, will not renest if failure intervenes at an advanced stage of incubation, as has been shown with the Black Drongo in south-west India. There are no reports of replacement clutches having been laid after failures at the chick stage. Drongos normally raise only one successful brood per year, with the exceptions of the Fork-tailed Drongo, which can raise two and even three successful broods per year in southern Africa, and the Black Drongo, which rears a second brood in north India but not in the south of that country, where the length of its breeding cycle does not allow a second brood.

Because of their very aggressive nature, drongos will regularly chase from their territory any animal likely to represent a danger. They fiercely defend a certain area around the nest from intrusion not only by neighbouring conspecifics, but also by any large birds that may represent a danger. They readily attack, among others, crows, various raptors such as sparrowhawks and goshawks (*Accipiter*) and eagles of the genera *Spizaetus*, *Eutriorchis* and *Haliaeetus*, as well as monkeys, cattle, dogs, and even humans who approach too close to the nest. Despite the comparatively small size of many drongos, no animal seems to be large enough to intimidate them when it comes to defending the nest.

Nevertheless, some bird species are accepted within the territory, but not in the nesting tree, one example being the acceptance by the Black Drongo in India of Rufous Treepies (*Dendrocitta vagabunda*) and orioles. Others are tolerated in the same nesting tree or in the immediate vicinity of the nest, about 5 m from it. These latter species, normally of similar size to or somewhat smaller than the drongos themselves, form a nesting association with them, building their nests close to those of drongos in order to benefit indirectly from the increased protection against predators they provide. Examples of this association include the Groundscraper Thrush (*Psophocichla litsitsirupa*) nesting with the Fork-tailed Drongo in southern Africa; the Red-vented Bulbul and Yellow-billed Babbler with the Black Drongo in India; and the Australasian Figbird (*Sphecotheres vieilloti*), Helmeted Friarbird (*Philemon buceroides*), Leaden Flycatcher (*Myiagra rubecula*) and Shining Starling (*Aplonis metallica*) with the Spangled Drongo in Australia.

Less favourable associations include that between dicrurids and brood-parasitic cuckoos. Indian Cuckoos (*Cuculus micropterus*) parasitize Ashy Drongo nests, Asian Drongo-cuckoos (*Surniculus lugubris*) and Common Koels (*Eudynamys scolopacea*) lay in nests of Black Drongos, the Australian race *cyanocephala* of the Common Koel and Pallid Cuckoos (*Cuculus pallidus*) parasitize Spangled Drongo nests, and the African Cuckoo (*Cuculus gularis*) has the Fork-tailed Drongo as its exclusive host.

After reaching independence, the young generally remain in the parents' territory until at least the start of the next breeding season, when they will be chased away by their parents, but they may still be tolerated at the periphery of the territory for a further year or so. The juveniles sometimes join the parents in chasing off predators and participate in the defence of the territory, but, as observed for the Aldabra Drongo, they will normally not assist them with the raising of the next brood. Juvenile drongos seem to pair up and become part of the breeding population when they are about two years old. This has been found to be the case during studies in India of Black Drongos ringed as chicks, one of which started to breed when 22 months old, and also with Aldabra Drongos, the young of which do not normally breed until at least two years of age. The breeding partners are likely to remain paired for at least several years, or even for life, and established pairs normally remain in the same territory from one year to the next. In the case of Spangled, Mayotte and Aldabra Drongos, the same pairs have been confirmed nesting in the same tree or in its vicinity for at least 2–3 years. Spangled Drongos have been known to use the same nesting sites for as many as eight consecutive years, although it is not known if the same pair was involved every year.

Very little is known about the life expectancy of drongos. Ringed Fork-tailed Drongos have been retrapped after six years in southern Africa, and undocumented reports mention estimated longevities of 15 years in Africa. In Australia, one ringed adult Spangled Drongo was retrapped nearly eight years later at the same place, and one colour-ringed adult Aldabra Drongo was seen again in the same area similarly after eight years. In Thailand, Lesser Racquet-tailed and Greater Racquet-tailed Drongos have been recovered after six and three years, respectively. Few records are available on the levels of predation on adult drongos, perhaps as a result of the excellent defensive behaviour of these species. Nevertheless, most efficient predators, such as falcons (*Falco*), do sometimes manage to take dicrurids. In Namibia, for example, a Red-necked Falcon (*Falco chicquera*) succeeded in capturing one adult Fork-tailed Drongo in mid-air.

Movements

Most drongos are mainly or entirely resident, as the majority of them live in tropical and subtropical wooded ecosystems with abundant insect resources available throughout the year. This is true of all African and Indian Ocean species, with only short-distance movements suspected for the Fork-tailed Drongo in southern Africa. Several Asian species, however, undertake true migratory movements, those living in east and central China, and some of the populations occurring along the Himalayan chain, migrating to South-east Asia or peninsular India; and some Australian drongos migrate north to New Guinea. These movements concern populations breeding in areas with the most temperate bioclimates, normally at the highest latitudes or altitudes, where abundance of insects or nectar decreases considerably in the winter months as a consequence of the lower temperatures. These populations therefore migrate to warmer subtropical or tropical areas offering more abundant and predictable food resources.

In China, the Ashy Drongo is more or less subject to long-distance movements, depending on the subspecies. In the northern part of its range the race *leucogenis* is a summer visitor, making a post-breeding migration along the east coast to non-

*The nestling period in **Black Drongos** is usually 16–17 days. For the first few days after leaving the nest, the fledglings are weak fliers and are vulnerable to predation. For two to three weeks, they remain recognizable by the short tail and the gape-flanges. Drongo fledglings remain dependent on the adults for four to seven weeks, and generally remain in their parents' territory until at least the start of the next breeding season. No drongo species is known to breed co-operatively, but in one instance, three fledgling Black Drongos were fed by the parents and also two helpers, probably the young from an earlier brood.*

[*Dicrurus macrocercus*, Panna National Park, Madhya Pradesh, India. Photo: Joanna Van Gruisen/Ardea]

breeding grounds in south China and from north Laos and Cambodia south to the Malay Peninsula; the more southerly race *salangensis* winters in south China, Hainan and Indochina, reaching the northern part of the Malay Peninsula. From the south-western parts of China, the subspecies *hopwoodi* migrates to Hainan and Indochina, while *innexus* is resident on Hainan. The subspecies *brevirostris* of the Hair-crested Drongo is widespread in central and eastern China, where it is only a summer visitor; it spends the non-breeding season in Hainan, Indochina, Thailand, south Myanmar and Tenasserim, generally at higher altitudes than those occupied by the resident nominate race and appearing during migration in more open habitat, such as parks and gardens. Again in China, the subspecies *cathoecus* of the Black Drongo, in its large continental range, is mainly a breeding visitor, spending the winter months in south China and South-east Asia and, rarely, reaching Sumatra, whereas in Taiwan the race *harterti* is resident.

A study conducted in 2003 on a coastal plain adjacent to the Gulf of Thailand gives some indication of the progress of the Black Drongo's autumn migration. The daily peak of passage occurred in the morning at 08:00–10:00 hours, with a further peak in the late afternoon, rarely after 18:00 hours, in contrast to that of the Crow-billed Drongo, which is frequently mist-netted at night. The first passage migrants were recorded at the end of September, and two peaks, with counts of more than 600 birds per hour, were evident, one in mid-October and one in late October, following two periods of heavy rain throughout much of Thailand. The passage was observed below 35 m and mainly below 8 m, often in groups of 5–20 birds across a 30-m front, with no apparent influence of wind direction.

In the Himalayas, the Ashy Drongo is a long-distance migrant, the subspecies *longicaudatus*, which breeds from extreme east Afghanistan eastwards to Bhutan, dispersing in winter to the plains of the Indian peninsula and the east of Sri Lanka. In the foothills, the nominate race of the Hair-crested Drongo is mainly resident from north India east to Assam, but is subject to seasonal movements down to the plains, depending on nectar supplies. For the Black Drongo, the subspecies *albirictus* is a summer visitor in east Afghanistan and north Pakistan, making a post-breeding dispersal to south-west Afghanistan or eastwards to the Indian plains, where it joins part of the population which breeds along the Himalayas and makes only altitudinal movements; birds of this race breeding in north and central Myanmar migrate a short distance to the southern part of that country, where some sedentary populations are present. Also breeding in the north-east Indian subcontinent, as well as in the extreme south of China and the northern part of South-east Asia, the monotypic Crow-billed Drongo is another significantly migratory species, shifting south to winter mainly in Peninsular Malaysia and Indochina; it is rare in Sumatra, an occasional visitor in west Java, and a vagrant in west Borneo and the west Philippines. This drongo, typically a species of dense forest during the breeding season, spends the rest of the year in more open and low habitats, including trees in cultivated areas, and mangroves and coastal shrubs. The other dicrurid species breeding along the Himalayan chain, the Bronzed Drongo and the two racquet-tailed drongos, are subject to only short-distance altitudinal movements, though sometimes reported also as vagrants in non-breeding areas.

Many data have been gathered locally concerning movements of the different populations of the Spangled Drongo in Australia. In general, these birds appear to be resident in the north, but, depending on their local distribution, they can be partly migratory or migratory from south to north, with an overlap of various migratory populations in the east and north of the country, local breeders being replaced by migrants from farther south. In the extreme north-west and north of Australia, the subspecies *baileyi* is resident. In the Cape York Peninsula, in north-east Australia, individuals observed during the October–March breeding season, when only the race *atrabectus* is present, are smaller than many of those seen in the autumn–winter months of April–September, when birds of this partly resident race mix with larger ones of the migratory nominate race. The nominate race, which breeds in central east Queensland southwards from near Townsville, migrates north, reaching mainly south-central New Guinea across the Torres Strait; in east Queensland and New South Wales, however, individuals of this race are recorded throughout the year

Despite the notorious aggressiveness of drongos, some species suffer high rates of nest predation and brood parasitism. The ***Fork-tailed Drongo*** *is the exclusive host of the African Cuckoo* (Cuculus gularis), *Asian Drongo-cuckoos* (Surniculus lugubris) *resemble Black Drongos* (Dicrurus macrocercus) *and lay in their nests. Turning to predation, eggs in more than 70% of Aldabra Drongo* (D. aldabranus) *nests may be preyed upon by rats, Pied Crows* (Corvus albus) *and other large birds, such as coucals* (Centropus), *herons (Ardeidae) and bulbuls (Pycnonotidae). After failure at the egg stage, drongos will generally build a new nest and lay a replacement clutch, but there are no reports of replacement clutches after failures at the chick stage.*

[*Dicrurus adsimilis*, Nylstroom, Limpopo, South Africa. Photo: Clem Haagner/ Ardea]

and are often considered residents, but they may also be the result of migratory populations replacing each other along the east coast. Records of this taxon from south of the breeding range, south of about 31° S, are considered to involve non-breeding visitors and may represent the extent of altitudinal movements. The species regularly descends from the eastern slopes of Great Divide towards the coast, attracted by high yields of nectar and insect food in coastal vegetation during the winter period.

Migration of drongos in Queensland is observed during the daylight hours. It is less concentrated towards the north and occurs over a longer period in the autumn compared with the southward spring passage. Movements are usually in small flocks of four or five individuals, and sometimes up to 30. In north-east Queensland, some migrating flocks are reported yearly along the coast, flying about 500 m offshore and 50–100 m above the water. Spangled Drongos are regularly observed on islands and moving across the Torres Strait, about 100 m above the sea, on their way to New Guinea in March–April or from New Guinea in October–November; in 1978, for example, more than 6000 birds per hour were heading south on a broad front in the early morning of 6th November. The return in south-east Australia of drongos wintering in north Queensland is reported earlier, usually in September–October and sometimes even late August; for example, 400 individuals per hour were counted in north-east Queensland as they migrated SSE on 6th October 1966, and up to 720 birds/hour were counted in late October. Northward departure of migrating drongos occurs mainly between March and May, with possible early records in February in New South Wales. Spangled Drongos spending the non-breeding season in New Guinea occupy the south-eastern part of the island, in the Trans-Fly region, and also the small islands in the north part of the Torres Strait; they are even more conspicuous than the resident race *carbonarius*, as they often occur in more open habitat.

Knowledge of drongo movements is based mainly on field observations, involving the presence or absence of a species depending on the season, identified distinctions between locally breeding subspecies and visiting races, and visible passage movements. Data derived from ringing operations are few. The development of ringing programmes and an analysis of the limited data available would certainly produce much useful information on the biology of the migratory dicrurids, their exact geographical dispersion, possible changes in their numbers over time, and other topics concerning these mainly common but still not well-known species.

Relationship with Man

Despite being very conspicuous and vocal birds, acknowledged as "short-tempered" and quarrelsome characters in the avian world, drongos are, curiously, not much represented in human cultures across their geographical range. Their remarkable courage in attacking and driving off other birds and animals much larger than themselves has earned them colloquial names in many native languages. In India, the Black Drongo is called the "King Crow" for this reason, and in Madagascar the drongo is referred to as "the king of the forest" in popular legends and beliefs. Congo tribes call the Velvet-mantled Drongo "Nkandongoe", meaning "angry leopard". On Mayotte, the endemic drongo's local name, *Marimoudou*, which means "the black Mary", refers only to the black colour of its plumage, but the bird has the reputation of being very aggressive near its nest and is treated with deference and, indeed, is sometimes feared.

In Australian slang, the name "drongo" has gained the significance of "loser" or "idiot", not because of any connection with the bird's behaviour, but in reference to a famous and unlucky Australian racehorse called "Drongo", which was probably named after the Spangled Drongo. This unfortunate horse never succeeded in winning a single race, having never been able to arrive first at the winning post in its entire career, which spanned the years 1921 to 1925.

The name "drongo", a shortened form of various French alternatives such as *Drongolon* and *Drongri*, is supposedly derived from an indigenous vernacular name used in northern Madagascar, but no current local name can be found to corroborate this, nor is there any etymological explanation to confirm such an origin.

In southern Asia, where up to seven species of drongo coexist, the Black Drongo and the Greater Racquet-tailed Drongo are probably the most popular species. These two are sometimes kept as cagebirds, probably for the beauty of their plumage and their impressive skills in imitating other birds and various other sounds (see Voice).

Black Drongos are significant consumers of insect pests of cultivated plants and trees. Several studies conducted in India, combining stomach-content analysis and observation, have identified this drongo as an efficient predator of arthropods in rice, pigeonpea (*Cajanus cajan*), groundnut and bean fields. In rice agro-ecosystems, about half of the prey taken were phytophagous, including 20% grasshoppers such as *Hieroglyphus banian*; in addition, more than 20% were dragonflies. The Black Drongo is

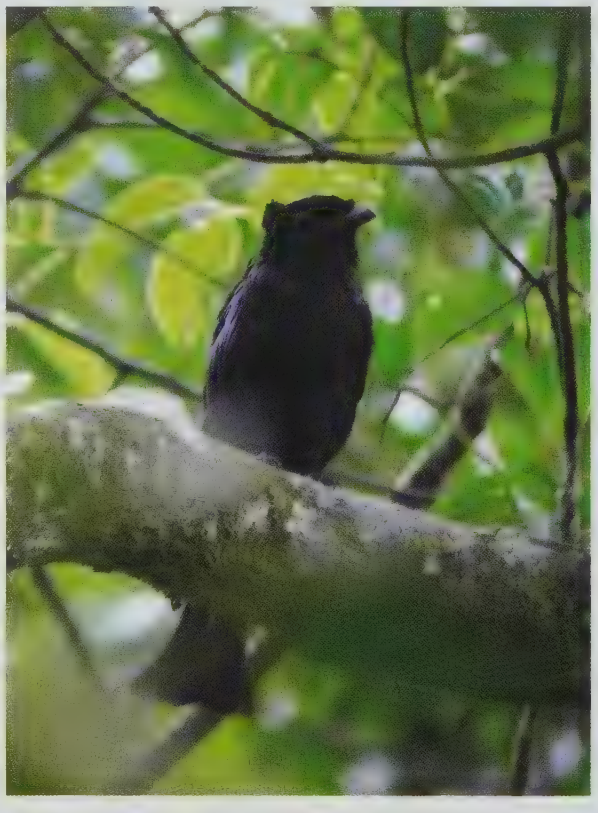
*The **Sri Lanka Crested Drongo** was until recently considered a race of the Greater Racquet-tailed Drongo* (Dicrurus paradiseus). *Its status has not yet been formally assessed, but this species meets the requirements to qualify as a restricted-range species. It is present only in the shrinking forest remants in the lowland wet zone of the Sri Lanka Endemic Bird Area, a range it shares with the race* leucopygialis *of the White-bellied Drongo* (D. caerulescens). *As the taxonomy of drongos is increasingly undergoing revision, the position of restricted-range subspecies should not be neglected, particularly as some of them may end up being treated as separate species. One case in question is that of the Tablas Drongo* (D. menagei), *hitherto considered a race of the Hair-crested Drongo* (D. hottentottus), *and long believed extinct, until its rediscovery in the late 1990s; it has recently been raised to species status. Its very small population and highly fragmented habitat suggest that it may need to be listed as Endangered or even Critically Endangered.*

[*Dicrurus lophorinus*, Sri Lanka. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

*Confined to the four main islands of Aldabra and some of their neighbouring islets, the **Aldabra Drongo** is the atoll's only extant endemic bird species, although the status of several other taxa, currently classed as subspecies, is unclear. Nowhere abundant, and with a tiny global range of 154 km² and a population size of only about 1500 individuals, it is particularly at risk from catastrophic events, such as diseases and cyclones. High nest-predation rates may limit the size of its population; this predation could be significantly reduced if introduced rats and cats were to be eradicated. Aldabra is a nature reserve, as well as a World Heritage Site, and the species' habitat is adequately protected, with no apparent decline in numbers reported. It is listed as Near-threatened.*

[*Dicrurus aldabranus*, Aldabra Is.
Photo: A. P. Leventis]

also a major predator of the tobacco caterpillar *Spodoptera litura* in rabi groundnut cultivation, and of the larvae of the scarce bordered straw moth (*Helicoverpa armigera*), often known as the Old World bollworm, in pigeonpea and wheat fields. It is also one of the five main natural predators of white grub (*Holotrichia*), the larvae of several carabid beetles and a damaging subterranean pest of several crops in India, which were found to be reduced by 45–65% following three subsequent ploughings. Provision of perches in fields greatly increased the number of drongos and the number of prey-hunting dives. Such practices have been recommended as an economically cheaper and environmentally safer alternative to the use of pesticides, the latter having, in particular, a negative impact on drongos through their toxicity and by reducing prey abundance.



Drongos are efficient predators also of wasps and bees, and can consequently have an adverse effect on honey-producers. Black Drongos and Spangled Drongos are both well known for preying upon bees. The former was reported to be the main predator of honeybees (*Apis mellifera*) after the Little Green Bee-eater (*Merops orientalis*) during the introduction of this bee in south India; both of these drongos are known to capture bees around hives, and up to 52 bees have been found in the crop of a single individual. On the other hand, Black Drongos also help to reduce significantly the numbers of the ferocious rock bee (*Apis dorsata*), which builds its nests under house roofs and can be dangerous to humans; two of the birds consumed up to twelve bees in half an hour. Similarly, Spangled Drongos capture wasps from nests on the walls of houses, and one individual was reported as eating hundreds of wasps over the course of about two days.

Perhaps the most negative event involving a dicrurid is the deliberate introduction by man of the Black Drongo from Taiwan to Rota Island, in the Northern Mariana Islands, in the 1930s in order to control destructive insects. By the early 1960s, the drongos had spread from Rota to colonize nearby Guam. Unfortunately, Black Drongos rapidly became occasional predators of small native passerines such as the Critically Endangered Rota White-eye (*Zosterops rotensis*) and the Endangered Guam Swiftlet (*Aerodramus bartschi*). They may well have played a significant role in the decline of the Rota White-eye and are considered a severe threat to the native forest avifauna of the Northern Marianas.

Status and Conservation

Widely spread across tropical and equatorial forests and savannas of the Old World, and generally common birds, the drongos living in mainland areas are not globally threatened species. Only two island forms are presently in this situation, the Comoro Drongo and the Mayotte Drongo, although future taxonomic studies may reveal more island forms to be added to this list, such as the Tablas Drongo. Three other drongos are listed as Near-threatened; these, too, are insular species, the Aldabra, Andaman and Sumatran Drongos. A further taxon, the Príncipe race of the Velvet-mantled Drongo, is often treated as a separate, monotypic species, and is then also listed as Near-threatened.

For most of the currently recognized drongo species, however, population sizes are not well known, and the lack of evaluation of numbers and trends is general. The Mayotte Drongo, restricted to a small island in the Comoro archipelago, in the western Indian Ocean, was no exception until recent years, when a specific study re-estimated the population size as being at least 2500 pairs, these present largely in forest reserves still threatened by illegal deforestation. This survey used point counts and other density measurements, and yielded figures of 42·4 pairs/100 ha in forest habitat and 10·4 pairs/100 ha in semi-cultivated habitat. Previously considered Critically Endangered, and still now as Endangered, owing to a global population underestimate of only about 100 individuals, the Mayotte Drongo's current status is not so perilous as had been feared and it should probably now be classed as Vulnerable, although it is still threatened by deforestation for cultivation and timber. The human population on the island, already dense, continues to increase, and the majority of the human inhabitants practise traditional food cultivation. In addition, the potential introduction of new nest predators, whether by accident or deliberately, should be treated as an important threat. Severe cyclones hit the island about every ten years, and their effect is often devastating, although the species has been able to recover from such events in the past. A network of 17 forest reserves has been established on Mayotte, and these should assist the species in its survival.

*The **Sumatran Drongo** is currently considered Near-threatened, but an evaluation of its population size and trends is needed in order to review this status, since the species is likely to be declining in conjunction with habitat loss and degradation throughout its range. A restricted-range species, it is found only in Sumatra. Although still fairly widespread, locally relatively common, and apparently tolerant of secondary and logged forests, its total population is undoubtedly smaller and its range more fragmented than in the past.*

[*Dicrurus sumatranus sumatranus*, Sumatra.
Photo: Ron Hoff]

Endemic to the Andaman Islands, the Near-threatened ***Andaman Drongo*** *is still a common resident in a variety of forest habitats. Although its range is very small, forested habitat is still relatively intact in the Andamans, and not so disturbed or fragmented to be of immediate concern. However, there are signs that pressure on forests is increasing. The race* otiosus *of the Greater Racquet-tailed Drongo* (Dicrurus paradiseus) *is also restricted to the Andaman Islands.*

[*Dicrurus andamanensis*, Andaman Is. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

The status of the Comoro Drongo, currently listed as Endangered, is no better known now than it was in the 1980s, when the population was assessed at about 100 individuals. Despite the total lack of protection of its habitat, however, it is thought not to be declining, primarily because of its apparent adaptation to degraded vegetation and its ability to persist in exotic vegetation. The species is confined to a few areas around the active volcano of Mount Karthala. Although the establishment of a protected area on Mount Karthala has been proposed, no progress has yet been made in achieving this objective.

On Aldabra, the third small island of the western Indian Ocean occupied by an endemic drongo, the status of the species concerned appears better. The Aldabra Drongo has a small population of about 1500 individuals, which is apparently not declining, and its habitat is well protected, Aldabra atoll being virtually uninhabited, and protected by its being a nature reserve as well as a World Heritage Site. A few thousand kilometres away, in the north-east Indian Ocean, the Andaman Drongo is common in wooded habitat of that archipelago. Its population size and trends have yet to be evaluated, its current range to be accurately defined and its conservation status to be reviewed in the light of increasing habitat deterioration. Only two small protected areas, totalling 80 km² of the inland luxuriant tropical forests, are present on these islands. The situation is the same on the much larger island of Sumatra, where the Sumatran Drongo is said to be a fairly common member of mixed-species foraging parties at middle altitudes. An evaluation of this species' population size and trends, on an island subject to severe loss and fragmentation of lowland forest, appears necessary in order to review its current conservation status of Near-threatened. The Tropical Rainforest Heritage of Sumatra covers approximately 25,000 km², a significant proportion of the remaining lowland and mountain forest.

The cases of two other insular species are different, as the taxonomic status of both has recently changed. The endemic Príncipe race of the Velvet-mantled Drongo was hitherto often treated as a full species, distinct from the two continental forms of the species, which are widely distributed in the forests of equatorial Africa. It was previously considered Near-threatened owing to its small range and to harmful changes in agricultural practices. Conversely, the Tablas Drongo, previously considered a subspecies of the Hair-crested Drongo, is now proposed as a full species, restricted to the small island of Tablas, in the central Philippines. Believed probably extinct towards the end of the last century, this drongo was rediscovered in the late 1990s in one of the extremely few and small remaining areas of closed-canopy forest in the north of the island. Its very small population, confined to highly fragmented suitable habitat, must be considered to be Critically Endangered, but it has not been "officially" assessed since the taxon has hitherto been treated only as a subspecies.

The situation of the "Principe Drongo", removed from the list of threatened species because no longer considered a full species, and of the Tablas Drongo, absent from the list because of its subspecies rank at the time, highlights the necessity to take into account the status of all insular forms. Actual numbers are very important for several Australasian taxa, each occurring on one or a few small islands or archipelagos; with such restricted ranges, many of them should probably be considered at least Near-threatened taxa. This applies particularly to the Wallacean Drongo, whose six races occur separately on different islands of the Lesser Sundas. Otherwise, the species most affected by this problem are the Hair-crested Drongo, widely distributed in the Indian Subcontinent, China and South-east Asia, and with ten endemic races on several small islands of the Sundas, the Moluccas and the Philippines, and the Spangled Drongo, occurring mainly in Australia and New Guinea, but with four races on different Moluccan islands, two on two islands of the Solomons and one in part of the Bismarck Archipelago. The Greater Racquet-tailed Drongo, also widespread in India, China and South-east Asia, has two subspecies separately restricted to the Andaman and Nicobar Islands, three confined to small islands in the South China Sea, and one in Java and Bali. The Black Drongo, too, has one race occurring only in Java and Bali. If the Sumatran Drongo is considered Near-threatened because of severe deterioration of its forest habitat, the same consideration could apply to four subspecies of the Ashy Drongo, two in mainland Sumatra and two on small islands of the Mentawai Archipelago, off the western coast, and, to a lesser extend, to one strictly montane race of the Lesser Racquet-tailed Drongo. It is appropriate, for the same reason, to mention the subspecies *viridinitens* of the Sumatran Drongo, which occurs only in the Mentawai Islands.

There are no globally threatened species among the drongos with mainland populations. The two drongo species listed as Endangered are both from small islands of the Comoros, in the Indian Ocean. The ***Comoro Drongo*** *has a highly localized distribution around Mt Karthala, an active volcano on Grand Comoro. In 1985, the population was estimated at around 100 individuals, although a few pairs have since been found elsewhere on the island. Most of the habitat in its range has been degraded, but the Comoro Drongo can persist in exotic vegetation, and does not appear to be declining. Field studies are needed to investigate its biology, range and population, and limiting factors. A protected area has been proposed on Mt Karthala.*

[*Dicrurus fuscipennis*, Grand Comoro, Comoro Is. Photo: Pete Morris]

All of the islands occupied by these different drongos subspecies are situated in equatorial or tropical climatic zones and are normally covered with dense evergreen forest. Most of them are already densely inhabited, and the others are under pressure of increasing human populations and consequent deterioration of natural forest habitat: both permitted and illegal logging, fragmentation of wooded areas, cultivation, mining, the building of new roads and infrastructure, and urban development. The Tablas Drongo illustrates well the potential risk of extinction of a species before its decreasing population has been properly evaluated. As taxonomic positions of drongos come under revision following the findings of various molecular-genetic studies (see Systematics), it seems important not to neglect all the restricted-range taxa of the Dicruridae, including subspecies.

The situation in Sulawesi and Borneo is not very different from that on Tablas. Probably because the highlands of Sulawesi, the regular habitat of this island's endemic drongo, do not suffer from intense degradation, the Sulawesi Drongo is classed as of Least Concern. Its counterpart in lowland forest of the island, the subspecies *leucops* of the Hair-crested Drongo, is facing a rapid increase in agriculture and changes in land use in lowland Sulawesi, a threat to the survival of this spectacular white-eyed drongo. The future of this species' two other white-eyed races, restricted to small islands in the Java Sea, also depends on the extent of the deforestation. In Borneo, a very large island with considerable expanses of threatened forested habitats, three dicrurid species are represented by endemic subspecies, namely the race *borneensis* of the Hair-crested Drongo, the race *brachyphorus* of the Greater Racquet-tailed Drongo, and the race *stigmatops* of the Ashy Drongo, the last being restricted to the mountain areas.

Three other large Asian islands host endemic species and subspecies of drongo and are also threatened by increasing human population and the consequent changes in natural forest habitat. In Taiwan, the race *braunianus* of the Bronzed Drongo, common in the interior mountain forests, possibly benefits directly from the "corridor" of conservation areas established along the central mountains, including the three large national parks of Sheipa, Taroko and Yushan and the three major wildlife habitat areas of Cilan, Danda and Guanshan, together covering a little more than 5000 km², about 14% of the island's total surface area. Another Taiwan endemic is the race *harterti* of the Black Drongo, which occurs in open country and is apparently adapted to farmland and suburban habitat. Off the south-east China coast, Hainan Island represents the entire range of the race *innexus* of the Ashy Drongo and race *johni* of the Greater Racquet-tailed Drongo. No data are available on the status of either, with no estimates of population size or trends. As Hainan is recognized for its evergreen tropical rainforests and monsoon forests, particularly rich in biodiversity, it is the focus of one of the three key projects presented in China: Sustainable Forestry Development Project, a World Bank Document published in 2002, with a view to developing and improving systems of conservation, management and sustainable use of forest resources. The island's two endemic drongos should certainly benefit from such attention to their forest habitat.

The third island is Sri Lanka, divided into two neatly distinct ecological zones, the dry zone and the wet zone, each having two drongos occurring in differing habitat types (see Habitat). Here, too, it is worth noting the change in taxonomic status of the Sri Lanka Crested Drongo, now generally treated as a full species but previously considered to be only an aberrant race of the Greater Racquet-tailed Drongo. *The 2007 Red List of Threatened Fauna and Flora of Sri Lanka* indicates that one in every five species of bird on the island is currently facing the risk of becoming threatened in the wild. This conclusion concerns mainly the lowland wet zone, the range of both the Sri Lanka Crested Drongo and race *leucopygialis* of the White-bellied Drongo, because of the increasing and severe alteration and fragmentation of natural habitats there. The dry zone is less subject to rapid deterioration, and the two taxa concerned, the subspecies *ceylonicus* of the Greater Racquet-tailed Drongo and race *insularis* of the White-bellied Drongo, may benefit from a large number of protected areas in that zone.

Unfortunately, there is a lack of data on population size and trends not only for insular drongos, but also for continental-mainland ones. Only some studies conducted in equatorial Africa appear to have produced measurements of densities for these rather widely dispersed species. In Gabon primary forest, the Shining Drongo, with 12–15 pairs per 100 ha, is commoner than the Square-tailed Drongo, with 7–8 pairs per 100 ha, and is more regular than the Velvet-mantled Drongo, which is recorded at 6–

17 pairs per 100 ha. As expected, the density of the Shining Drongo is lower in Gabon secondary forest, where only 6–8 pairs per 100 ha were found. In mature forest in Liberia, the Shining Drongo is found at 10–20 pairs per 100 ha, whereas the Velvet-mantled Drongo is less common, with up to a maximum of 10 pairs per 100 ha. Studies in southern Africa have confirmed the importance of woodland type for the density of drongo populations: for Fork-tailed Drongos, for instance, densities per 100 ha of 13, 18 and 25 individuals were found in, respectively, mopane, acacia and miombo savannas, or 3–33 birds per 100 ha in different types of acacia woodland.

Limited information on densities is available for the Spangled Drongo. In south-east New Guinea, the subspecies *carbonarius* occurs at a density of 6 birds per 100 ha in a lowland rainforest near Port Moresby. In northern Australia, in north Northern Territory, the race *baileyi* is found at 70–80 individuals per 100 ha in Kakadu National Park, but the figure drops to only 3 birds per 100 ha in South Alligator River area; and in north-east Queensland the nominate race of this drongo occurs at a density of 20 birds per 100 ha.

Only a few members of the family, such as the Fork-tailed Drongo in Africa, the Black Drongo in Asia and the Spangled Drongo in Australia, have adapted well to man-made habitats such as gardens and residential areas. These species may gain from feeding opportunities created by humans, typified by the concentrations of insects around lights at night, from which the more forest-dwelling White-bellied Drongo occasionally benefits (see Food and Feeding). Fork-tailed Drongos, accompanied by rollers, bee-eaters and other birds, commonly attend savanna fires during each dry season in eastern and southern Africa, where they catch insects fleeing from the flames; the same occurs with the Black Drongo in parts of Asia, where fire is frequently used as a management tool. Together with other birds, such as House and Large-billed Crows, Common Mynas and Bank Mynas (*Acridotheres ginginianus*) and Cattle Egrets (*Bubulcus ibis*), Black Drongos readily follow the plough on cultivated fields, seizing insects and annelids disturbed by the machinery. The majority of drongos, however, still require natural habitats for their survival.

This brief analysis of the conservation status of the Dicruridae indicates that a main priority is that of undertaking an evaluation of the population size of each species, and in particular of all restricted-range island species and races. It should be possible, through field studies, to provide information on trends in numbers and range, such information being essential for the detection of declines, and for scientists to propose and justify conservation actions needed in order to improve the status of these birds, especially with the current level of habitat changes induced by the rapid development of human societies. The developing of programmes designed to increase environmental awareness on all islands harbouring a restricted-range species or subspecies and, where appropriate, the encouraging of locally organised ecotourism are two other directions which could be followed.

Drongos are very prominent and popular birds that can be easily used as flagship species for conservation programmes related to tropical forests. This applies in particular to the endangered or rare island forms of Mayotte, Grand Comoro, Aldabra, Príncipe, Tablas, the Andaman Islands and Sumatra. As they are consumers of insects, they can function also as bio-indicators of the health of tropical forests and agro-ecosystems. Nevertheless, despite the fact that most of them are very common and widespread birds, basic aspects of the taxonomy, breeding biology and status of many dicrurids are still poorly known and merit attention from ornithologists internationally.

*Confined to Mayotte in the Comoro Islands, the **Mayotte Drongo** is currently listed as Endangered. It is still commonly found above 200 m around the four mountains that retain large expanses of humid natural forests in the north and centre of the island, and at lower altitudes along the west coast. All these sites of prime natural habitat are protected by law, but steady human population growth has led to illegal clearance, and the introduction of new nest predators is potentially a very serious threat. An old estimate suggested just 100 individuals remained, but point counts and surveys of density in 2002–2004 indicate a minimum population of 2500 pairs.*

[*Dicrurus waldenii*, Mayotte, Comoro Is. Photo: Pete Morris]

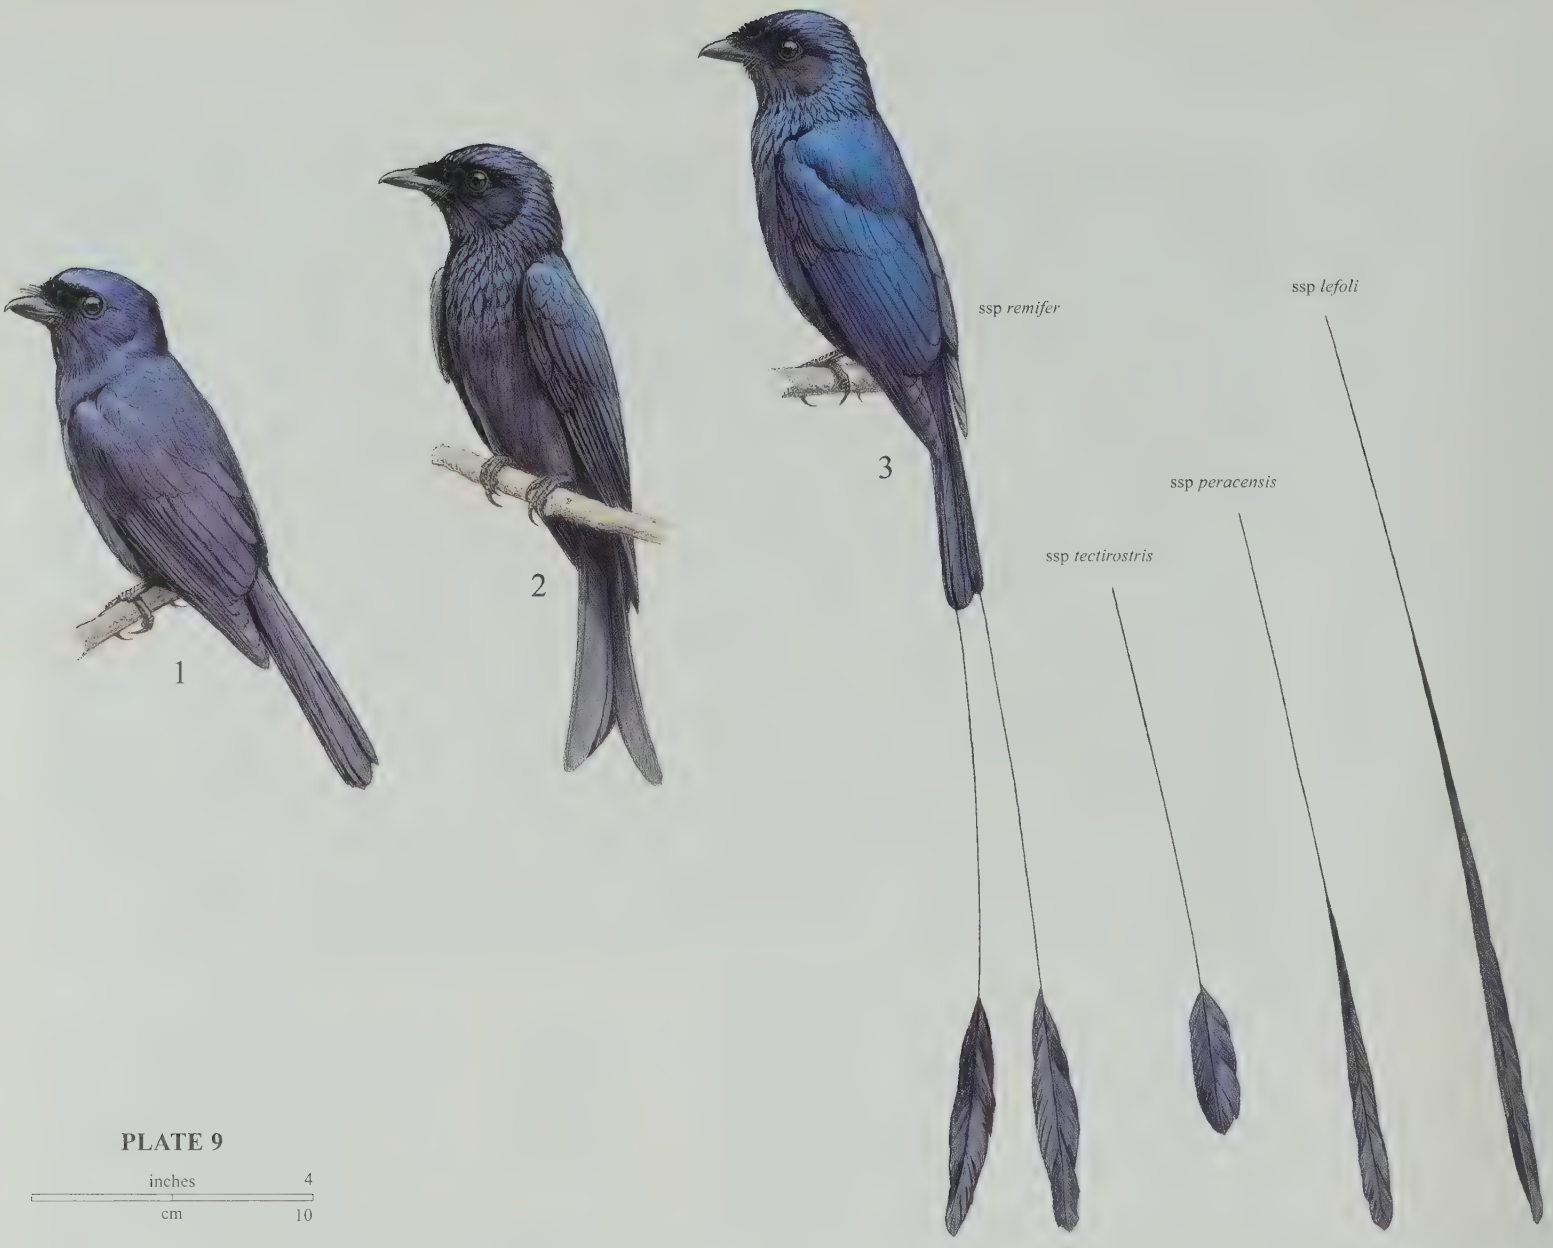

PLATE 9

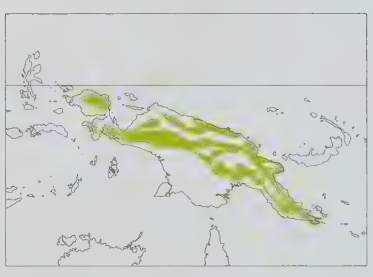
inches 4
cm 10



Genus *CHAETORHYNCHUS* A. B. Meyer, 1874

1. **Pygmy Drongo**

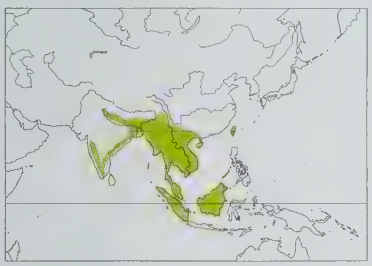
Chaetorhynchus papuensis

French: Drongo papou **German**: Rundschwanzdrongo **Spanish**: Drongo Papú
Other common names: Mountain Drongo, Papuan (Mountain) Drongo

Taxonomy. *Chaetorhynchus papuensis* A. B. Meyer, 1874, Arfak Mountains, New Guinea.
Considered the most primitive drongo, differing from *Dicrurus* in having twelve (not ten) rectrices. Recent molecular-genetic study, however, indicates that genus may belong in fantail family (Rhipiduridae). Clinal variation in size, W populations (mean male wing measurement 122 mm) on average larger than those in SE (118 mm), with intermediate values in intervening regions. Monotypic.
Distribution. Mountains of New Guinea.
Descriptive notes. 20–22 cm, including tail 9–10 cm; male 36–45 g, female 27–39 g. A small sooty-black drongo with tail slightly rounded (not forked), rather short bill strongly compressed, upper mandible strongly hooked, rictal bristles very long. Has frontal band pure velvety black, slight crest of brilliant purple-blue; glossy steel-blue feathers on upperparts, becoming faint on flanks and belly; concealed white patch at base of scapulars; iris brown; bill and legs black. Sexes similar, female a little smaller than male; central tail feathers exceed outer ones by 1–9 mm for male, 1–11 mm for female. Immature is duller than adult and has white gape. Voice. Noisy. Song an explosive, rapid jumble of varied short notes, many squeaky and metallic, some lower and nasal, duration 4·5–5 seconds; another song a beautiful melodious mixture of loud whistles, squeaks, chirps and warbles. Calls include mildly explosive jangle of notes; rapid metallic ticking, "sick-tsick, ts-ts-tsik-tsik" or "tsei-tsutsutsutsu"; single strong and metallic "tsei", or "peep", repeated 5–7 times; multisyllabic slur, descending and then rapidly rising, initially harsh and buzzy, ending with clear and squeaky notes; occasionally short nasal, squeaky notes, "cha-cha-cha, chep, chep-pip" and "sscsh-sschsh-tchick". Often utters explosive calls when flushed. Captured individual, when released, uttered low, monotone fantail-like note as it flew away.

Habitat. Hill forests from 200 m to 1600 m, mainly 600–1400 m; typical bird of forest interior. Altitudinal ranges of this species and *Dicrurus bracteatus* seem to be nearly mutually exclusive, latter occurring in lowland forest.
Food and Feeding. Feeds on insects and spiders (Araneae). Hunts in middle stage of forest. Typically, perches upright on horizontal branch, tail pointing straight down, often wingtips hanging below tail; sometimes flicks tail from side to side or upwards. Captures prey by sallying in middle and lower strata. Has been reported as behaving in manner of monarch-flycatcher (Monarchidae) or fantail. Forages alone or in small groups, joining mixed flocks of e.g. Old World warblers (Sylviidae), fantails and monarch-flycatchers; flock-leader species changes according to altitude, generally Rusty Pitohui (*Pitohui ferrugineus*) up to 600 m, Variable Pitohui (*Pitohui kirhocephalus*) at c. 600–1000 m, Hooded Pitohui (*Pitohui dichrous*) c. 1100–1300 m and Black Pitohui (*Pitohui*

nigrescens) from 1200 m to at least 1700 m. Present species benefits by taking insects flushed by flock-members, but may also force other birds to give up captured insects. On the other hand, acts as sentinel, giving alarm at approach of predators. Reported as following Buff-tailed Sicklebill (*Drepanornis albertisi*) while foraging on bark and epiphytes; sometimes follows human observer.
Breeding. Nest a small shallow basket, hung from tree fork. No other information available.
Movements. Resident.
Status and Conservation. Not globally threatened. Fairly common to scarce, and widely distributed. In W & C New Guinea, traditional tribal lifestyle has had little impact on ecosystems, but situation changing as a result of extensive logging concessions and shifting human populations; road-building also resulting in new settlements, followed by further deforestation for agriculture and timber. In S of range large areas are inaccessible, but new roads under construction for development of mining (copper, gold) and large commercial logging operations. In NW & W, the species may benefit from several protected areas, e.g. Foja Nature Reserve (c. 10,000 km²), covering complete altitudinal range of lowland to montane forest.
Bibliography. Barker *et al.* (2004), Beehler (1978b), Beehler *et al.* (1986), Coates (1990), Diamond (1987b), Stattersfield *et al.* (1998), Vaurie (1949).



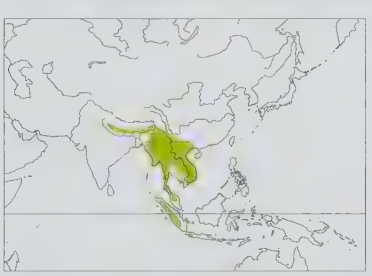
Genus *DICRURUS* Vieillot, 1816

2. Bronzed Drongo

Dicrurus aeneus

French: Drongo bronzé **German**: Bronzedrongo **Spanish**: Drongo Bronceado

Taxonomy. *Dicrurus aeneus* Vieillot, 1817, India.
Formerly placed in a monotypic genus, *Chaptia*. Appears similar to *D. remifer* in general plumage characteristics (apart from absence of racquets); possibly originates from an ancient form related to *D. annectans*. Clear trend of decreasing size from N to S. Nominate race intergrades with *malayensis* in C Peninsular Malaysia (Pahang and N Selangor). Three subspecies recognized.
Subspecies and Distribution.
D. a. aeneus Vieillot, 1817 – Indian subcontinent (Himalayan foothills E from Uttar Pradesh, S through hills of Bangladesh to Eastern Ghats, and Western Ghats S from R Tapti), SE Asia (S to C Peninsular Malaysia), and S China (SE Xizang, W & SW Yunnan, S Guangxi, Hainan).
D. a. braunianus (Swinhoe, 1863) – interior mountains of Taiwan.
D. a. malayensis (Blyth, 1846) – C Peninsular Malaysia, Sumatra and Borneo.



Descriptive notes. 23–24 cm; 22–30 g. A small drongo with glossy plumage, well-forked tail, and very depressed and flattened bill; feathers of crown, hindneck and upper breast long and pointed (but not becoming hackles). Nominate race is black, strongly glossed metallic blue-green or purple (depending to light) on crown, nape, mantle and breast (elongated feathers with gloss limited to tips), especially spangled on throat; frontal band, chin and upper throat, flanks and belly to undertail-coverts deep matt black; rump often grey; slender tail (105–131 mm) has central feathers black, glossed green, outer feathers black, depth of fork 19–39 mm; iris dark reddish-brown or crimson; bill and legs black. Sexes similar in plumage, male a little larger than female. Juvenile has upperparts duller and less heavily spangled than adult, is uniformly sooty brown and initially not spangled below, iris brown; first-winter has white spotting on breast, belly, flanks and underwing-coverts, and less forked tail (sometimes looking square-ended). Race *malayensis* is smaller than nominate (tail 90–111 mm), with tendency to be slightly glossier, particularly on rump, belly very dark grey, axillaries and underwing-coverts with a few white spots; *braunianus* is largest (tail 117–130 mm), has resplendent deep metallic bluish-green on upperside, plumage somewhat smoky on belly, white spots on axillaries, bill shorter and much broader than nominate and well covered with feathers. Voice. Noisy and demonstrative during breeding season, less so otherwise; reported as singing on moonlit nights in Thailand. Song pleasant, with varied short phrases of loud musical whistles or harsh notes, rapid chatters, downstrokes and twangy notes, nasal churrs and rolling strophes. Calls include a dry sound followed by 2 quick high-pitched nasal notes, "gzrrt nyip-nyip"; downslurred whistles, "sleeurk, sleeurk", produced by pairs or trios; loud continuous chorus of sharp or harsh notes given by groups in Bhutan. Much mimicry of raptors, such as Crested Serpent-eagle (*Spilornis cheela*) in Malaysia, also of upland passerines e.g. Javan Cuckoo-shrike (*Coracina javensis*) and Orange-bellied Leafbird (*Chloropsis hardwickii*).
Habitat. Occupies all kinds of forest or wooded habitats (except sometimes the deepest and wettest): broadleaf evergreen and moist-deciduous forest, mixed bamboo-jungle, secondary growth, forest edge, also tea, coffee and rubber (*Hevea*) plantations; fruit gardens in Kerala (SW India); subcostal peatswamp-forest in S Thailand and Peninsular Malaysia; teak (*Tectona*) or oak (*Quercus*) and pine (*Pinus*) forests, depending on altitude, in Myanmar; confined to primary forest in Borneo. In Himalayas occurs in foothills, in Nepal occasionally up to 2100 m (usually below 1200 m in winter); hills, probably to 1400 m, in Sumatra; recorded at maximum of 1500 m in Malay Peninsula; to 2000 m in China, and apparently restricted to mountainous regions up to 2000 m in Taiwan. Avoids more open habitat, but reported as breeding near a village.
Food and Feeding. Mainly insectivorous; prey include flies (Diptera), Hymenoptera and Lepidoptera. Reported as consuming flower nectar. Hunts in canopy, including crown of giant emergent trees, in open spaces or edges of forest, and on edge of cultivated areas in Malay Peninsula. Hawks winged insects, making short sallies, and often swooping close to ground, then looping back to same perch; also makes vertical sorties from treetop, diving back with wings held closed after a capture. In Malaysia, reported as perching on small trees or bamboo and hawking after prey from them, usually at middle-storey level; in Borneo often seen on rivers, skimming water to catch flies in manner of a swallow (Hirundinidae). Along forested or wooded margin of small roads, utilizes wires as still-hunting perches. Usually seen singly or in pairs (members of which widely separated); also a regular member of mixed feeding parties of insectivorous birds.
Breeding. Season mainly Apr–May, but also in Feb in SW India (Kerala), Mar in Nepal and to Jun in N India (Sikkim). Nest built by both parents (in Borneo observed to operate with great precision, in perfect collaboration), a shallow irregular cup, extremely compact, of various materials, e.g. bark and decayed wood lined with dead strips of small vine in Malay Peninsula, fine grass, fibre and a few dry bamboo leaves in India, plantain (*Musa*) leaves and jute in E India, well felted and cemented together, and fixed in branch fork with plant fibres and cobwebs; size varying from large (external diameter and depth 10·2–12·3 cm × 5·1–7·2 cm) to, more often, small (externally 8·9 cm across and 5·1 cm deep, internally 6·3 cm wide and 3·8 cm deep), with generally very thin interior (nest can look fragile but is really very strong, as well put together and strengthened with covering of spider webs); suspended in hammock fashion 2–6 m above ground in small fork of slender branch in outer part of tree, preferentially above water or track, or in bamboo, either on hanging and waving spray of bamboo (9–15 m high) or among mass of upright twigs growing from lower nodes between 1·5 m and 4·5 m; in Assam (NE India), often in rather small tree standing in thin open scrub-jungle or at the edge of forest surrounding tea estates. Clutch generally 4 eggs, occasionally 3, pale pinkish-fawn to pale salmon-pink with irregular zone of dark cloudy spots, sometimes reddish or purplish, around broad end (rarely, spots distributed over whole surface and more numerous at larger end); average 21·1 × 16·1 mm (nominate race), 21 × 15·7 mm (*malayensis*) and 25·5 × 20 mm (*braunianus*); incubation by both sexes, period 13 days; both also feed chicks, no information on duration of nestling period.
Movements. Resident; in highest parts of range, e.g. in Nepal, generally makes post-breeding descent to lower levels.
Status and Conservation. Not globally threatened. Common and widespread in most of range. Fairly common in Himalayan area; common in Western Ghats, and locally common in Bangladesh; the most common forest drongo in N Myanmar and common in S China. Common in Thailand, where present in several protected areas, e.g. Khao Yai National Park, and more or less common in N & C Malay Peninsula (recorded in Pasoh Forest Reserve); widespread in Indochina, and reported (at least until 1970s) as common in dense forests in Cambodia. Race *malayensis* is common resident throughout lowlands of S Malay Peninsula, but extinct in Singapore since 1950s; common also in Sumatra and throughout lowlands of Borneo. In Taiwan, *braunianus* uncommon except in mountainous forested regions, where reported as common; an increasing area of lower slopes (to 1000 m, but mainly 100–500 m), however, is intensively cultivated and faces continuing forest destruction.

3. Lesser Racquet-tailed Drongo

Dicrurus remifer

French: Drongo à rames **German**: Spateldrongo **Spanish**: Drongo de Raquetas Chico

Taxonomy. *Edolius remifer* Temminck, 1823, Java.
In the past, sometimes separated in a monotypic genus, *Bhringa*, characterized by morphology of outer pair of tail feathers. Has previously been considered to be closely related to *D. aeneus* on account of very similar plumage characteristics (except racquets), an hypothesis compatible with findings of recent DNA studies. Races intergrade wherever they come into contact: *peracensis* with *tectirostris* in W Thailand (Ban Rahaeng region), Vietnam (C Annam) and S Laos (Bolovens Plateau), and with *lefoli* on Thailand–Cambodia border. Four subspecies recognized.
Subspecies and Distribution.
D. r. tectirostris (Hodgson, 1836) – lower Himalayas from N India (E from Garhwal and Kumaon) E to Arunachal Pradesh, Assam, Nagaland, Manipur and Mizoram, E Bangladesh, S China (SE Xizang, W & S Yunnan and SW Guangxi), Myanmar (except extreme S), N Thailand, N Laos and N Vietnam (S to Huè).
D. r. peracensis (Stuart Baker, 1918) – S Myanmar (Tenasserim) and SW Thailand S to N Peninsular Malaysia (S Selangor and S Pahang), S Laos and S Vietnam (S to S Annam).
D. r. lefoli (Delacour & Jabouille, 1928) – mountains of S Cambodia (Cardamom and Elephant Ranges).
D. r. remifer (Temminck, 1823) – Sumatra (Barisan Range and Batak Highlands) and W Java.

Descriptive notes. 26 cm, excluding outermost tail feathers (c. 30–40 cm to end of tail); five males 39–49 g, 5 females 35·5–44 g (*peracensis*); four males 48–51 g (*tectirostris*). Distinctive black drongo, characteristic square tail having greatly elongated bare-shafted outermost pair of rectrices; tuft of frontal feathers very dense and brush-like, projecting forwards to cover greater part of bill and producing flat-looking head. Nominate race has entire upperside black, with extremely metallic and brilliant gloss which changes from green to bluish or purple according to light; centre of throat to breast black but highly spangled, frontal feathers, cheek, lores, chin, side of throat and belly velvety black, flanks without gloss and silvery grey; underwing-coverts and axillaries with small white tips; shaft of outermost pair of rectrices completely bare and wire-like from level of central feathers, except for barbs on both sides distally, forming long, narrow paddle-like spatula or racquet, webs of which taper on to shaft for short distance (central rectrices 104–116 mm; outer rectrix 392–453 mm, bare shaft 150–246 mm); iris red or brownish-crimson; bill and legs black. Female is similar to male but smaller, with shorter tail including similar racquets. Juvenile lacks both frontal brush and racquets, has tail slightly forked, gloss below restricted to small spangles on throat and in band across upper breast, axillaries broadly tipped white, iris brown; typical long racqueted rectrices acquired at next moult, when gloss appears above and extends farther below, white spots on axillaries still numerous but become smaller, frontal brush developing; adult plumage complete after third moult. Races differ mainly in size and shape of tail-racquets: *tectirostris* has broad racquets starting abruptly from shaft, central rectrix 117–129 mm, outer rectrix 402–532 mm, bare shaft 182–306 mm, length of racquet 81–120 mm, width of racquet 21–30 mm; *peracensis* is similar to nominate, but distal webs on outer rectrix arise more gradually from shaft, and racquet becomes both very long and narrower, cigar-shaped (length 154–228 mm, width 14–20 mm); *lefoli* has web on outer rectrix occupying three-quarters of length of shaft and racquet rather long, narrow and streamer-like (bare shaft 125 mm, length of racquet 330 mm). Voice. Has one of the most extensive repertoires of all drongos. Extremely varied vocalizations include musical and metallic whistles, short plaintive, downslurred, sweet notes, loud harsh rattle sounds and discordant downslurred "kreer" whistles, mechanically repeated or in irregular series, also warbling strophes and many other melodious or raucous sounds; also explosive clear piping "keep" notes, and sequence of 7 bell-like notes within an octave, "doh-ray-mee-

doh-ray-mee-doh", or doubled as "cheek-cheek, bo-peep, bo-peep, cheek-cheek"; large amount of mimicry of many other mountain and forest bird species, e.g. woodpeckers (Picidae), leafbirds (*Chloropsis*), bulbuls (Pycnonotidae), Old World warblers (Sylviidae) and others.

Habitat. Humid broadleaf evergreen and deciduous forest; frequents shaded edge of openings, fire-lines, cultivation clearings and forest streams, also dry open woodlands and bamboo-jungle in China. Occurs at 900–2000 m in Indian Subcontinent; from lowlands to 1200 m (mostly 450–750 m) in Myanmar, but common also from 900 m to 1800 m in SE (Karen area); from foothills to 1800 m in China; not below 450 m in Malay Peninsula; 600–2500 m, principally 1200–1800 m, in Sumatra and Java. Replaces *D. paradiseus* at higher elevations, but overlaps with it at lower altitudes.

Food and Feeding. Mainly insectivorous; beetles (Coleoptera), Lepidoptera, alate termites (Isoptera) and other winged insects recorded in diet, as also are spiders (Araneae). Also takes flower nectar. Typically arboreal, within dense foliage of canopy. Hawks prey principally beneath canopy, dashing in bold swoop from perch, to which it returns after each sortie, generally flying slowly, long tail feathers undulating through air; capable of great speed in pursuit of termites on the wing. Forages singly and in pairs; often associates with mixed-species flocks, including those with *D. paradiseus*.

Breeding. Season mainly May, also Apr and Jun. Nest built by both sexes, a small shallow cup made of fine roots or other vegetable fibres and pliable stems, bound together or around twigs of branch fork with finer fibres and few cobwebs, outside diameter 7·5–11 cm, inside depth 2·5–4 cm, often scarcely more than 5 mm thick at bottom and looking like a thick network roughly built (contents visible through all sides), old nest sometimes taken apart and material reused; suspended from fork of small branch, usually less than 7 m from ground, occasionally within reach of human hand, seemingly mainly close to open place where ample light and sunshine (which increase the numbers of aerial insects, a main food source), e.g. jungle-clad ravine surrounded by tea or other plantation, patches of cultivation in forest, open glade alongside river. Clutch 3 or 4 eggs, warm salmon-pink to terracotta, with blurred blotches of darker terracotta, fairly dense at larger end, or dark reddish-brown mixed with secondary grey marks over whole surface (rarely, white to pale salmon-pink or yellowish-pink with variety of pale purplish-brown or reddish spots, blotches or freckles), average size 25·5 × 18·4 mm; incubation and brood-tending by both sexes, no information on duration of incubation and nestling periods; fledglings cared for by both parents.

Movements. Mainly resident; local post-breeding descent from higher elevations in Himalayas. Breeding summer visitor in parts of S China.

Status and Conservation. Not globally threatened. Locally common in Indian Subcontinent; in Myanmar, widespread in suitable forest in N & E, rare in S, confined to bamboo in higher Karen areas but quite common in Karen Hills and Karenni; in Thailand, local in W (recorded in Huai Kha Khaeng Wildlife Sanctuary) but absent from C; locally common in China. In Peninsula Malaysia, race *peracensis* regular and common, present in still extensive habitat, but more dependent on closed forest than are other local drongos. Nominate race possibly threatened by deterioration of forest habitat in Sumatra, where loss of lowland forest already extensive. Race *lefoli* has very small range, restricted to mountains of S Cambodia; requires research to determine exact distribution, numbers and trends.

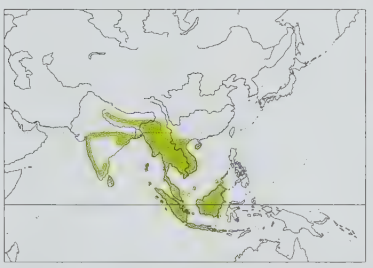
4. Andaman Drongo

Dicrurus andamanensis

French: Drongo des Andaman **German**: Andamanendrongo **Spanish**: Drongo de Andamán **Other common names**: Small Andaman Drongo (*andamanensis*); Large Andaman Drongo (*dicruriformis*)

Taxonomy. *Dicrurus andamanensis* Beavan, 1867, Port Blair, Andaman Islands.
In the past sometimes placed in genus *Dissemuroides*. Considered closely related to *D. paradiseus*, having similar plumage. Exhibits apparent cline of decreasing size from N to S, with birds of intermediate size on Middle Andaman; species possibly better treated as monotypic. Two subspecies provisionally recognized.
Subspecies and Distribution.
D. a. dicruriformis (Hume, 1873) – Great Coco I, Table I (N Andamans).
D. a. andamanensis Beavan, 1867 – all main islands of Andamans.



Descriptive notes. 28–29 cm (nominate), c. 35 cm (*dicruriformis*). Distinctive glossy drongo with deeply forked long tail, large black bill with sharply hooked upper mandible, at base of which a straight or back-curving tuft c. 2 cm long of thin hairy filaments (distinctly barbed to the tips); feathers on each side of neck slightly elongated (not enough to form hackles). Male nominate race is black, except for brownish primaries, and velvety black abdomen, flanks and undertail-coverts; whole plumage glossed with green, but gloss on lower throat and upper breast more limited to end of feathers (tending to form vague and sober spangles); wing-linings silvery brown (paler than upperwing), axillaries and underwing-coverts tipped white; tail long (153–167 mm), rather deeply forked (47–58 mm), outer pair pointed and strongly curved upwards, four inner rectrices becoming progressively shorter towards central pair; iris deep brown or blackish; bill and legs black. Female is similar to male, but a little smaller, with less deeply forked tail. Juvenile is browner and less glossed than adult, lacking frontal filament, has more white tips on axillaries and underwing-coverts, tail initially more square-ended. Race *dicruriformis* is similar to nominate but much larger, tail 150–182 mm, depth of fork 62–70 mm. Voice. Song a uniform series of repeated strophes of loud, jangling, syncopated groups of notes, first dull and clipped, last notes metallic and bell-like. Calls include loud, liquid "tseep" repeated monotonously for several minutes, and single, very short, hard, squeaky jangles; also a fast "shleeup", starting as harsh hissing buzz and finishing in short jangle. Jerks tail upwards slightly after each note.
Habitat. Evergreen and broadleaf tropical moist lowland forests and edges; open forest and scrub-jungle. In N of range, jungle immediately within belt of coconut palms (*Cocos nucifera*) surrounding coast.
Food and Feeding. Mainly winged insects, including ants (Formicidae). Prey caught mostly by aerial hawking. Frequently perches head upwards on vertical trunk, in manner of a woodpecker (Picidae), pressing tail against bark and ascending in flitting hops to take ants. Gregarious, in flocks of a dozen to 20 individuals; often forages with other species, including e.g. Asian Fairy-bluebird (*Irena puella*), White-headed Starling (*Sturnia erythropygia*), Bar-bellied Cuckoo-shrike (*Coracina striata*), Small Minivet (*Pericrocotus cinnamomeus*). Parties also often seen to follow groups of primates and catching large insects disturbed by them.
Breeding. Nests found from early Apr to mid-May. Nest a shallow cup or cradle composed of fine dry twigs firmly woven together, scantily lined with black hair-like rhizomorphs, bound to the support by spider webs; suspended 4·6–9 m above ground from forked twig of very large forest tree, generally a dry or leafless one, or, more rarely, of small tree standing in open forest or scrub-jungle. Clutch 2 or 3 eggs, very variable (at least half a dozen types), commonest having pale salmon-pink ground colour spotted all over with pale brownish and some underlying spots of pale grey, other types white with purple-brown spots, streaks or speckles in zone at large end, average size 24·8 × 18·3 mm. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Andaman Islands EBA. Common. Although this species' habitat is relatively intact and it appears to be reasonably numerous throughout its range, it is potentially at risk owing to the small size of its global range and indications of increase in human pressure (increasing human population, cultivation, grazing, logging, development). Some evergreen and deciduous forests in Andamans are protected, e.g. Mount Harriet and Saddle Peak National Parks (covering c. 80 km²).
Bibliography. Ali & Ripley (1987a), Anon. (2008i), Butchart & Stattersfield (2004), Collar *et al.* (2001), Grimmett *et al.* (1998), Rasmussen & Anderton (2005a, 2005b), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stuart Baker (1924, 1933), Vaurie (1949).

5. Greater Racquet-tailed Drongo

Dicrurus paradiseus

French: Drongo à raquettes **German**: Flaggendrongo **Spanish**: Drongo de Raquetas Grande **Other common names**: Large Racquet-tailed Drongo; Northern Large Racquet-tailed Drongo (*grandis*); Southern Large Racquet-tailed Drongo (*paradiseus*); Ceylon Large Racquet-tailed Drongo (*ceylonicus*); Andaman Racquet-tailed Drongo (*otiosus*); Nicobar Racquet-tailed Drongo (*nicobariensis*)

Taxonomy. *Cuculus paradiseus* Linnaeus, 1766, Thailand.
In the past sometimes placed in genus *Dissemurus*. May form a superspecies with *D. lophorinus*; often treated as conspecific, but differs in tail morphology and probably in voice. Molecular-genetic studies required in order to elucidate true relationship between the two. Few intergrades between Sri Lanka race *ceylonicus* and *D. lophorinus* reported in past along border between wet and dry zones, but interbreeding not now possible, since suitable habitat no longer remains between the two ecological zones, now completely separated. Geographical variation based mainly on biometrics, but exhibits parallel clinal decrease in size from N to S in both W & E parts of range. Race *rangoonensis* intergrades with *grandis* in N and with nominate in S; birds from C & S India described as race *malabaricus*, but considered intermediates; *hypoballus* intergrades with nominate in N of its range and with *platurus* in S; proposed race *adelphus* (from Nias I), described on basis solely of difference in wing measurements, synonymized with *platurus*; island races (including those in Borneo) very similar to one another. Further studies would probably lead to reduction in number of accepted races. Thirteen subspecies currently recognized.
Subspecies and Distribution.
D. p. grandis (Gould, 1836) – S foothills of Himalayas from N India (Kumaon) E to extreme N Assam, N Myanmar (S to N Chin Hills and N Shan States), S China (extreme SE Xizang, W & S Yunnan) and N Indochina.
D. p. rangoonensis (Gould, 1836) – C India, Bangladesh, C & S Myanmar (S Chin Hills, S Shan States S to N Tenasserim), N & NE Thailand, C Laos and C Vietnam.
D. p. paradiseus (Linnaeus, 1766) – S peninsular India, S Myanmar (Tenasserim and Mergui Archipelago), SW, C & SE Thailand and S Indochina.
D. p. ceylonicus Vaurie, 1949 – N, E & S Sri Lanka.
D. p. otiosus (Richmond, 1902) – Andaman Is.
D. p. nicobariensis (Stuart Baker, 1918) – Nicobar Is.
D. p. johni (E. J. O. Hartert 1902) – Hainan I (S China).
D. p. hypoballus (Oberholser, 1926) – Malay Peninsula (except S).
D. p. platurus Vieillot, 1817 – Peninsular Malaysia S of 4° N (including islands except Tioman I), Sumatra (including Simeulue, Banyak Is and Nias I), Riau Archipelago, Lingga Archipelago and Bangka I.
D. p. microlophus (Oberholser 1917) – islands in S China Sea (Tioman I, Anambas Is and N Natunas).
D. p. banguey (Chasen & Kloss, 1929) – Balambangan I and Banggi I, off N Borneo coast.
D. p. brachyphorus (Bonaparte, 1850) – Borneo, including Laut I (off SE coast).
D. p. formosus (Cabanis, 1851) – Java and Bali.

Descriptive notes. c. 30–65 cm (total length varying greatly, depending on tail length); three adults 74–85 g (nominate), three males 100–124 g (*grandis*), two adults 71–73 g (*ceylonicus*). A large, distinctive drongo characterized by presence of two wire-like twisted spatula-tipped streamers in tail (tip broadly webbed on inner side of shaft, very narrowly on outer side); generally a backward-curving tuft or crest on forehead, more or less developed. Nominate race is black with fairly strong metallic blue or greenish-blue gloss (except on quills, lower abdomen and flanks), breast spangles rather small and not sharply defined, trace of gloss on edges of crest feathers and on outer webs of primaries and rectrices; feathers around neck, when well developed, form glossy cape covering shoulders; elongated frontal feathers form backward-curling crest with mean length of 24 mm (longest feathers reaching to posterior part of crown); average length of central rectrix 138 mm, of outermost rectrix 393 mm, of tail-racquet 89 mm; iris blood-red; bill and legs black. Sexes similar. Immature is browner and less glossy than adult, with white fringes on feathers of abdomen and undertail-coverts and white tips of axillaries rather broad and abundant, tail shorter, racquets poorly developed, crest rudimentary, iris brown; subadult less glossy than adult, crest not so well developed, tail-racquet smaller and not so curly, narrow fringes of white on undertail-coverts and abdomen, axillaries tipped with white (this marking persisting, but spots much smaller and fewer, in otherwise perfectly adult birds). Races vary mainly in presence or absence of crest, shape of crest, length and shape of outer tail feathers, various other measurements, least variable being those of bill, wing and central tail feather (figures below are average measurements): *grandis*, with prominent cape, is largest in all average measurements, central rectrix 157 mm, outer rectrix 498 mm, tail-racquet 103 mm, crest 58 mm (frontal feathers longer and more erect than in S races and main feathers broader and longer, reaching nape or beyond); *rangoonensis* is smaller, with breast spangles large and sharply defined, pointed feathers at side of neck forming well-developed cape, central rectrix 146 mm, outer rectrix 400 mm, racquet 95 mm, very large crest 42·5 mm (reaching well beyond crown); *ceylonicus* is similar to nominate but smaller, with breast spangles less well defined and a shorter cape, central rectrix 133 mm, outer rectrix 268 mm, racquet 79 mm, shorter crest 22 mm (feathers reaching only top of crown), immature has outer rectrix almost fully webbed, subadult has shaft bare, with narrow fringe of barbs persisting on both sides, and straight; *otiosus* is large, identical to *rangoonensis* except for little or no crest, central rectrix 144 mm, outer rectrix 407 mm, racquet 98 mm, bill powerful and long; *nicobariensis* is very similar to nominate, from which distinguishable only by having smaller tail-racquet; *johni* differs from *grandis* and *rangoonensis* in having crest more upward-curving, softer, lacking hairy frontal plumes, and in having main feathers broader and less pointed, shoulder cape less prominent, central rectrix 144 mm, outer rectrix 415 mm, racquet 89 mm, crest 52 mm; *hypoballus* has glossy feathers of breast arranged into well-defined spangles, pointed feathers at side of neck forming short cape, frontal feathers forming short but well-developed crest, central rectrix 124 mm, outer rectrix 333 mm, racquet 74·5 mm, crest 16 mm; *platurus* is similar to previous, except that elongated frontal feathers mostly directed upwards, forming bushy tuft, more rarely a short crest sometimes curving backwards, but exceptionally a little larger in general measurements, with racquets a little less long and broad, central rectrix 126 mm, outer rectrix 350 mm, racquet 70·5 mm; *brachyphorus* is smallest of all races, central rectrix 116 mm, outer rectrix 301 mm, racquet 51·5 mm, lacks crest, has small bristly frontal plumes projecting forward over ridge of culmen, ill-defined spangles on breast (also, tendency for abnormal development of outer tail feathers, including lack of racquet, feather either shorter than or equal to rest of tail, or more or less fully webbed); *banguey* is very similar to previous, but with longer wing; *microlophus* is considerably larger than *brachyphorus* (but size variable, depending on island), a few frontal feathers showing tendency to point upwards and forming short bushy tuft (absent on many specimens), gloss on breast feathers restricted to tips and tending to form spangles; *formosus* is distinct from all other races in small size, rather short but developed crest curving backwards on to crown, long tail-racquets, central rectrix 128 mm, outer rectrix 343 mm, racquet 97 mm, crest 15 mm. Voice. Very noisy, with large variety of vocalizations, extremely long and diverse chatters, including mimicry; starts to call long before dawn, a monotonous "kit-kit-kit-kit-kit...", almost

Tablas Drongo (*Dicrurus menagei*); 10. Sulawesi Drongo (*Dicrurus montanus*); 11. Sumatran Drongo (*Dicrurus sumatranus*); 12. Wallacean Drongo (*Dicrurus densus*); 13. Balicassiao (*Dicrurus balicassius*); 14. Spangled Drongo (*Dicrurus bracteatus*); 15. Ribbon-tailed Drongo (*Dicrurus megarhynchus*).

continuously until sunrise, then producing large repertoire of loud calls and churrs or melodious bell-like notes and whistling. Typical song a loud jangling outburst repeating a few jerky staccato notes in regular pattern, with a clear strident note followed by nasal sound, the strophe starting and ending abruptly. Pairs perform duets; in SW India (Kerala; nominate race), one bird starts with sharp double rising note, answered with low-pitched whistle, and so on. Calls are long repetitive series of loud notes: in NE India (*grandis*), series of very short piping, rapidly repeated identical whistles, "vit-vit-vit"; in S India, resonant staccato, musical bell-like "clink, link, link"; in Kerala, call uttered fairly regularly after sunset and often in morning reported as "chooo-choóp, chooo-choóp, chooo-choóp"; in Borneo (*brachyphorus*), one creaky note followed by double fluty one, repeated twice at regular intervals, "crey-fulut". Able to mimic perfectly the calls or complete songs of wide variety of birds of different families: small raptors, koel (*Eudynamys*), Indian Cuckoo (*Cuculus micropterus*), woodpeckers (Picidae), hornbills (Bucerotidae), pitas (Pittidae), babblers (Timaliidae), thrushes (Turdidae), Old World orioles (Oriolidae), magpie-robin (*Copsychus*), even an introduced laughingthrush (*Garrulax*) in a Singapore parkland, the imitation produced promptly after original call and repeated after each; has been observed even to imitate perfectly the agitated behaviour of a Jungle Babbler (*Turdoides striata*); in captivity, may imitate song of a canary (*Serinus*), mewing of a cat, or two or three lines of a whistled song. In flight, long tail feathers produce characteristic humming noise, audible from long distance.

Habitat. Generally in humid broadleaf evergreen or deciduous lowland forests, to 800 m in Malay Peninsula, 1000 m in Myanmar and Thailand, 1400 m in China and 1500 m in India, but reported in the low S plains in Nepal. Also peatswamp-forest and mangroves, bamboo-jungle and teak (*Tectona*) stands, neglected overgrown rubber (*Hevea*) plantations, tall secondary growth in villages or suburban surroundings, plantations, timbered gardens, and orchards and parklands. Occasionally, appears in wooded patches or tall isolated trees in cultivation areas or open country. In Sri Lanka, race *ceylonicus* is found in low-country dry zone and in drier parts of hills, to 700 m. In areas where distribution overlaps with that of *D. remifer*, the two species tend to avoid each other (e.g. in Thailand and Malay Peninsula); in India, however, the two have been reported as present in same mixed flock.

Food and Feeding. Primarily insectivorous; some small vertebrates also taken. Nectar, e.g. of *Bombax ceiba*, *B. insigne* and *Erythrina*, an important complementary item. Grasshoppers and locusts (Acrididae), butterflies and moths (Lepidoptera), beetles (Coleoptera) and termites (Isoptera) form large proportion of diet; bees (Apidae) seem particularly favoured by race *grandis*. Crepuscular habits, hunting far into dusk, as well as during daytime. Hunts mainly in middle stratum or interior canopy. Feeds almost entirely on the wing, swooping from elevated lookout post, to which it returns after catching prey. Tree-frogs and small lizard seized on ground; larvae picked from tree trunks and branches in agile swoops and carried away in claws. In Peninsular Malaysia, attracted to insects on fruiting banyans (*Ficus*), and occasionally took small figs. Often a participant in mixed-species foraging flocks, e.g. with White-bellied Tree-Pie (*Dendrocitta leucogastra*), woodpeckers, monarch-flycatchers (Monarchidae) and leafbirds (*Chloropsis*) in Kerala; seems to benefit from arthropods disturbed by other animals, e.g. foraging woodpeckers in a Malaysian lowland rainforest, or crab-eating macaques (e.g. *Macacus fascicularis*), arboreal squirrels (Sciuridae), malkohas (*Phaenicophaeus*) and leafbirds as they move along branches. When in mixed-species flocks, present species plays important role in its vocal alarm calls against aerial predators. In India, pairs sometimes reported as associating with *D. remifer*, foraging side by side in mixed-species parties. Kleptoparasitism on laughingthrushes, mainly by single individuals accompanying mixed flocks, reported in C Myanmar; attacks initiated from low perch (1–2 m above ground) and delivered at birds foraging on ground for large prey (grasshoppers).

Breeding. Season mainly Apr–Jun/Jul in N Indian Subcontinent, Mar–Apr in Kerala (SW India), Apr–May in Andaman Is and Mar–May in Sri Lanka; Feb–Jul in Peninsular Malaysia, but mostly May in Thailand and from Mar to mid-Jun (even to Aug) in Myanmar; nest-building May in China; eggs Dec–May in Sumatra; breeding recorded Sept in Java. Apparently pairs for life. Seems to be attached to territory throughout year (in Kerala, c. 250 ha of well-wooded country); especially aggressive during nesting, when mobs and attacks large raptors, Great Hornbill (*Buceros bicornis*), other birds e.g. Large Frogmouth (*Batrachostomus auritus*) and even humans. Leaf-picking behaviour during courtship described. Nest built by both sexes, a small cradle of fine twigs, rootlets, grass stems or other vegetable fibres (e.g. broken leaves, moss or lichen), often so coarsely and thinly bound together with cobwebs that contents visible from below (nest of race *grandis* said to be "more or less like a transparent net"), for race *rangoonensis* external diameter 15 cm, depth 7·5 cm, interior dimensions 10 × 5 cm; hung in fork of horizontal branch, far from trunk and generally 5–15 m above ground, sometimes at 1·5 m (*grandis*), 2 m (*otiosus*) or up to 20 m (*ceylonicus*) or more (*rangoonensis*); in some areas, bases of leaf stalks of *Borassus* palm used as nest-site; nest tree in open bamboo-jungle, often a pinkado tree (*Xylia dolabriformis*), or in open meadow-like country, tea plantation, or on edge of road or rice paddy, very often a mango tree (*Mangifera indica*) in garden or outskirts of village, or rubber tree in Malaysia, and in Andamans race *otiosus* reported as nesting generally high up on more or less inaccessible branches of big tree, either in dense high forest or in very open forest; nesting sites used continuously over many years. Clutch usually 3 eggs, sometimes 4, but only 2 or 3 in S Myanmar (nominate race), ground colour white (rarely), pale pinkish-salmon or cream to warm pinkish-terracotta (the last not rare in N races), with large dark reddish to red-brown and purple blotches (more numerous at larger end) with secondary marking in pale grey or pinkish-grey, the same variety in all races; average size 27·8 × 20·2 mm (nominate), 27·6 x 20·3 mm (*rangoonensis*), 30·4 × 21·6 mm (*grandis*), 26·6 × 20·7 mm (*ceylonicus*); incubation of eggs and tending of chicks by both sexes, no information on duration of incubation and nestling periods; in Kerala, fledglings accompany parents closely and are fed by them with decreasing frequency and regularity for c. 5 months, although able to find food independently after less than 3 months, family bond apparently maintained until mid-Dec and young disperse by middle of Feb. Brood parasitism by Indian Cuckoo (*Cuculus micropterus*) reported.

Movements. Mainly resident; only a summer visitor in SW Yunnan (China). Vagrant in Uttar Pradesh (N India).

Status and Conservation. Not globally threatened. Regular and common in main parts of range; rare on Hainan. Found in many protected areas, e.g. Kazranga National Park (Assam), Peechi and Anamalai Wildlife Sanctuaries (S India), Khao Yai National Park (Thailand), Taman Negara National Park and Pasoh Forest Reserve (Peninsular Malaysia), Danum Valley Conservation area (N Borneo); on Hainan, endemic race *johni* is present in large mountainous Hainan EBA (13,000 km²), which is subject to severe natural habitat loss. Insular races which are well distributed and adaptable to man-modified habitats (e.g. *ceylonicus* in dry zone of Sri Lanka, where an important network of protected areas) seem not to be at any great risk. In contrast, races occurring only on small islands are directly threatened, as they have small populations in often largely disturbed habitat. Races *otiosus* and *nicobariensis* found only on, respectively, Andaman Is (6400 km²) and Nicobar Is (1800 km²); recent rapid settlement of these islands by people from Indian mainland (increasing agriculture and grazing, logging, coconut plantation), and proposal to create a free port and other facilities for international shipping on Great Nicobar (despite latter's status as Biosphere Reserve), place severe pressure on remaining natural forests and represent serious threats for endemic birds; few small protected areas in Andamans, e.g. Mt Harriet and Saddle Peak National Parks (covering 213 km²) and two new national parks (covering 536 km² of primary forest) in Nicobars. Race *microlophus*, present in N Natuna Is (covering 1750 km²) and other very small S China Sea island groups, appears threatened by loss of forest habitat, e.g. the large Pulau Natuna Forest IBA is unprotected.

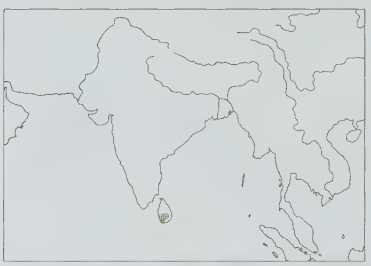
6. Sri Lanka Crested Drongo



Dicrurus lophorinus

French: Drongo drongup **German**: Regendrongo **Spanish**: Drongo Cingalés
Other common names: Ceylon Black-crested Drongo, Ceylon Crested (Black) Drongo

Taxonomy. *Dicrurus lophorinus* Vieillot, 1817, Sri Lanka.

Has in the past been placed in monospecific *Dissemurulus*, or in *Dissemuroides*. May form a superspecies with *D. paradiseus*; often treated as conspecific, but differs in tail morphology and probably in voice. Molecular-genetic studies required in order to elucidate taxonomic status. Few intergrades with race *ceylonicus* of *D. paradiseus* formerly reported along border between wet and dry zones, but interbreeding not now possible, since suitable habitat no longer remains between the two ecological zones, now completely separated. Monotypic.

Distribution. Wet zone of SW Sri Lanka: from R Deduru Oya (in N) S to R Walawe (in SW).

Descriptive notes. 31–34 cm, excluding tail; two adults 70 g. Black plumage has metallic blue or greenish-blue gloss, except on lower abdomen and flanks, and on spangled throat and upper breast; deep velvety black on forehead and frontal tuft, latter looking like a short, dense, rounded and stiff crest, longest feathers of which curve over forehead; axillaries and underwing-coverts tipped white; long tail (161–200 mm) deeply forked (50–75 mm), outer feathers with complete webs strongly curved upwards and inwards; iris dull brownish-red or brown; bill neatly hooked, black; legs black. Sexes alike. Juvenile is less glossy than adult, greyer on abdomen, with smaller crest, and larger white tips on axillaries and underwing-coverts. Voice. Very noisy, with large repertoire of metallic calls and rich melodious notes and whistles, including mimicry of other birds, e.g. mynas (Sturnidae). Song an explosive mixture of whistles, bell-like, fluty or sweet grinding notes and harsh scoldings, including short strophes (sometimes preceded by thin and very soft nasal "nyit") of rapidly alternating jangling, clear, silvery and musical notes or repeated soft nasal chatters reminiscent of sounds made by a bulbul (Pycnonotidae); harsh churring notes may alternate with soft ones, whereas other song types have few or no harsh clanging notes. Song possibly distinct from that of race *ceylonicus* of *D. paradiseus* in being higher-pitched, less raucous and less sibilant, at times less repetitive and more irregular in pattern. Calls include nasal and mechanical "urdle-eee" or quick "urd-lee", and succession of loud disyllabic or single twanging notes.

Habitat. Tall, dense humid forests with ample undergrowth; common in lowlands and lower hills at 300–1200 m, but reported to 1700 m (Adam's Peak).

Food and Feeding. Insects. Hawks insects in air, swooping down on them, often from perch on high looping liana. Very sociable; several pairs often forage together and with other forest birds.

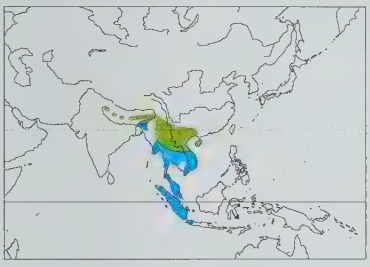
Breeding. Season Mar–May, mostly Apr. Nest a flimsy cup or shallow cradle made of roughly bound grass, roots or other vegetable fibres, rather small for the size of the bird, built mostly c. 6–7·5 m above ground in tall tree, generally at fork on outside of tree but recorded also among leaves near trunk, usually inside forest but perhaps sometimes at border of field; very like nest of race *ceylonicus* of *D. paradiseus*, but looking more untidy and not so well bound together with coweb. Clutch 2–4 eggs, generally 3, almost white (rare) to pale salmon-pink, often with tint of lilac or mauve, blotched and spotted reddish-brown with secondary markings of pale lavender, usually sparingly distributed over whole surface but rather more numerous on larger end, average 27·8 × 20·1 mm; very similar to eggs of race *ceylonicus* of *D. paradiseus*, but appear more heavily marked. No other information.

Movements. Resident.

Status and Conservation. Not assessed. Until recently treated as race of *D. paradiseus*; probably not globally threatened, but should be considered a Restricted-range species, present in SW part of Sri Lanka EBA. Over the past 40 years, Sri Lanka has suffered rapid deforestation as a result of expanding human population, leading to increased gathering of wood for fuel, and clearance for permanent agriculture, rubber (*Hevea*) plantations and settlements. Only 4·6% of original closed-canopy forest still preserved, but four important protected areas include largest remnants of lowland and montane rainforest in Sri Lanka's wet zone: Sinharaja National Heritage Wilderness Area, Peak Wilderness Sanctuary, Horton Plains National Park and Hakgala Strict Nature Reserve, totalling 320 km². Monitoring of the abundance and range of this species appears essential in order to rectify the current complete lack of information on its population, numbers and trend. Earlier reports of this taxon's presence in SW India (1933, Goa and Travancore) thought to be probably erroneous.

Bibliography. Ali (1969), Ali & Ripley (1987a), Anon. (2007a), Grimmett *et al.* (1995), Henry (1971), Rasmussen & Anderton (2005a, 2005b), Ripley (1981), Saha & Mukherjee (1981), Stattersfield *et al.* (1998), Stuart Baker (1924, 1933), Tweeddale (1878), Vaurie (1949).

7. Crow-billed Drongo



Dicrurus annectans

French: Drongo à gros bec **German**: Krähendrongo **Spanish**: Drongo Picogordo

Taxonomy. *Bhuchanga annectans* Hodgson, 1836, Nepal.

Earlier theory that this is a relatively ancient form, with close resemblance to *D. macrocercus*, not supported by recent DNA studies, which suggest comparatively recent separation from *D. paradiseus*. Monotypic.

Distribution. Breeds NE Indian Subcontinent (Himalayan foothills E from Uttarakhand), N & C Myanmar, S China (Yunnan, Guangxi, Hainan), N Thailand and N & C Indochina. Non-breeding far NE India, Bangladesh, probably S China, and S SE Asia S to Sumatra and W Java.

Descriptive notes. 27–29 cm; 44–68 g. Stout drongo having thick bill with equal width and depth at nostril level, covered at base by dense short feathers (partially concealing nostrils); tail flared and shallowly forked, outer feathers curving slightly outwards. Frontal band, lores and ear-coverts are dull black, rest of head, most of body and wing-coverts black, glossed steel-blue (contrast between glossy edge parts and matt base of feathers on head, breast and upper back characteristic); upper flanks iron-grey, some of the underwing-coverts and axillaries spotted with white at tips; tail fairly long (116–133 mm) and forked (depth of fork 17–26 mm); iris blood-red; bill and legs black. Differs from very similar *D. macrocercus* in being more glossy (blue, rather than greenish), with shorter tail less deeply forked, and deeper bill. Sexes similar, male a little larger than female. Juvenile is uniformly brownish-black, iris hazel or deep brown; first-winter has white spotting on breast, belly and undertail-coverts, and less pronounced tail fork than adult. Voice. Songs include loud musical whistles and churrs; characteristic descending series of harp-like notes or upslurs; short metallic trills and low-pitched whistles. Duet by pair in Bhutan consists of one bird (presumably female) singing monotonous and continuous low-pitched rhythmic series of 4 notes, "tu-tugudu", while partner produces short song of 3–4 melodious high-pitched fluty notes (final note stressed and protracted), "wet-wet-wet teeer". In Thailand, a varied chatter includes mix of irregular dissonant notes, nasal whistles and very diverse grinding calls. Varied sweet, melodious and plaintive "fuweeeit" "fuweeeyu" calls mixed with harsh "sqrsh".

Habitat. For breeding prefers dense broadleaf evergreen forest, moist deciduous forest or edge of forest, occasionally more or less open country; from plains into foothills, to 800 m (occasionally higher) in India, preferentially in lowlands in Nepal, to 1450 m in Bhutan. On migration and in winter found in wooded habitat, including closed forest, tree plantations, wooded gardens, secondary growth, coastal shrubs, mangroves, in lowlands and hills to 1100 m; in Malay Peninsula, migrants recorded at up to 1200 m but winter visitors generally not above 600 m.

Food and Feeding. Feeds principally on insects, including ants (Formicidae) and termites (Isoptera). Still-hunts from shaded perch, capturing prey at ground level in open areas, in clearings and along forest paths. Takes aerial insects by sallying from hidden perch or, less often, by more prolonged hawking. Generally singly or in pairs; joins mixed-species groups foraging at large swarms of flying ants and termites.

Breeding. Apr–May, but to the end of Jun for some birds. Nest built by both sexes, in c. 5 days, a very small, shallow cup of grasses, rootlets and fibres, bound with cobweb, very strong and firmly fixed on supporting branch, average external diameter 12 cm, depth 5 cm, internal diameter 6–8 cm, depth c. 2–3 cm, placed 7–12 m above ground (exceptionally lower) and rather inaccessible in horizontal fork at end of tree branch, generally not far from edge of dense forest or by path. Clutch 3–4 eggs, mainly pale cream (occasionally pure white) or buff, more rarely warm salmon, streaked with red-brown or purple-brown, with underlying streaks of pale grey or lavender, markings more numerous and often more or less confluent at broad end (aberrant eggs reported, speckled or spotted), average size 26·3 × 19·4 mm; incubation by female; male remains nearby in calling distance, for defence of eggs and young; no information on duration of incubation and nestling periods.

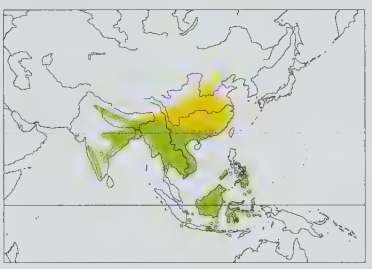
Movements. Migratory. Spends non-breeding period in E Bangladesh and adjacent NE India, and from S Myanmar and S Thailand S through Malay Peninsula (mainly on coasts and small islands, rarer inland, uncommon S to Singapore) and islands to Sumatra (rare) and Java (occasional in W coastal forest and mangroves). Passage Sept–Nov, and from early Mar (Malaysia) to May, but some individuals may stay longer in winter range, or even fail to migrate, as observed on Pukhet I (S Thailand) in mid-Jun. Resident on Hainan. Data for S China and Indochina lacking or contradictory. Vagrant in N Borneo and W Philippines (Sulu Archipelago).

Status and Conservation. Not globally threatened. Uncommon and local throughout range; somewhat more common in Bhutan. Appears very dependent on natural forests for breeding, and could be adversely affected by man-induced habitat changes. Considered a common migrant and common winter visitor in Malay Peninsula in middle of 20th century; now given as locally "Near-threatened", almost "Vulnerable", in Peninsular Malaysia on account of mid-winter importance of decreasing closed-canopy lowland forest, the species being unable to thrive in tree plantations with little understorey.

Bibliography. Ali & Ripley (1987a), Chen Fuguan *et al.* (1998), Chong Lillian Tsin (1932), Dickinson *et al.* (1991), Glenister (1951), Grimmett *et al.* (1998), Harrison (1962), King *et al.* (1975), Medway & Wells (1976), Meyer de Schauensee (1984), Parkers (1960), Rasmussen & Anderton (2005a, 2005b), Strange (2000), Stuart Baker (1924, 1933), Vaurie (1949), Wells (2007), Wildash (1968).

8. Hair-crested Drongo

Dicrurus hottentottus



French: Drongo à crinière **German**: Haarbuschdrongo **Spanish**: Drongo Crestudo

Taxonomy. *Corvus hottentottus* Linnaeus, 1766, Cape of Good Hope; error = Chandernagor [Chandannagar], West Bengal, India.

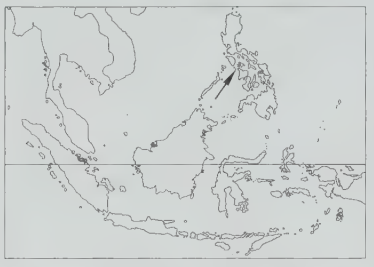
Formerly considered conspecific with *D. menagei*, *D. sumatranus*, *D. densus* and *D. bracteatus*; DNA studies have indicated close taxonomic relationship of present species with *D. balicassius*, *D. bracteatus* and *D. megarhynchus*, and all of these, together with *D. montanus* and the aforementioned species, could be part of a superspecies containing eight species. Two Philippine races, *striatus* and *samarensis*, included within present species although having some similarity also to neighbouring *D. balicassius* (tail shallowly forked, outer rectrices flat, iris brown), are placed by some authors in *D. bracteatus* (despite absence of some specific characteristics of latter); inclusion within present species (or *D. bracteatus*) could be argued on basis of velvety black mantle (*D. balicassius* has whole upperside, including tail, very strongly glossed), but, on other hand, both races lack some other characters specific to present species (i.e. frontal hair-like filaments, large tail with end of outer feathers twisting inwards and outwards). Further taxonomic research essential in order to clarify true relationships among all of these species. Race *banggaiensis* sometimes synonymized with *pectoralis*, and in the past with *leucops*. Clinal decrease in size from N to S, birds in C India being similar to those of Myanmar and Thailand, intermediate between those of Himalayan foothills and those of S India (extreme length of male tail 149–164 mm in Himalayas, 132–155 mm in C India, 114–128 in SW India). Nominate race intergrades with *brevirostris* from S China (W Yunnan) and N Myanmar E to N Vietnam. Proposed race *chrishna* (described from Nepal foothills), allegedly larger than specimens from C & S India, is regarded as not distinguishable from nominate; *termeuleni* (Thousand Is, in Jakarta Bay, in W Java) considered inseparable from *jentincki*, but insufficient evidence available, and further study required. Race *banggaiensis* has sometimes been merged with *leucops* or *pectoralis*. Fourteen subspecies currently recognized.

Subspecies and Distribution.

D. h. hottentottus (Linnaeus, 1766) – peninsular India (Western Ghats; West Bengal and Orissa S through Eastern Ghats to N Tamil Nadu), and Himalayan foothills from E Punjab and Himachal Pradesh E to Bangladesh and NE India (Arunachal Pradesh, S Assam hills), N & C Myanmar (S to Tenasserim), N Thailand, S China (SE Xizang, W Yunnan), Cambodia, S Laos and S Vietnam.
D. h. brevirostris (Cabanis, 1851) – breeds C & S China (S from Shaanxi, S Shanxi and Jiangsu), N Myanmar, N Laos and N & C Vietnam; non-breeding throughout Indochina, Thailand and lower Myanmar.
D. h. palawanensis Tweeddale, 1878 – W Philippines (Palawan).
D. h. cuyensis (McGregor, 1903) – WC Philippines (Semirara, Cuyo).
D. h. samarensis Vaurie, 1947 – EC Philippines (Samar, Biliran, Leyte, Calicoan, Panaon, Bohol).
D. h. striatus Tweeddale, 1877 – S Philippines (Basilan, Mindanao, Nipa).
D. h. suluensis E. J. O. Hartert, 1902 – SW Sulu Archipelago (Tawitawi, Simunul and Sibutu), in SW Philippines, and Maratua I (off E Borneo).
D. h. borneensis (Sharpe, 1879) – Borneo.
D. h. leucops Wallace, 1865 – mainland Sulawesi and surrounding archipelagos to NE, SE & S; Matasiri I (in Java Sea).
D. h. banggaiensis Vaurie, 1952 – Banggai Is, off E Sulawesi.
D. h. pectoralis Wallace, 1863 – Sula Is (WC Moluccas).
D. h. guillemardi (Salvadori, 1890) – Obi (C Moluccas).
D. h. faberi Hoogerwerf, 1962 – Panaitan (Prinsen) I and islands in Jakarta Bay, in W Java.
D. h. jentincki (Vorderman, 1893) – E Java, Bali, and islands in Java Sea (Masalembu Besar and Kangean Is).

Descriptive notes. c. 32 cm (nominate), 28 cm (*brevirostris*), 25·5 cm (*borneensis*), 26–32 cm (*leucops*), 24 cm (*palawanensis*); four males 86–102 g and two 2 females 76 g and 90 g (India). Nominate race has long hair-like feathers (83 mm) springing from forehead, extending over hindcrown and upper back; plumage black, very brightly glossed metallic blue-green, with numerous breast spangles and broad and very large, long and glossy neck hackles, contrasting with velvety-black mantle; wing-coverts and rectrices brightly glossed, inclining to bronze-green; lores, frontal feathers and underparts velvety black, unglossed; distinctive tail nearly square-ended, inner four pairs of rectrices ending almost at same level as outer pair, latter a little longer, spiralling and twisted inwards and upwards; iris reddish-brown or dark brown; bill noticeably pointed and downcurved, not hooked at tip, dark grey to black; legs black. Female is like male, but duller, less velvety. Juvenile is browner and less glossed than adult, with shorter frontal filaments, shorter hackle feathers of breast and neck, and axillaries and underwing-coverts tipped with white. Race *brevirostris* is similar to nominate but has shorter bill slightly curved and with very small hook, tends to have proximal part of frontal filaments partially and finely barbed (rather than mostly bare), tail a little less forked, and gloss more green than blue (especially on rectrices); *faberi* is smaller than nominate (tail 115–127 mm), deeper black above and below, wings metallic green, iris creamy white; *jentincki* resembles previous, but tail longer (122–143 mm), plumage less deep black, metallic hue less intense and more greenish; *borneensis* looks blue in general colour, with strongly purplish-blue gloss, is smaller than preceding two (tail 110–117 mm), with large spangles and rather short frontal filaments (44 mm) always present, bill small and rather strong, iris scarlet to pale red-brown; *guillemardi* is large (tail 146–150 mm), plumage blue-black, has well-developed long, broad and very well-glossed neck hackles, short frontal feathers, hair-like filaments of medium length (average 46 mm) present in half of specimens, iris brown; *pectoralis* is like last but smaller (tail 120–133 mm), has longer, broader and more glossy hackles, brilliant metallic bluish-green wings, frontal filaments lacking in half of specimens, iris red; *banggaiensis* is bluish, similar to *guillemardi* but somewhat smaller, has frontal filaments present in smaller proportion of specimens, differs from previous race in being larger and in having brown (not red) iris; *leucops* is very similar to *guillemardi* but has white iris, frontal filaments shorter (10–36 mm) and present in smaller number of specimens, bill small, strong, barely hooked; *suluensis* has red iris, is similar in size and colour to *pectoralis*, but differs in more deeply forked tail and in having frontal filaments always present; *palawanensis* has red iris, but differs from *borneensis* in having four inner pairs of rectrices becoming gradually longer, tips of outermost with very slight tendency to curl upwards, no frontal filaments, general coloration brownish-black with gloss greenish (instead of bluish), hackles and breast spangles considerably fewer and smaller, some specimens larger (26·5–29 cm) than average; *cuyensis* is similar to previous, with gloss strongly greenish, but larger and glossier, the hackles and breast spangles large and abundant (as in *borneensis*), glossy reflections spreading irregularly from hindneck onto mantle, iris dark reddish-brown to dark brown; *samarensis* has tail very short, straight and square-ended, plumage greenish blue-black with brilliant gloss on wings and tail, velvety mantle, very short neck hackles, abundant and sharply defined spangles on throat and upper breast, no frontal filaments, but peculiar feathering at base of bill, iris dark reddish-brown to dark brown; *striatus* is like last, but tail a little longer and slightly forked. Voice. Especially noisy in breeding season. Very variable. Songs start with mostly loud, harsh, incisive "tchip" notes or jarring nasal buzzes, becoming melodious bell-like or jangling notes at different pitches and tempo; composition of strophes extremely varied, loud metallic notes including harsh chattering and scolding, raspy and screeching sounds, whining "beep" notes. Calls include typical disyllabic "tsit-weet", second note upslurred and mellower than first, repeated after short pause; in Borneo (*borneensis*), loud "tsit-wit" sometimes followed by lower "wuu"; other calls are loud hard incisive "tchip" in slow and irregular series, and subdued clanging notes constantly uttered; another type is a double "creaking gate" call; nominate race in India gives short repetitive series of 2 or 3 notes of different pitch, alternating with scratchy sound; mimics calls of many other bird species. Race *samarensis* (Bohol, in Philippines) seems to have much more melodious calls and song, with fluty and liquid whistled notes and few or no creaky sounds, given in rhythmic and repetitive fashion; *leucops* produces long, plaintive and melodious downslurred whistle. Has noisy flight.

Habitat. Essentially a forest-dweller. Inhabits mostly broadleaf evergreen and moist deciduous forest, secondary growth, thick scrub and small tree-jungle, and less often bamboo forest in India; bamboo-jungle and pine (*Pinus*) forest in China; monsoon forest on islands in E of range. Sometimes found in parks and gardens on migration. Occurs from lowlands to 1400 m in India, occasionally to 2000 m in Himalayas; below 1050 m in Nepal, 250–1850 m in Bhutan; up to 1000 m in hilly parts of China; below 1500 m in Philippines and 1700 m in Sulawesi; in Borneo, recorded



mainly at lower montane elevations to 1500 m in Kalimantan; occasionally recorded at c. 2400 m in SE Asia. In hilly forest areas of India, breeds nearly always near bottom of deep valleys. Prefers open parts of forest, clearings and forest edge; found also in lightly wooded areas in Vietnam.
Food and Feeding. Food mainly insects and nectar, in variable proportions. Large variety of insects captured, including hornets and wasps (Hymenoptera), ants (Formicidae), locusts and crickets (Orthoptera), cicadas (Cicadidae), beetles (Coleoptera, including scarabaeids) and other large prey. Nectar reported as important source of food in Indian Subcontinent, but insects possibly the primary target as flowers with thick sweet nectar, e.g. those of cotton tree (*Bombax ceiba*), attract myriads of insects, which easily caught by insectivorous birds. In E China, Borneo and Java, has been reported as feeding on emerging termites (Isoptera) and other ground insects, and on small lizards. Generally hawks insects from a perch, capturing them on the wing, often returning to same perch; sometimes follows monkeys or squirrels (Sciuridae) to catch insects disturbed by them. Forages also by searching leaves, tree trunks, and flowering forest trees in full bloom, using the long and tapered bill to reach into flowers, particularly kapok (*Ceiba pentandra*), *Butea monosperma*, *Chorisia speciosa*, *Delonix regia*, *Bombax*, *Erythrina indica*, *E. stricta*, *E. lithosperma*, *Acrocarpus*, introduced eucalypts (*Eucalyptus*) in India, and *Bombax ceiba* in Myanmar. In N Sulawesi, race *leucops* reported as taking insects from tree trunks in manner of a woodpecker (Picidae). Forehead and throat often coated with pollen, indicating that this species is promoter of cross-fertilization; reported as eating pollen in China. Forages singly and in small parties; occasionally gathers to mob predator or to feed in grove of flowering trees.
Breeding. Season poorly documented: Apr to late Jun in N Indian Subcontinent, Feb–Apr in S India, Apr–Jul in SE Asia (late Mar to May in Myanmar); laying May and early Jun and young fledglings in latter half of Jun in E China; nests with eggs found mid-Mar and mid-May in Borneo; birds in breeding condition Feb–May in Philippines; reported as single-brooded in Hong Kong. During breeding period, very noisy and very aggressive towards any cause of disturbance. Nest built by both sexes, seemingly taking equal parts, a deep saucer of grass, rootlets, tendrils of creepers, base so flimsy than contents usually visible from below, but structure strong enough to prevent young from falling through, varying in size from 20–23 cm in diameter externally and 10–11 cm internally (recorded in Nepal) to very small, c. 9 cm across (4 cm internally), and typical measurements in India c. 15–18 cm broad and 4–6 cm deep externally, and 9–10 cm broad and 3·8–4·4 cm deep internally; suspended in horizontal fork, usually at end of small branch, occasionally built at base of leaf fronds in crown of palm, on upper surface of bough, or (in China) slung on two or three sprays of bamboo near top of plant, and sited usually 5–8 m above ground, sometimes much higher or, conversely, lower (reachable by hand from ground), or sometimes placed in relatively small tree standing in open forest or mixed jungle of bamboo and trees, in India occasionally in jungle-covered ravine running through tea-growing land, in S Myanmar (Tenasserim) mainly at very end of thinnest branches of teak (*Tectona*), thingan (*Hopea odorata*) or other trees, in Assam several nests within short distance of large flowering cotton tree situated well inside forest; in study in mixed forest in China, height of nest above ground 2·2–14·2 m, length of branch 1·4–9 m, distance of nest from main branch 1–8 m (main factors in nest-site selection were short distance to mountain ridge, to water, to edge of wood or to trail, good presence of tall trees, low density of shrubs and herbage). Clutch 3–4 eggs, rarely 2 or 5, varying greatly in colour, from pure white to deep salmon (most commonly pale cream), and in markings, from being covered with longitudinal blotches of rather pale reddish-brown, lilac or purple-red, also sparsely with deep purple freckles (more numerous at larger end) to having pale red specks almost invisible and secondary markings absent or lavender-grey; average size (nominate race) 29·2 × 21·2 mm; incubation by female, rarely assisted by male, both sexes tend chicks, no information on duration of incubation and nestling periods.
Movements. Generally resident, except in N part of range. Most Chinese breeders (race *brevirostris*) migrate mainly to Indochina, Thailand and S Myanmar, wintering at higher altitudes than areas occupied by resident nominate race; occasional in winter in C China and regular in S China, small numbers wintering in Hong Kong, where a common summer visitor and passage migrant mid-Apr to mid-May and during late Sept, when individuals and small groups appear at sites where species not known to breed. In N India, S Himalayan range or S China, nominate race subject to seasonal movements depending on nectar supplies; vagrant in winter in W India (Kutch, in W Gujarat). Vagrants occasionally reported in e.g. SE Russia (S Ussuriland), Korea, Japan, Taiwan.
Status and Conservation. Not globally threatened. Fairly common in Nepal and Bhutan, locally common in Himalayan foothills in India, also in Bangladesh; uncommon in Indian peninsula in Western Ghats and Kerala, rarely reported in Tamil Nadu. Very common in summer in hilly parts of China, rare in lowlands; locally common in SE Asia (rare and local in Cambodia in 1950s). Common in forest areas of Philippines and Borneo; recorded in Kinabalu and Crocker Range Parks, in N Borneo. Quite common in lowland and secondary forests of Java, especially in drier E parts, and in Bali. Most of the island races may be considered as having restricted range and are mainly confined to Endemic Birds Areas (EBAs): *guillemardi* on small extreme S island of Northern Maluku EBA (total area 27,000 km²), *banggaiensis* and *pectoralis* on islands of Banggai and Sula Islands EBA (7200 km²), *suluensis* on Maratua I and in Sulu Archipelago EBA (1500 km²), *palawensis* in Palawan EBA (14,000 km²), *samarensis* on N islands of Mindanao and the Eastern Visayas EBA (120,000 km²), *striatus* on main island of latter EBA, and *leucops* in two EBAs (Sangihe and Sulawesi); races *cuyensis* (on Semirara, 55 km², and Cuyo, 130 km²) and *faberi* occur in other very small islands, but not linked to any EBA. All these mainly deforested islands are still subject to rapid degradation of this species' remaining natural habitat as a result of logging concessions (e.g. Sula, Mindanao) as much as illegal or domestic logging, massive human encroachment, industrial timber production, easy road access to protected areas (e.g. to Mount Apo National Park, on Mindanao, for construction of a geothermal power station), mine exploitation (coal on Semirara, gold in E Mindanao) and other human factors. Protected areas cover only a small part of some of these rainforest habitats, in Philippines e.g. a network of Environmentally Critical Areas is established on Palawan (the most deforested island in Philippines) and Rajah Sikatuna National Park on Bohol (race *samarensis* recorded). On Sulawesi, several protected areas under threat from illegal logging and mining include Lore Lindu Biosphere Reserve (race *leucops*), where research and eco-development programmes, as well as programmes to increase public awareness, have been set up.

9. Tablas Drongo

Dicrurus menagei

French: Drongo de Tablas **German**: Tablasdrongo **Spanish**: Drongo de Tablas

Taxonomy. *Chibia menagei* Bourns and Worcester, 1894, Badajos, Tablas Island, Philippines.
Has in the past been placed in a monospecific genus, *Dicrachibia*. Until recently was normally treated as conspecific with *D. hottentottus*; the two may form a superspecies with *D. montanus*, *D. sumatranus*, *D. densus*, *D. balicassius*, *D. bracteatus* and *D. megarhynchus*. Monotypic.
Distribution. Tablas I, in WC Philippines.

Descriptive notes. 35·5 cm. Distinctive drongo with very long (164–192 mm) and very deeply forked (70 mm) tail, elongated outer rectrices curving rather widely outwards and slightly upwards; when perched on branch, may remain in horizontal position, with tail hanging vertically down. General colour of plumage is dull black with purple tinge, velvety (rather than glossy); has small neck hackles, short scanty breast spangles; iris dark brown; bill and legs black. Differs from *D. hottentottus* mainly in tail shape and length. Sexes similar, female little smaller than male. Juvenile has brownish-black head and underparts, iridescent blue-black back and wings, tail splayed at end. Voice. Poorly known; seems not to be very vocal (unlike both *D. hottentottus* and *D. balicassius*), and vocalizations appear to be distinct from those of nearby race *palawanensis* of *D. hottentottus*. A typical call, lasting c. 1 second, a rasping sound like that of a cicada (Cicadidae), uttered irregularly at intervals of 2–10 seconds; another typical rasping, "dzak-tsee-ik", in duet occasionally answered with short "jieeh" call. Also "tsee-ik" call, sometimes accompanied by opening and closing of tail in scissor fashion. Appears not to act as flock sentinel.
Habitat. Relatively mature, closed-canopy forest; occasional records at edge of clearings, none in open areas. Recorded in mid-canopy of tall trees, often near stream.
Food and Feeding. Insectivorous. Hawks insects in air, also searches among leaves and on trunks; forages mostly in manner of *D. hottentottus*, but was never found to feed at flowering trees during recent observations. Small groups observed while foraging in vine tangles in manner of coucal (Cuculidae), searching for insects in dead leaves. Observed to hold dead leaf with one foot while hanging on to vine with other foot, and stripping out insects with its bill.
Breeding. Nest a small cup made of thin twigs and diverse vegetable fibres, coarsely woven, in form of three-quarters of a sphere (neatly deeper than typical drongo nest), suspended from slender branches among foliage in outer part of tall tree, high above stream. No other information available.
Movements. Resident.
Status and Conservation. Not assessed. Until recently treated as a race of *D. hottentottus*; probably globally threatened. Rare. Had apparently not been reported for many decades before observations in 1998–2002; in 1997, was considered probably already extinct. Believed to merit listing as Endangered or even Critically Endangered. Conservation concern justified by extreme degradation of forest habitat on an island of only 686 km². A "well-wooded" island at beginning of 20th century, Tablas is now almost completely devoted to agricultural activities and livestock-rearing, with rice fields in lowland areas and rough pasture or coconut (*Cocos nucifera*) plantations in hills; small-scale logging still a threat. A few forests remain, mainly in N, with largest areas around and between Mt Palaupau (585 m) and Mt Progreso (640 m), but remnants of original forest more than 10 m tall found only around summit and SE slopes of Mt Palaupau, and maintained as watershed protection for towns of San Agustin and Calatrava. Very few of the scattered forests officially registered cover more than 100 ha, and none in S seems to be mature. Additional surveys to estimate numbers and distribution of this species are required, as is protection of all of the remaining natural habitat on the island.
Bibliography. Allen (2006a, 2006b), Bourns & Worcester (1894), Collar (1997), Collar *et al.* (2001), Dickinson *et al.* (1991), Kennedy *et al.* (2000), duPont (1971), Vaurie (1949).

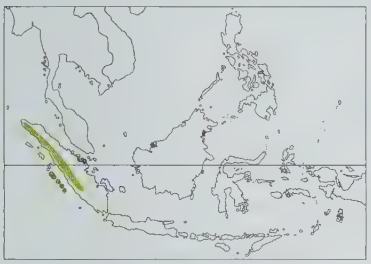
10. Sulawesi Drongo

Dicrurus montanus

French: Drongo des Célèbes **German**: Bergdrongo **Spanish**: Drongo de Célebes
Other common names: Celebes (Mountain) Drongo

Taxonomy. *Dicruropsis montana* Riley, 1919, Besoa, Taewo Mountains, north-central Sulawesi.
Formerly considered conspecific with *D. hottentottus*; the two may form a superspecies with *D. menagei*, *D. sumatranus*, *D. densus*, *D. balicassius*, *D. bracteatus* and *D. megarhynchus*. Differentiation of this small montane taxon may be the result of its retreat uphill in face of invasion by lowland race *leucops* of *D. hottentottus*, from which it differs completely; appears to be closely related to Halmahera race *atrocaeruleus* of *D. bracteatus* of neighbouring Moluccas, its possible origin. DNA studies required in order to clarify taxonomic position and relationships. Monotypic.
Distribution. Mountains of Sulawesi.

Descriptive notes. 25 cm; 38 g. General colour is strongly bluish-black with purple iridescence; mantle velvety black; short neck hackles, relatively small and narrow breast spangles; tail long (135–150 mm) and deeply forked (35 mm), tips of outer rectrices curving upwards; iris brown or dark brown-red; bill straight, black; legs black. Differs from similar *D. bracteatus* (of race *atrocaeruleus*) mainly in much smaller size; from *D. hottentottus* (of race *leucops*) in smaller size, especially smaller bill and feet, shorter, narrower and less glossy neck hackles and breast spangles, more deeply forked tail with tips of outer rectrices not curving so much. Sexes similar, female smaller than male but with longer tail. Juvenile apparently undescribed. Voice. Poorly known; duet songs include disyllabic or trisyllabic harsh grating "trrsh-trrsrh-trrrsh", answered with soft whistles e.g. low-pitched "twuu", or double descending "tee-twuu".
Habitat. Forest and woodland, from 550 m to 1800 m. Occasionally found in same localities as *D. hottentottus* (race *leucops*) in N peninsula, around limits of respective ranges, where the two are apparently reproductively isolated.
Food and Feeding. Insectivorous. Forages singly and in pairs; joins mixed-species flocks.
Breeding. No specific information available.
Movements. Resident.
Status and Conservation. Not globally threatened. Restricted-range species: present in Sulawesi EBA. Uncommon to locally fairly common. Confined to Sulawesi, where widely distributed through-



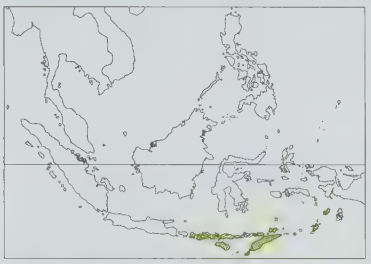
out most of the island. Population not evaluated, and no information available on a perceived decline; land clearance for settlements (mostly illegal) and sugar-cane plantation and unsustainable logging have led to deforestation, but principally in lowlands forests, particularly in S peninsula. In lowland rainforests ecoregion (500–1000 m; 116,000 km²), where 8% of area protected, illegal logging continues to be the biggest threat to integrity of remaining forests. In montane rainforests ecoregion (above 1000 m; 75,000 km²), situation appears relatively secure, principally in N & E, with 23% of area protected, e.g. Lore Lindu Biosphere Reserve, although extensive erosion on surrounding deforested slopes represents a threat, as do hunting and fires.
Bibliography. Anon. (2008i), Coates & Bishop (1997), Stattersfield *et al.* (1998), Stresemann & Heinrich (1940b), Vaurie (1949), White & Bruce (1986), Wikramanayake *et al.* (2001).

11. Sumatran Drongo

Dicrurus sumatranus

French: Drongo de Sumatra **German**: Sumatradrongo **Spanish**: Drongo de Sumatra

Taxonomy. *Dicrurus sumatranus* R. G. W. Ramsay, 1880, Ayer-Angat, Paio and Mount Sago, Sumatra.
Formerly considered conspecific with *D. hottentottus*; the two may form a superspecies with *D. menagei*, *D. montanus*, *D. densus*, *D. balicassius*, *D. bracteatus* and *D. megarhynchus*. DNA studies required in order to clarify taxonomic position and relationships. Two subspecies recognized.
Subspecies and Distribution.
D. s. sumatranus R. G. W. Ramsay, 1880 – highlands of Sumatra (Batak Highlands and Barisan Range, from Aceh S to Mt Kaba, in Bengkulu).
D. s. viridinitens (Salvadori, 1894) – Mentawai Is (Siberut, Sipura, N & S Pagai), off W Sumatra.



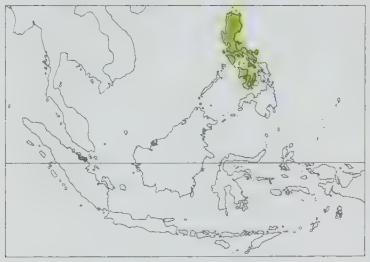
Descriptive notes. c. 29 cm. Distinctive drongo with tail nearly square-ended, outer rectrices straight or with very slight tendency to curve outwards; bill rather short. Male nominate race is black with deep ultramarine-blue gloss and purplish iridescence, mantle pure velvety black; small feathers at base of bill covering nearly two-thirds of length of bill; rictal bristles much exaggerated, projecting nearly as far as tip of bill; neck hackles narrow and well developed; tail 105–108 mm, depth of fork 7 mm; iris red; bill and legs black. Female is like male but smaller, although tail measurements similar to those of male. Juvenile undescribed. Race *viridinitens* is smaller than nominate, but with longer tail shallowly forked (average length 115 mm, depth of fork 9 mm), gloss strongly greenish, and lacks frontal filaments. Voice. Poorly known; includes melodious call of 3 whistled rapid notes, "tee-tiyeeah". One song a nasal disyllabic introduction followed by a series of 6–7 loud, clipped fluty trilled notes, final note separated.
Habitat. Submontane and lower montane dry primary forest or tall secondary forest, and forest edge, up to 800 m and possibly 1500 m, especially hill dipterocarp and lower montane forest; reported also at sea-level (e.g. Way Kambas National Park), but more abundant at middle altitudes. May occupy part of the niche normally filled by woodpeckers (Picidae) where latter absent or uncommon.
Food and Feeding. Insectivorous. Sallies from perch, hawks insects in air. Searches trunks and among leaves. On W islands (race *viridinitens*), small parties often seen to follow groups of primates, catching large insects disturbed by the mammals; frequently observed when perched, head up, on vertical trunk of tree (e.g. *Sterculia macrophylla* on Siberut I), tail pressed against bark in manner of woodpecker, and ascending in flitting hops to take ants (of genus *Iridomyrmex*); individual drongos can maintain this upright position for as long as 30 seconds. A fairly common member of mixed-species foraging flocks.
Breeding. Individual seen in early Apr while feeding two nestlings in tree beside river in lowland forest. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Sumatra and Peninsular Malaysia EBA. Fairly widespread, and locally relatively common. Nominate race fairly common at middle elevations within lower area of mountains; very common in Mamas Valley, in S Aceh. Race *viridinitens* frequent in all habitats, but restricted to a few small islands covering total of 6500 km²; W half of Siberut has been a national park (1900 km²) since 1993, but not well protected after new logging permit granted in 2001 for an area of 500 km², while remaining forest continues to be subject to large-scale logging activities. Nominate race may be adversely affected by habitat degradation and extensive loss of lowland forests to agriculture and logging; its apparent tolerance of secondary and logged forests, however, suggests only moderate decline. At end of 1990s, there were 20 protected areas in Barisan Range, the more important for montane-forest conservation being Gunung Leuser, Kerinci-Seblat and Bukit Barisan Selatan National Parks (constituting the Tropical Rainforest Heritage of Sumatra, c. 26,000 km²). This species' total population is undoubtedly smaller and its range more fragmented than in the past. More data on numbers and trends required.
Bibliography. Anon. (2008i), Butchart & Stattersfield (2004), Collar *et al.* (2001), van Marle & Voous (1988), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Vaurie (1949), White & Bruce (1986), Whitten (1982).

12. Wallacean Drongo

Dicrurus densus

French: Drongo de la Sonde **German**: Wallacedrongo **Spanish**: Drongo de Wallacea
Other common names: Greater Wallacean Drongo (*densus*)

Taxonomy. *Dicrourus* [sic] *densus* Bonaparte, 1850, Timor.
Formerly considered conspecific with *D. hottentottus*; the two may form a superspecies with *D. menagei*, *D. montanus*, *D. sumatranus*, *D. balicassius*, *D. bracteatus* and *D. megarhynchus*. Taxonomy of drongos inhabitating Lesser Sundas requires more detailed studies, both of molecular genetics and of vocalizations. Apparently no direct connection between race *megalornis* of present species and race *amboiensis* of *D. bracteatus*, despite extreme proximity of Gorong Is (occupied by former) to E tip of Seram, in SE Moluccas (occupied by latter). Supposedly smaller race *renschi* (described from Sumbawa) treated as synonym of *bimaensis*, type locality of which also Sumbawa. Six subspecies recognized.
Subspecies and Distribution.
D. d. vicinus Rensch, 1928 – Lombok, in W Lesser Sundas.
D. d. bimaensis Wallace, 1864 – Sumbawa, Komodo, Rinca, Flores, Pantar, Alor and Gunungapi.
D. d. sumbae Rensch, 1931 – Sumba.
D. d. densus Bonaparte, 1850 – Roti, Timor, Wetar and Sermata.
D. d. kuehni E. J. O. Hartert, 1901 – Tanimbar Is, in extreme E Lesser Sundas.
D. d. megalornis G. R. Gray, 1858 – Gorong I, Watubela Is and Kai Is, in SE Moluccas.



Descriptive notes. 28–38 cm, 30·5 cm and 33 cm (two nominate), 27·6 (three *biamensis*). Nominate race has general coloration dull blue-black with greenish gloss, except on mantle, which entirely dull; long neck hackles; feathers at base of bill well developed and extending forwards over culmen; tail long and deeply forked (male 173–181 mm, average depth of fork 49 mm), with tips slightly upcurved; bill thick, heavy and highly arched, ending in strong downward curve; iris red; bill and legs black. Sexes similar, male larger than female. Juvenile has iris dark brown, not red. Races differ mainly in size, in glossiness and in bill size, W races generally smaller, glossier, less green, and smaller-billed than E ones: *vicinus* has smaller wing than nominate, considerably shorter tail (118–127 mm) scarcely forked (6–17 mm), shorter bill more compressed and not so arched, feathers at base rather long and curling far forward over culmen and nostril, general colour bluer, a little glossier, mantle velvety, ends of outer rectrices curving up; *bimaensis* is similar to previous but smaller, tail short (120–127 mm) and even less forked (average 11 mm), tips of outer rectrices more upcurled, particularly in small birds of Sumbawa (tail of which very short, 105–108 mm), feathers at base of bill slightly longer and curling farther forward, plumage bluer, with more velvety mantle; *sumbae* also is smaller than nominate (but not so much as preceding race), tail 136–151 mm, about half as deeply forked (20 mm), bill shorter and less arched, feathers at bill base a little smaller and with less tendency to curve forwards, neck hackles long and narrow, gloss stronger and bluish, with metallic reflections extending to mantle; *kuehni* differs from nominate in having longer wing, but shorter tail less deeply forked (average male 26 mm, female 23 mm), glossy feathers of crown extend farther back, glossy reflections spread from neck onto mantle, bill more highly arched and a little less compressed; *megalornis* is clearly larger, male tail 168–183 mm, also slightly forked (25 mm), similar to last race but with no (or very few) metallic reflections on mantle, bill longer, still heavier and thicker, but less arched, female distinctly smaller than male. Voice. Poorly known. On Sumba (race *sumbae*) a song consists of rather short phrases of chopped percussive notes, twittery and liquid, starting with harsh rapid "churr"; on Flores (*bimaensis*) song includes continuous repetitive high-pitched musical and liquid twittering, curiously resembling that of small passerine such as a finch (Fringillidae) or a lark (Alaudidae); on Timor (nominate) a series of scratchy corvid-like calls alternating with very high or low-pitched grinding notes.
Habitat. Humid forest and various wooded habitats, from tall primary forest to mangroves and disturbed areas; also along roadsides with large trees or nearby plantations, or more open areas such as savanna and cultivation (race *sumbae*), and margins of semi-evergreen forest and secondary woodland (*kuehni*). Sea-level to montane forests; to 1650 m on Flores.
Food and Feeding. Insectivorous. Perches under canopy, sallying from horizontal branch to seize insects. Forages singly and in pairs; on Sumba, occasionally in groups of up to ten individuals in flowering trees. Often seen near troupes of crab-eating macaques (*Macaca fascicularis*) on Sumba. In Tanimbar Is, not observed to associate with mixed-species flocks.
Breeding. A few data from Flores: one nest c. 10 m above ground; eggs in Oct–Dec, pinkish-cream with light brown marking, or pure white and sparsely marked with small black spots and larger pale violet-grey blotches, average 29·4 × 20·8 mm. No other information.
Movements. Resident.
Status and Conservation. Not globally threatened. Fairly common to common, and widespread. Some races confined to one or few islands of Lesser Sundas have restricted range, all of them included in Endemic Bird Areas (EBAs): nominate in Timor and Wetar EBA (34,000 km²); *sumbae* in Sumba EBA (11,000 km²); *vicinus*, on Lombok, and *bimaensis*, distributed from Sumbawa to Alor, both in Northern Nusa Tenggara EBA (39,000 km²); *kuehni*, in Tanimbar Is, in Banda Sea Islands EBA (7100 km²). All of these islands are subject to intense deforestation resulting mainly from shifting cultivation, grazing, burning, and gold-mining and copper-mining (Sumbawa). Total protected area is less than 10% of N chain of Lesser Sundas, and principally for important areas of montane forest, and this comprises Gunung Rinjani National Park (on Lombok), Tambora Selatan (on Sumbawa), Ruteng Nature Reserve (on Flores), Tuti Adagae Recreation Forest (on Alor). Only one reserve (Langgaliru Nature Reserve) protected on Sumba in 1998, and this island now covered in dry grassland and savanna woodland as a result of forest clearance and practice of burning. Monitoring of distribution and population trends is necessary for all of these insular forms.
Bibliography. Bishop & Brickle (1999), Coates & Bishop (1997), Linsley *et al.* (1999), Mees (2006), Stattersfield *et al.* (1998), Strange (2001), Vaurie (1949), White & Bruce (1986).

13. Balicassiao

Dicrurus balicassius

French: Drongo balicassio **German**: Philippinendrongo **Spanish**: Drongo Balicassio

Taxonomy. *Corvus balicassius* Linnaeus, 1766, Philippines.
Recent DNA studies indicate close relationship with *D. hottentottus*; both may be part of a superspecies that includes also *D. menagei*, *D. montanus*, *D. sumatranus*, *D. densus*, *D. bracteatus* and *D. megarhynchus*. Considered to be an early inhabitant of Philippine archipelago, not interbreeding with and well differentiated from representatives of related *D. hottentottus* present on W & S borders of its range. Nominate race intergrades with *abraensis* in NC Luzon (in region of Lingayen Gulf). Birds from Mindoro described as additional race, *mindorensis*, supposedly slightly larger and having metallic reflections of upper breast greenish-blue (instead of bluish-green), but comparison of specimens with a series of nominate allow complete integration in latter. Three subspecies recognized.
Subspecies and Distribution.
D. b. abraensis Vaurie, 1947 – N Philippines (N & C Luzon).
D. b. balicassius (Linnaeus, 1766) – N & C Philippines (C & S Luzon, Polillo, Lubang, Verde, Mindoro, Marinduque, Catanduanes).
D. b. mirabilis Walden & E. L. Layard, 1872 – WC Philippines (Ticao, Masbate, Panay, Guimaras, Negros, Bantayan, Cebu).

Descriptive notes. 26 cm; male 63·3–78·8 g, female 65–80 g. Frontal feathers and lores velvety black, otherwise whole of upperside black with strong metallic blue-green gloss, this extending over tail; feathers of crown, hindneck, throat and upper breast with gloss limited to tips and margins; feathers of side and back of neck lanceolate, forming short hackles. Nominate race has frontal feathers elongated and curved well forwards; belly black and glossy; flanks and rump silky-looking white or silvery grey (not normally visible), tips black and glossy; tail rather short (109·5–123 mm), shallowly forked (6·5–16·5 mm), outer rectrices flat and curving very slightly outwards; iris reddish dark brown; bill short and sharp, black; legs black. Sexes similar. Immature is similar to adult, but browner and less glossy. Race *abraensis* is duller than nominate otherwise rather similar, but a little larger, with heavier and larger bill, almost square-ended tail with average length greater for male (119 mm) than for female (114 mm) and depth of fork 4·2 mm, gloss more purplish, grey or white of flanks and rump more restricted, frontal feathers curved less far forwards; *mirabilis* is similar to nominate, except plumage from lower breast to undertail-coverts pure silky white in colour, flanks greyish, frontal feathers shorter, also slightly smaller than nominate but with longer bill, similar slightly forked tail (depth of fork male 7–15 mm, female 3–10 mm), male uncommonly slightly smaller than female (male wing 134–141 mm, female 135–143 mm; male tail 111–118·5 mm, female 109–122 mm). VOICE. Song a very pleasant mixture of clear whistled series interspersed with harsh notes and other sounds; on Luzon, nominate race recorded as singing in groups of 3–4 for long periods, as if engaged in competition, an extraordinary variety of repeated short phrases, including melodious whistles sometimes reminiscent of a turdid thrush or Old World warbler (Sylviidae), repeated nasal notes, chuckling and rolling sounds, plaintive calls, twangy or grinding notes (but no harsh squeaks, jumbles or grating tones). On Cebu, *mirabilis* produces very varied strophes of upslurred or downslurred warbling melodious whistles of contrasting tones, followed by succession of harsh sounds, including introductory "tchur-tchur-tcheeur", rapid cascade of 6–10 clipped "tcha-tcha-tcha-tcha-tcha-tcha", and final longer "tcheeur". Species often imitates other forest birds, e.g. Philippine Hawk-eagle (*Spizaetus philippensis*), Bar-bellied Cuckoo-shrike (*Coracina striata*), or other passerines.

Habitat. Subtropical or tropical moist lowland forest, to 1200 m. During study in Mt Isarog National Park (S Luzon), found to be common at 450 m, and noted only a few times at edge of forest near 900 m, but not at any higher elevation.

Food and Feeding. Few data. Catches insects and other prey by flying out from open perch, generally in understorey and canopy level. Often seen in pairs or small groups; very occasionally joins mixed-species flocks.

Breeding. Nest with eggs in Mar and birds with enlarged gonads Oct–Jul; probably breeds in all months of year. One nest found, an open globular cup, as deep as it was wide, made of brown rough plant fibres (stems and rootlets) with a little cobweb, 9 m above ground and coarsely wrapped around slender horizontal fork and a third larger branch; contained 3 eggs, visible through base of nest, and incubating adult (with head and tail overlapping cup) visible through roughly woven sides. No other information.

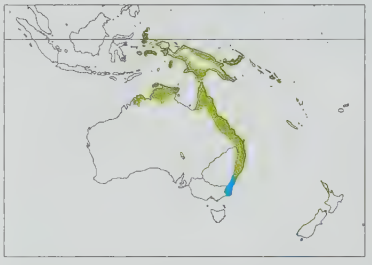
Movements. Resident.

Status and Conservation. Not globally threatened. Common. The three races are present in areas of major importance for biodiversity and conservation, especially *abraensis*, which is restricted to N part of Luzon EBA. Many islands within species' range are subject to rapid deforestation. On Luzon, the largest remaining primary lowland forest in Philippines (in Sierra Madre), reduced to only 6850 km² in 1990s (17% of the area forested in 1930s), is under logging concession; Mindoro, Negros and Panay almost completely deforested by 1988 (natural habitat remaining in, respectively, 8·5%, 4% and 8% of initial areas). Logging a primary threat throughout Philippines; other seriously adverse factors include growing of temperate or semi-temperate vegetables on bench terraces (in Cordillera Central, on Luzon), marble-mining and encroaching slash-and-burn cultivation (Mindoro), clearance of forest for subsistence agriculture, logging for domestic use (Negros and Panay), and spread of sugar plantations and urbanization (Cebu). Several protected areas cover main mountain ranges in Luzon, including foothills (e.g. Northern Sierra Madre, in N, Mt Makiling, in C, and Mt Isarog, in S), or only lowlands, e.g. Quezon National Park (at 300–420 m). On Cebu, one of the less forested islands of Philippines, race *mirabilis* has been recorded in Tabunan Forest, the last surviving fragment of forested habitat of Central Cebu National Park. On Negros, the protected status of Mount Canlaon National Park has not prevented total clearance of lower slopes.

Bibliography. Dickinson *et al.* (1991), Goodman & Gonzales (1990), Kennedy *et al.* (2000), McGregor (1909), Mearns (1909), Ocun (2006), Pasquet *et al.* (2007), duPont (1971), Stattersfield *et al.* (1998), Vaurie (1947, 1949).

14. **Spangled Drongo**

Dicrurus bracteatus



French: Drongo pailleté **German**: Glanzfleckdrongo **Spanish**: Drongo Escamoso

Taxonomy. *Dicrurus bracteatus* Gould, 1843, eastern and northern coasts of Australia.

Recent DNA studies indicate close relationship with *D. hottentottus*, with which formerly considered conspecific; both may be part of a superspecies that includes also *D. menagei*, *D. montanus*, *D. sumatranus*, *D. densus*, *D. balicassius* and *D. megarhynchus*. Some races, e.g. *buruensis* and *amboinensis*, which differ from others structurally and apparently also vocally, may represent separate species; further studies of vocalizations and DNA analysis required. Proposed island races *ultramontanus* (described from Aru Is) and, off SE New Guinea, *propinquus* (D'Entrecastaux Archipelago) and *dejectus* (Louisiade Archipelago) overlap so much in measurements and pattern with mainland *carbonarius* that all are synonymized with latter; likewise *manumeten* (described from Manusela, on Seram) is subsumed in *amboinensis*. Eleven subspecies currently recognized.

Subspecies and Distribution.

D. b. morotensis Vaurie, 1946 – Morotai, off N Halmahera (N Moluccas).
D. b. atrocaeruleus G. R. Gray, 1861 – Halmahera, Bacan, and West Papuan Is (Kofiau I).
D. b. buruensis E. J. O. Hartert, 1919 –Buru I, in SW Moluccas.
D. b. amboinensis G. R. Gray, 1861 – S Moluccas (Seram, Ambon, Haruku, Saparua).
D. b. carbonarius Bonaparte, 1850 – lowland New Guinea and satellite islands (including Boigu, Dauan and Saibai, in N Torres Strait), and Aru Is.
D. b. laemostictus P. L. Sclater, 1877 – S Bismarck Archipelago (Umboi and New Britain).
D. b. meeki Rothschild & E. J. O. Hartert, 1903 – S Solomon Is (Guadalcanal).
D. b. longirostris E. P. Ramsay, 1882 – S Solomon Is (San Cristobal).
D. b. baileyi Mathews, 1912 – NW Australia (N Kimberley Division, Bathurst I, Melville I, and N Arnhem Land).
D. b. atrabectus Schodde & Mason, 1999 – NE Australia (Cape York Peninsula and NE coast of Queensland S to Burdekin R); may migrate to Torres Strait and SC New Guinea.
D. bracteatus Gould, 1843 – coastal E Australia from Burdekin R area S in Queensland (inland to Great Divide) to NE New South Wales (rarely breeding S of 31° S); migrates to NE Australia, islands in Torres Strait and SC New Guinea.

Descriptive notes. Male 30–32 cm, average 88 g; female 28–30 cm, average 76 g; five *amboinensis* average 26·5 cm; *carbonarius* male average 84 g, female 79·5 g (both sexes average 72 g). Nominate race has whole plumage blackish, glossed with metallic green on crown, wing-coverts and outer webs of uppertail-coverts, contrasting velvety mantle; gloss on crown, throat and upper breast limited to tips and marginal ends of feathers, forming sharply defined oval or pointed spangles (gloss lacking on lores, forehead and rest of underparts); glossy feathers on side of neck elongated, forming lanceolate hackles; remiges brownish-black; underwing-coverts with white tips and iridescent greenish-blue edges; tail long (125–136 mm), moderately forked (average depth of fork 14 mm), with characteristic upward-turned tips; hefty and slightly hooked bill, numerous thick rictal bristles partly covering nostrils; iris bright red; legs and feet black. Sexes similar, male slightly larger than female. Juvenile is browner or dusky black and less glossy than adult, with undertail-coverts and belly feathers tipped white, giving spotted appearance, iris brown. Races vary mainly in size and in degree of gloss: *atrabectus* differs from nominate principally in being significantly smaller, with slightly narrower white tips on primary underwing-coverts, juvenile has more underparts feathers with white tips or fringes; *baileyi* is like nominate but slightly larger; *morotensis* has weaker and smaller bill, smaller wing, but longer tail (134 mm) more deeply forked (19 mm), outer rectrices less curved, is less glossy in dull blue, with rather short breast spangles and slightly longer neck hackles; *atrocaeruleus* is larger, with long wing, long tail (150–165 mm) rather moderately forked (16 mm), outer rectrices moderately curved outwards and upwards distally, long and heavy bill, frontal feathers well developed, rictal bristles long and strong, throat and breast with large spangles, general colour strongly bluish-black with purple iridescence; *amboinensis* is smaller than last, duller blue-black, with throat and breast spangles very much smaller, neck hackles poorly developed, shorter wing, shorter tail (135–141 mm) rather deeply forked (22 mm), bill rather long but strongly compressed laterally, with very weak rictal bristles, lacks curved frontal feathers; *buruensis* has long tail (163–174 mm) very deeply forked (42 mm), its length greater than that of wing, differs further from previous in having bill slightly more arched, larger, more numerous and glossier breast spangles, general colour purplish, and mantle invaded by a few metallic reflections (not dull or velvety); *carbonarius* is similar to *atrocaeruleus* but smaller in wing, tail (125–149 mm), depth of tail fork (17 mm), and bill, hackles shorter, white tips on underwing-coverts less prominent, longer bristles covering more of nasal groove than in nominate, purplish plumage with dark bluish iridescence, but variable (populations throughout New Guinea show variation in iridescence colour from purplish-blue to blue-green); *laemostictus* is similar to previous, but has deeper tail fork (21 mm), slightly longer bill, glossier plumage, metallic feathers of crown larger, spangles a little more numerous and larger, and hackles considerably longer and more brilliant; *meeki* has tail much less forked and not curving upwards at tip, metallic feathers of crown as large as previous race, throat and breast spangles fewer and small, rictal bristles more developed, longer and very strong; *longirostris* has longest bill of all races (29–33 mm), strongly compressed laterally, with short rictal bristles, lacking curved frontal feathers, and tail is flat, straight and scarcely forked (7 mm), iris brown to dark red. VOICE. Vocalizations of nominate race not well known, but adults reported as very noisy near nest or when feeding fledglings. During flight display, distinctive song of 5–6 single notes in series during descent and ceasing when bird is c. 3 m above ground, or a discordant jangle before display and during ascent, followed by torrent of rapid sharp twittering during descent; pairs reported as duetting or jangling in unison; alarm in presence of cuckoo (Cuculidae) or bird of prey a repetitive chatter of discordant and harsh sounds (often the first species to raise alarm), given also when chasing conspecific; sometimes 20 birds in chorus at dusk. Calls either melodious and whistling or grating and noisy, including harsh and grinding notes repeated for several minutes. Mimicry of many and varied other birds, including goshawk (*Accipiter*), Blue-faced Honeyeater (*Entomyzon cyanotis*), Little Wattlebird (*Anthochaera chrysoptera*), Noisy Miner (*Manorina melanocephala*), Pied Butcherbird (*Cracticus nigrogularis*) and Australian Magpie (*Cracticus tibicen*). Calls of Australian races wintering in New Guinea or occurring in S Torres Strait islands often resemble those of New Guinea race *carbonarius*. Vocalizations of latter mostly metallic-sounding, often high-pitched or squeaky, loud, ringing and conspicuous, varying greatly: shrill metallic upslur given singly or as 2 or 3 notes; 2-note disyllabic "kichew, kichew" repeated many times; double loud metallic upslurred shrill "tleei-tleei"; metallic call (0·5 seconds) consisting of harsh note followed by 2 ascending clear notes, repeated many times at intervals of 3–6 seconds; rapid "tutuchiew" or "tutuchiewtutuchie"; high-pitched "ping"; rapid trilled note followed by metallic slur, "prrrtiew"; peculiar pair of nasal notes, falling and then rising; harsh grating "kraaaa"; short, harsh, grating note followed by two pairs of squeaky falling and rising notes, "aaa-kuchi(-kuchi)"; harsh note followed by shrill, metallic disyllable, "tchaak-titiew"; slightly descending series of harsh, grating notes followed by 2 shrill metallic notes, "tchuck-tchuck-tchuck-tiew-teu"; slightly disyllabic nasal note with klaxon-like quality; low "phew-phew-phew" whistle sometimes given in flight. Short fluty calls resembling those of Old World oriole (*Oriolus*) or magpie-robin (*Copsychus*) recorded on Seram (race *amboinensis*), and long descending churr on Halmahera (*atrocaeruleus*). Race *laemostictus* rather quiet, calls lacking metallic clinking notes, some consisting of repetitive soft and short buzzes, others more scratchy and grinding sounds; on Buru (*buruensis*), one bird gave soft low whistles at long intervals, and when duetting longer rolling "rurrrrrru" calls and high-pitched trills answered by 3–4 slightly rising short whistles. Solomons races (*meeki* and *longirostris*) call less and more quietly, with varied chattering, piping and whistling notes.

Habitat. Large variety of tropical wooded habitats: rainforest, monsoon and gallery forests, mangroves, teak (*Tectona*) plantations, tall secondary forest, forest edge, also villages and sometimes suburban gardens. In Australia, occurs also in vine forests, in ecotone between rainforest or monsoon forest and open eucalypt (*Eucalyptus*) forest, and in wet or even dry sclerophyll woodlands or forests; regularly recorded in gardens and streets in some urban areas, more commonly near native vegetation, extending to temperate zone. Lowlands and hills, mainly to 600 m, locally to 1450 m in New Guinea; higher only in disturbed habitat, to 1600 m (New Britain) or 2000 m (Bacan).

Food and Feeding. Omnivorous; food mainly winged insects, but also caterpillars and teak moth (*Hyblaea*) pupae, and occasionally small vertebrates and fruits; diet also includes nectar (tongue has brush-like tip). Vertebrates taken include lizards, bats and, at least in Australia, small birds such

as Striated Pardalote (*Pardalotus striatus*); nectar taken from *Erythrina*, *Grevillea*, *Eucalyptus*. Has been recorded as predator of honeybees (*Apis mellifera*) in Australia, and taking wasps (Hymenoptera) from nest on walls of house; seen either to wipe bees against branch to remove sting or, returning to perch, carefully to transfer prey to feet, hold it against perch and peck off the sting. Perches upright on horizontal branch and sallies out to capture insects in flight, mostly from middle levels of forest up to canopy, often catching prey flushed by other birds, e.g. Rusty Pitohuis (*Pitohui ferrugineus*) in New Guinea and mainly Black-faced Cuckoo-shrikes (*Coracina novaehollandiae*) in Australia; forages also among foliage and branches, occasionally pouncing on to ground or trunk; catches insects emerging from ground at dusk. Congregates and forages in burnt areas, also at flowers of *Callistemon* in Australia. Steals prey from other birds in air; seen to target White-bellied (*Coracina papuensis*) and Black-faced Cuckoo-shrikes, Magpie-lark (*Grallina cyanoleuca*), Australasian Figbird (*Sphecotheres vieilloti*) and Willie Wagtail (*Rhipidura leucophrys*). Generally solitary, but pair-members sometimes associate loosely. Little information on association with mixed flocks. Reported in New Guinea as member of itinerant mixed-species foraging association, the "black and brown flocks" (distinctive in that member species converge on two alternative plumage colours, and that flock retains its character through many geographical and altitudinal changes of species composition); these include bird-of-paradise (Paradisaeidae), New Guinea Cuckoo-shrike (*Coracina melas*), and Tawny-breasted Honeyeater (*Xanthotis flaviventer*) associations, groups of species hierarchically led by New Guinea Babbler (*Pomatostomus isidorei*) or Rusty Pitohui, all medium-sized to large forest passerines that forage from understorey to lower canopy. In Australia, three or four individuals may join together in chasing small bats, but sometimes observed in mixed-species flocks, mainly with Black-faced Cuckoo-shrikes, occasionally with Yellow-eyed (*Coracina lineata*) or White-bellied Cuckoo-shrikes, mostly during non-breeding season; one flock with ten Black-faced and one White-bellied Cuckoo-shrikes and two individuals of present species reported as feeding on fruits. In New Guinea, observed to drink water from forest pool during dry season.

Breeding. In Australia season Sept to early May, occasionally from Jul, with laying mainly Oct–Jan (races *baileyi* and *atrabectus*) or Nov–Feb (nominate); Oct–Nov (*carbonarius*) in New Guinea area; nest with two eggs in mid-Dec in Moluccas (*atrocaeruleus*). Solitary pairs, but pairs sometimes close together, e.g. twelve active nests found each c. 45 m from nearest neighbour. Pre-breeding display described in Australia: one individual gave call and was joined by second bird, the two standing side by side, facing away from each other, calling, flicking tail and shaking wings, the first then turned to face the other, calling in unison, and turned again, while bobbing and bowing, this display repeated three times before the second individual flew to nest (c. 20 m away). Nest built by both sexes, taking 4–9 days (in Australia), a shallow cup of twigs, rootlets, stalks and tendrils of vine or fine grass, bound with spider web or other fine materials, lined with fine materials, firm but open enough for eggs to be seen from below, two nests had external diameter 15 cm, depth 7·6–10·2 cm, internal diameter 9–10 cm, depth 3·2–4·4 cm; slung in fork of horizontal branch, often of eucalypt in Australia, 4–18 m above ground, same site may be used for several consecutive years (up to eight recorded, but not known if by same individual birds); may nest in or near tree containing nest of other species, such as figbird (*Sphecotheres*) or Helmeted Friarbird (*Philemon buceroides*), or e.g. 5 m from nest of Leaden Flycatcher (*Myiagra rubecula*), once even close to tree with more than 150 Shining Starling (*Aplonis metallica*) nests and five figbird nests; estimated territory c. 3 ha in New Guinea (race *carbonarius*); parents attack any potential predator coming near nest. Clutch 2–5 eggs, often 5 or 3–4 (depending on region) in Australia and 2–3 in New Guinea area, ground colour ranging from pinkish-white, pale purplish-grey, purplish-white or pale creamy buff to almost white, with large patches of brownish brick-red and purple markings or small deep purplish, pinkish-red, lavender or chestnut dots, mostly at large end, average 29·8 × 20·7 mm (Australia), 28–31·5 × 21–23 mm (New Guinea area), one egg of race *atrocaeruleus* had "white ground upon which are distributed hairlines, blotches of secondary pale greys and lilacs, most in evidence at the larger end, with darker blotches and spots of liver-brown and sepia capping the larger end", 29·5 × 21·5 mm; incubation probably by both sexes, period c. 19 days; both also feed chicks, nestling period c. 3 weeks; fledglings accompanied by parents for up to 50 days. Nests parasitized by Common Koel (*Eudynamys scolopacea*) and Pallid Cuckoo (*Cuculus pallidus*).

Movements. Resident in New Guinea area (*carbonarius* and insular races) and generally in N Australia (*baileyi*); partly migratory in E Australia (nominate), some moving S of NE New South Wales (limit of breeding range) as far as Tasmania and even Kangaroo I, where very rare vagrant in May–Jul. Main E Australian population moves N after breeding, to N Queensland (Cape York Peninsula) and SE New Guinea (in Trans-Fly region), passing through Torres Strait from mid-Mar to end Apr, usually in small groups flying low over water, as well as up to 100 m; return S in flocks of up to 30 individuals in Oct–Nov. In New Guinea, an individual of nominate race not in full adult plumage seen in Dec suggests that some immatures may remain through year in non-breeding area; female in breeding condition recorded in Jan perhaps an indication that nominate may breed within range of *carbonarius*. Analysis of measurements shows that breeding populations of NE Queensland migrate N to New Guinea, and that populations breeding farthest S migrate as far as N Australia but do not cross Torres Strait, resulting in mix of small resident *atrabectus* and larger migrant nominate in Cape York Peninsula during winter. Migrates in daylight, from tree to tree or 25–40 m above forest, also 550 m offshore (50–100 m above water), and parallel to river (in Trans-Fly). In E Australia, apparent post-breeding altitudinal movements from E slopes of Great Divide towards coast reported.

Status and Conservation. Not globally threatened. Nominate race common; in SE Queensland, said to have increased in 1980s; formerly rare in Blue Mts (New South Wales) but now more common, frequency and occurrence increasing around Sydney in 1970s and 1980s, e.g. densities of up to 70–80 birds/100 ha in 1980s (compared with only 20 birds/100 ha in NE Queensland in same decade). Race *baileyi* confined to NW Australia EBA, especially in coastal mangroves and monsoon rainforest (density 70–80 birds/100 ha in Kakadu National Park, but only 3 birds/100 ha at S Alligator R); *atrabectus* occurs on Cape York Peninsula and in NE Queensland wet tropics, which hold some of the largest national parks in Australia, remaining lowland forests, covering a quarter of area, now partly protected. In breeding and non-breeding ranges in E & SE Australia, numbers said to have possibly increased. No known threats, except through capture by cats or mortality caused by flying against windows or lighthouses during migrations. Widely distributed race *carbonarius* common and ubiquitous in lowland forest in whole New Guinea; recorded in Lorentz National Park (West Papua), which subject to illegal logging, agricultural expansion and trade in rare species; in 1982, population in lowland rainforest study site near Port Moresby comprised 60 birds/100 ha. Races restricted to small islands may be at risk of rapid decrease or even extinction through severe deterioration of habitat; all occur in Endemic Bird Areas (EBAs). In Moluccas, two of the four races are subject to dramatic forest loss owing mainly to timber concessions, agricultural development and mining (gold on Bacan, nickel on Halmahera): *morotensis*, confined to Morotai I, and *atrocaeruleus*, on Halmahera and small surrounding islands of Northern Maluku EBA, which includes six protected areas, two of them (Lolabata, Ake Tajawi) covering more than 1000 km². Race *buruensis* is present in Buru EBA, where montane forest largely undisturbed in late 1990s, but now threatened by agriculture and logging; two protected areas exist, of which one (Gunung Kapalat Mada) covers 17% of the ecoregion. Race *amboinensis* is distributed on four islands of Seram EBA, still well forested except in coastal lowlands (at least until end of 1990s), but suffering from habitat loss caused by agriculture and timber activities, despite existence of seven protected areas (16% of the EBA), the most important being Manusela National Park. E of New Guinea, each of the three races is restricted to lowlands and hills of one or two relatively small islands, which have suffered and continue to suffer extensive loss and logging of lowland forest: *laemosticus* is widespread on New Britain (Bismarck), and in the Solomons *meeki* is uncommon on Guadalcanal and *longirostris* is common on San Cristobal. For all of these endemic populations regular survey of numbers and trends is required, with the aim of maintaining the great diversity of taxa in this region.

Beehler *et al.* (1986), van Bemmel (1947a), Blakers *et al.* (1984), Coates (1990), Coates & Bishop (1997), Diamond (1987b), Ford (1996), Hartert (1929), Higgins *et al.* (2006a), Parker (1963), Ramm (1998), Rand (1938b), Schodde & Mason (1999), Stattersfield *et al.* (1998), Strange (2001), Vaurie (1949), White & Bruce (1986), Wood (1996).

15. Ribbon-tailed Drongo

Dicrurus megarhynchus

French: Drongo de Nouvelle-Irlande **Spanish**: Drongo de Nueva Irlanda
German: Bandschwanzdrongo
Other common names: New Ireland Drongo

Taxonomy. *Edolius megarhynchus* Quoy and Gaimard, 1830, Dorey, New Guinea; error = Port Praslin, New Ireland, Bismarck Archipelago.

Recent DNA studies indicate that this species is most closely related to *D. bracteatus*, and also close to *D. hottentottus*; all may be part of a superspecies that includes also *D. menagei*, *D. montanus*, *D. sumatranus*, *D. densus* and *D. balicassius*. Differs from them principally in its very distinctive tail, but also in longer wings and larger bill. Monotypic.

Distribution. New Ireland, in Bismarck Archipelago.

Descriptive notes. 51–56 cm (up to 63 cm including elongated tail feathers); two birds 129 g, 130 g. Male is black to bluish-black, with strong blue-steel gloss on crown, wings and tail (except outermost tail feathers), neck with glossy blue streaks, upper breast sparsely spangled with glossy blue spots, underwing-coverts sparsely tipped with white; frontal feathers well developed and extending about half to two-thirds along culmen; outermost tail feathers enormously elongated (average length 384 mm) and fully webbed to the tips, extending 14–17 cm beyond rest of tail, distal third or quarter of shaft twisting spirally inwards (these feathers often broken, not fully grown or absent); iris orange-red or dark red; bill strong, black; legs black. Female is similar to male but smaller, with shorter tail-steamers. Juvenile undescribed. Voice. Very varied vocalizations, including high-pitched fluty notes, rapid upslurs, low-pitched soft disyllabic whistles given in slow and quiet succession; another remarkable repeated strophe consists of a rolling sound dropping into low-pitched deep twanging note. Calls include distinctive liquid whistle of several similar notes, and a whistled series, without harsh notes. Flares tail when calling. Voice different from that of *D. bracteatus*, even if some calls appear similar to those of New Guinea race *carbonarius* of latter.

Habitat. Primary lowland forest, hill forest, stunted mossy montane forest and tall secondary growth; sea-level to 1800 m.

Food and Feeding. Small invertebrates. Forages mainly in middle stage to canopy, but also, at higher elevations, in substage of mossy forest. Perches upright, tail dangling, on open perch within cover, from where it sallies for winged insects; also picks arthropods from surface of branches and leaves. Fairly shy and less noisy than *D. bracteatus*, and rather difficult to observe.

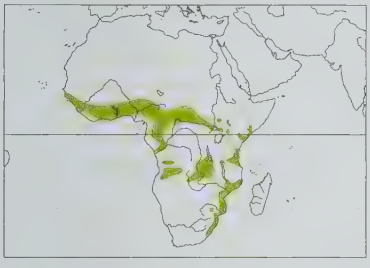
Breeding. No information available.

Movements. Resident.

Status and Conservation. Not globally threatened. Restricted-range species: present in New Britain and New Ireland EBA. Fairly common to common. Global population trends not evaluated, but believed not to approach the level of population decline that would merit conservation concern. Nevertheless, natural forest is declining, threatened by logging or destruction for industrial plantations; this species, restricted to a small range (area of New Ireland is 8650 km²), could therefore become Near-threatened in the future.

Bibliography. Anon. (2008i), Beehler (1978a), Coates (1990), Mayr & Diamond (2001), Vaurie (1949).

PLATE 11



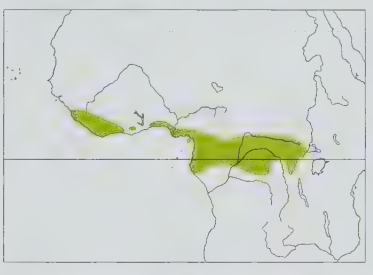
inches 5
cm 13

16. Square-tailed Drongo

Dicrurus ludwigii

French: Drongo de Ludwig **German**: Geradschwanzdrongo **Spanish**: Drongo de Ludwig
Other common names: Sharpe's Drongo (*sharpei*)

Taxonomy. *Edolius ludwigii* A. Smith, 1834, Durban, South Africa.
Recent DNA studies indicate that closest relative is *D. atripennis*. Distinctive race *sharpei* may merit treatment as a separate species. Five subspecies recognized.
Subspecies and Distribution.
D. l. sharpei Oustalet, 1879 – S Senegal E to Nigeria, Cameroon, Central African Republic, S Sudan, Uganda and W Kenya, extending S to N Angola and N DRCongo.
D. l. muenzneri Reichenow, 1915 – S Somalia, E & SE Kenya, and E & S Tanzania.
D. l. saturnus Clancey, 1976 – Angola (W escarpment E to Moxico), SE DRCongo (Katanga) and Zambia.
D. l. tephrogaster Clancey, 1975 – S Malawi, E Zimbabwe, and Mozambique (N of R Limpopo).
D. l. ludwigii (A. Smith, 1834) – E South Africa, Swaziland and S Mozambique.



Descriptive notes. 18–19 cm; 25–35 g. The smallest African drongo, with slightly notched, almost square-cut tail (c. 85–95 mm). Male nominate race is entirely black, with uniform dark bluish-green gloss above and from breast to flanks and belly; flight-feathers uniformly blackish-brown; sometimes underwing and axillaries lightly marked with white feather tips that seem to persist on adults (not visible in field); iris pale orange to bright orange-red or blood-red; bill heavy and hooked, black; legs black. Differs from *D. atripennis*, which has similar tail, in significantly smaller size. Female is smaller and less glossy than male. Juvenile resembles female, but speckled pale greyish on mantle and breast, eyes brown; immature has pale tips on underwing-coverts and whitish fringes on belly and undertail-coverts. Races differ mainly in plumage colour or gloss, and tail length and shape: *muenzneri* is like nominate, but male has gloss below slightly more pronounced and more extensive, female underparts sooty black with blue-green across breast and white tips on axillaries and underwing-coverts; *tephrogaster* male is similar to previous, but less deep black, greener on crown and mantle, with rump, uppertail-coverts and underparts duller and greyer, wing shorter, female greyish on rump, uppertail-coverts and underparts; *saturnus* resembles nominate, but even less glossy, more greenish or bronzy; *sharpei* has bluish-violet gloss, black underparts, tail slightly less forked and feathers less lyre-shaped compared with other races, sexes similar. Voice. Very vocal, with extensive repertoire combining repeated disyllabic calls e.g. "tyip-tyip", single notes regularly repeated in varied tones and lengths, "toylu, toylu...", and phrases with explosive whistles and hard buzzy sounds. Includes upslurred repeated short notes or downslurred whistles and buzzes, e.g. "dzi-dzi-dzi-dzi-dwee", "zer-chi-hooey", or whistles only, e.g. "toypulee", "chi-chu-hooey", sometimes ending with loud "chop" ("tssyow" or "tssyoh" in Tanzania). Clear regional differences: in W Africa more muted calls compared with E birds, which have more "ringing" tone. In S Africa, song often introduced with low-pitched chatter, followed by loud whistles, "chu-wee-ju", "chop-suey" and nasal "dzi-dzaa-dzi-dzi" calls and trisyllabic twanging "tswing-tswing-tswing". Pairs perform quiet but rapidly delivered territorial duets combining short whistles and continued chattering of liquid notes like those of a bee-eater (*Merops*), including clicking sounds such as "tec-why-tyee" or "piu-took-why-tyee" from male, to which female gives harsh nasal reply (Gabon). Possibly imitates the brief call of African Goshawk (*Accipiter tachiro*) in flight.
Habitat. Wide variety of woodland habitats, with preference for edges, patches, glades, clearings and secondary growth. Present in gallery forest with dense undergrowth, wooded dense savanna in W Africa, mature and primary forest; follows riverine forests into cultivated areas and large degraded forest patches around villages. Associated with thick low forests in S Cameroon and Sudan. Sea-level to 1350 m in Cameroon, 1500 m in Mozambique, 1600 m in DRCongo and Zimbabwe; up to 2000 m in Tanzania and 2100 m in Sudan. In Kenya, *sharpei* present only above 1000 m in wet areas, whereas *muenzneri* present at lower altitude in riverine forests of semi-arid zones. Race *tephrogaster* reported in middle stratum of lowland and mid-altitude evergreen forest in Zimbabwe, *saturnus* in middle stratum of moist evergreen and riparian forest in Zambia, nominate in middle stratum and subcanopy of evergreen forests, rarely frequenting undergrowth. Clearly less of a forest-dweller than *D. atripennis*, which confined to primary forests where the two species meet, whereas present species tends to be more in fringes. In Gabon primary forest found almost exclusively in canopy and emerging trees, while *D. atripennis* occupies lower strata; but present also in lower strata (5–15 m) in secondary forests, where *D. adsimilis* occupies higher strata.
Food and Feeding. Insects, e.g. moths (Lepidoptera), locusts (Acrididae), mantises (Mantidae), beetles (Coleoptera), termites (Isoptera); in S Africa, reported as also taking nectar, and a potential stealer of food from other birds. Perches upright on bare branch, periodically twitching tail; darts out and seizes large insects in typical swooping flight, or snatches them from foliage; takes many termites during emergences of latter. Holds large items with the claws and uses bill to cut them into pieces. Lives in pairs or small family groups; joins mixed-species foraging parties, where it takes advantage of insects disturbed by other flock-members.
Breeding. Season roughly Feb–Jun N of equator and Sept–Apr in S, e.g. Nov–Apr in Gabon and Sept–Jan in S (peak Oct–Nov in Zimbabwe); laying Apr in Ghana, May in Liberia and Uganda, Sept in Zambia, Sept–Jan in Zimbabwe, Sept–Oct in Malawi, Oct–Apr in South Africa (KwaZulu-Natal), Nov (and fledglings Feb–Apr) in Gabon; fledglings late Mar in Togo and Apr–May in Nigeria. Monogamous; highly territorial, especially near nest, will attack and chase much larger birds, including raptors, but less noisy and aggressive than other forest drongos. Nest comparatively small for a drongo, external diameter c. 7·5 cm (interior cup 5–5·5 cm broad, c. 2·5 cm deep), made from large flakes of lichen, leaf petioles and dry plant stems, bound with cobweb, cobweb used also to secure nest to branches; attached in hammock fashion (looking like inverted low-crowned hat and held by the brim), usually at end of well-shaded, horizontal slender forked branch, either in outer branches of tall tree (at 25–35 m above ground in *Newtonia* in Zimbabwe) or in lower branches (2–8 m); destruction of nest after use or abandonment has been recorded, as has repeated use of material to build new nest; forest floor below nest covered with accumulated white droppings. Clutch 2 or 3 eggs, average 2·6 in South Africa and Malawi, plain white or pinkish-cream with faint lilac blotches and spots, or with zone of lavender-grey and tiny dark brown specks, mainly at larger end, c. 21 ×16 mm; incubation of eggs and rearing of brood by both parents, no information on duration of incubation and nestling periods.
Movements. Resident.
Status and Conservation. Not globally threatened. Locally common; rare or uncommon in some regions, such as Somalia (where largely confined to lower Jubba riverine forest), N & E of Gambia, N Ghana, and higher parts of its altitudinal range. Density in Gabon primary forest 7–8 pairs/100 ha. Thought not yet to have suffered any significant population decline. Even though the species uses cleared and secondary habitats, deforestation should be considered a potential threat. In S of range, destruction of coastal forest will result in fragmentation and contraction of range of nominate race.

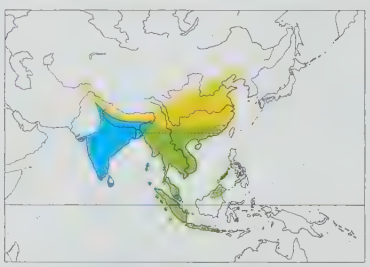
17. Shining Drongo

Dicrurus atripennis

French: Drongo de forêt **German**: Glanzdrongo **Spanish**: Drongo Selvático

Taxonomy. *Dicrurus atripennis* Swainson, 1837, Sierra Leone.
Recent DNA studies indicate that closest relative is *D. ludwigii*. Monotypic.
Distribution. Sierra Leone, SE Guinea, Liberia, S Ivory Coast and S Ghana E in forest to NE DRCongo, S to S Gabon and C PRCongo.

Descriptive notes. 21·5–24 cm; 35–47 g. The glossiest drongo in Africa. Male has head and body entirely black with strong characteristic shining steel-green to sometimes purplish-blue reflections, most pronounced on upperparts, throat and breast; forehead and lores velvety black, stiff feathers covering base of upper mandible; flight-feathers blackish-brown with shining outer edges of secondaries, wing-coverts and tertials black with some bluish gloss; tail slightly forked (length 89–111 mm, fork 5–15 mm); iris dark red (described as crimson in Gabon); bill and legs black. Differs from *D. ludwigii* in larger size, glossier plumage, larger tail with deeper fork. Female is similar to male but on average slightly smaller, with less gloss on throat and belly. Juvenile is sooty black, with some greenish gloss on wings and tail only. Voice. Lively and noisy. Territorial pair performs duets combining loud sharp notes, melodious whistles and harsh scratchy cries. Song sometimes introduced with brief chatter, and composed of single ringing notes grouped into few short phrases, repeated in very irregular rhythm, often finishing on single resounding note. Less twangy than that of *D. adsimilis*, with sequences of single or double notes rapidly and rhythmically repeated (4–13 times), including monotonous metallic whistles in changing tones (first sequence twanging, then more percussive, and so on), a steady "chyip-chyip" or a rapid succession of characteristic explosive ringing notes, "quick! quick! quick! quee! quirt!". Other vocalizations include double "pee-hee" whistles, double "jreeeep-jreeeep" screeches, buzzy "za-za-za" rattles, clicking sounds like "kli-tokli", "widdly-klock", "kewp-kewp" chuckles like those of *Turdus* thrush, liquid descending "chilly-poppa", and whistled and buzzy notes given in succession. Mimics calls of other birds, e.g. Red-billed Helmet-shrike (*Prionops caniceps*), Rufous Flycatcher-thrush (*Stizorhina fraseri*) and Bocage's Bush-shrike (*Chlorophoneus bocagei*).
Habitat. Restricted to primary forest and oldest secondary forest, from sea-level to lower hills; to at least 1000 m in Liberia. The most typical forest drongo, penetrating deeper into shady mature woodland stands. Occupies lower canopy and dense shrubs, usually between 5 m and 25 m, whereas *D. ludwigii* occupies higher canopy.
Food and Feeding. Mainly large insects (50–60 mm). In NE Gabon, observed to feed on Orthoptera, beetles (Coleoptera), moths (Lepidoptera), mantises (Mantidae), cicadas (Cicadidae), as well as flying termites (Isoptera). Stomach contents beetles, dragonflies (Odonata), cicadas, Orthoptera, spiders (Araneae) and millipedes (Diplopoda) in DRCongo; beetles, ants (Formicidae) and grasshoppers (Acrididae) in Liberia. Catches aerial prey (e.g. Lepidoptera) by sallying out from horizontal perch or a liana loop, usually below 20 m; other items taken by gleaning or hover-gleaning. Big items held with the claws and cut into pieces with bill. Follows swarms of carnivorous ants such as makokou (*Dorylus wilverthi*) for hours, sallying rapidly for disturbed insects in forest middle levels (5–20 m high) or plunging after falling prey; competes with and sometimes aggressive towards other large ant-followers, such as bulbuls (Pycnonotidae), hornbills (Bucerotidae) and small raptors. Lives in pairs and in family groups of up to five individuals, often associated with other species such as greenbuls (*Phyllastrephus*) and paradise-flycatchers (*Terpsiphone*). Conspicuous member of mixed-species foraging parties, following "searchers" and "beaters" from above foliage, and benefiting from insects disturbed by them. Indicates, together with Bates's Paradise-flycatcher (*Terpsiphone batesi*), approaching predators, by using powerful alarm calls and plunging into vegetation, prompting similar escape reactions from other birds.
Breeding. In Liberia more frequently reported Aug–Jan and displays and territorial behaviour Sept–Nov, but birds with enlarged gonads also in Mar and Jun; laying Aug–Dec in Liberia, May–Nov in Nigeria, Jan–Mar in Gabon, Aug–Sept in PRCongo; in DRCongo, May–Sept in N Ituri and Feb in Kivu. Lives as territorial pair; aggressive, chases other drongos and other bird species, including raptors and *Tockus* hornbills, and seen to harass African Harrier-hawk (*Polyboroides typus*) or even beating Crowned Hawk-eagle (*Stephanoaetus coronatus*). Nest a small shallow cup built from rootlets and lichens between twigs of horizontal forked branch, held with cobwebs and decorated with lichens, so simple and thin that contents visible through the structure; located 3–12 m above ground. Clutch 2 eggs (three clutches in Kivu, Gabon and Sierra Leone), and two chicks reported from nest in S Cameroon; egg creamy brown with irregular brown markings, average of



On following pages: 18. Ashy Drongo (*Dicrurus leucophaeus*); 19. White-bellied Drongo (*Dicrurus caerulescens*); 20. Comoro Drongo (*Dicrurus fuscipennis*); 21. Black Drongo (*Dicrurus macrocercus*); 22. Fork-tailed Drongo (*Dicrurus adsimilis*); 23. Velvet-mantled Drongo (*Dicrurus modestus*); 24. Mayotte Drongo (*Dicrurus waldenii*); 25 Madagascar Crested Drongo (*Dicrurus forficatus*); 26. Aldabra Drongo (*Dicrurus aldabranus*).

two eggs 24·6 × 17·3 mm; incubation possibly by both parents, both feed chicks, no information on duration of incubation and nestling periods.
Movements. Resident.
Status and Conservation. Not globally threatened. Widespread in African equatorial forests. Locally frequent in Liberia, Sierra Leone and S Ghana, very localized in S Ivory Coast; rare or uncommon in narrow coastal band in S Togo, S Benin and Nigeria. Locally common in S Cameroon, Equatorial Guinea, N & C PRCongo, extreme S Central African Republic, and N, C & E DRCongo. The commonest drongo in Gabon. Densities of 12–15 pairs/100 ha in Gabon primary forests, down to 6–8/100 ha in secondary stands; locally 10–20 pairs/100 ha in Liberia. Believed not to have suffered any significant population decline, although threats of large-scale deforestation exist, especially in Congo Basin.
Bibliography. Bannerman (1953), Bates (1930), Brosset & Érard (1986), Chapin (1954), Cheke & Walsh (1996), Colston & Curry-Lindahl (1986), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Fry *et al.* (2000), Gatter (1997), Pasquet *et al.* (2007), Schouteden (1960), Vaurie (1949), Willis (1983a).

18. **Ashy Drongo**
Dicrurus leucophaeus

French: Drongo cendré **German**: Graudrongo **Spanish**: Drongo Cenizo
Other common names: Pale/Grey Drongo; Indian Grey Drongo (*longicaudatus*); Assam Grey Drongo (*hopwoodi*); Burmese Grey Drongo (*nigrescens*); White-cheeked (Grey) Drongo (*leucogenis*)

Taxonomy. *Dicrurus leucophaeus* Vieillot, 1817, "Ceylon"; error = Java.
Recent DNA studies indicate that this Asian species is closest to the African group of drongos, providing evidence of a dispersal from Africa c. 10 million years ago. Dark race *longicaudatus* and white-faced race *leucogenis* formerly treated as two separate species. Subspecific taxonomy complicated, as many races not clearly differentiated and, in most of mainland, races are highly migratory. Race *hopwoodi* intergrades with *longicaudatus* in West Bengal and Bhutan, and with *mouhoti* in NE Myanmar, NW & W Laos and C Vietnam; *nigrescens* intergrades with *mouhoti* in S Myanmar and with *bondi* in SE Thailand; in China, pale race *leucogenis* intergrades with dark *salangensis* along R Yangtze, and latter may intergrade with *mouhoti* in N Vietnam (N Tonkin). Proposed race *beavani* (described from E Afghanistan) considered inseparable from *longicaudatus*; *celaenus* (from Simeulue, off NW Sumatra) and *palawanensis* (Palawan, in W Philippines) considered too poorly differentiated from nominate to warrant recognition. Fourteen subspecies recognized.
Subspecies and Distribution.
D. l. longicaudatus Jerdon, 1862 – breeds in S Himalayas from extreme E Afghanistan E to Bhutan; non-breeding at lower altitudes and through Indian peninsula (except Punjab, Sind and arid parts of Rajasthan and Gujarat) S to Sri Lanka.
D. l. hopwoodi Stuart Baker, 1918 – breeds in E Himalayas (E from Bhutan), SW & S China (from E Xizang E to S Guangdong), N & C Myanmar E to N Vietnam; migrates S to West Bengal, S Assam, Bangladesh, S China (Hainan) and S Myanmar, N & E Thailand and S Laos.
D. l. leucogenis (Walden, 1870) – E & C China from Liaoning S (E from N Gansu and Sichuan) to NE Guangdong; migrates to S China, N Laos, E Thailand, Cambodia, Tenasserim and Malay Peninsula (both W & E coastal plains).
D. l. salangensis Reichenow, 1882 – SE China S of R Yangtze (to Fujian–Guangdong border); migrates S to Hainan, S Indochina, E, C & S Thailand and Malay Peninsula.
D. l. innexus (Swinhoe, 1870) – Hainan.
D. l. mouhoti (Walden, 1870) – C, SW & E Myanmar, N & E Thailand and C Indochina; migrates to S Myanmar, S Thailand and Cambodia.
D. l. bondi Meyer de Schauensee, 1937 – W & E Thailand, Cambodia, S Laos and S Vietnam.
D. l. nigrescens Oates, 1889 – S Myanmar (Tenasserim) and Malay Peninsula (W of Main Range) S (including Phuket I and Pinang I) to Johor; post-breeding dispersal S to Singapore.
D. l. batakensis (Robinson & Kloss, 1919) – N Sumatra (Aceh and Batak Highlands).
D. l. phaedrus (Reichenow, 1904) – C & S Sumatra.
D. l. leucophaeus Vieillot, 1817 – Simeulue, off NW Sumatra; Java, Bali, Lombok; and SW Philippines (Busuanga, Culion, Palawan and Balabac).
D. l. siberu Chasen & Kloss, 1926 – Siberut, off W Sumatra.
D. l. periophthalmicus (Salvadori, 1894) – Sipura and Pagai Is, off W Sumatra.
D. l. stigmatops (Sharpe, 1879) – N Borneo.

Descriptive notes. 25·5–29 cm (nominate), 23–26 cm (*leucogenis*); 26–28 cm, 32–45 g (*longicaudatus*); 26–30 cm, 40–55 g (*hopwoodi*); one female c. 24 cm, 34 g (*salangensis*). Nominate race has plumage entirely ashy grey, rather dark on throat and underparts, with (as all races) velvety dark frontal band and blackish chin; tail long (122–136 mm) and deeply forked (28–41 mm), outer rectrices slightly flaring outwards and upwards; iris bright red; bill robust, black; legs black. Sexes similar in plumage, male slightly larger than female. Juvenile is browner than adult, with slight white fringing on belly to undertail-coverts, has wing and tail considerably shorter than adult, iris brown. Race *longicaudatus* has head, neck and wing quite black and glossy, back and tail very deep slaty blue-grey with unglossed greyish underparts, tail longer (156–170 mm) and more deeply forked (63–84 mm) than nominate, outer rectrices also turning outwards, small bill large at gape, slightly hooked at tip; *hopwoodi* is unglossed blue-grey, variable in colour and size, but always lighter above and below than preceding race, with tail shorter (138–170 mm) and less deeply forked (39–63 mm); *mouhoti* is smaller and paler than previous, blue-grey above and pale soft ashy grey below, rather similar to nominate but a little larger in all measurements, tail considerably longer (135–154 mm) and more deeply forked (41–56 mm), frontal band and lores grey-black, ear-coverts lighter grey; *bondi* is like last, but smaller and on average paler; *nigrescens* is dark slaty grey, like *longicaudatus* but paler and lighter grey below, distinctly smaller, tail shorter (146 mm) and less deeply forked (49 mm), frontal band and lores dusky black and ear-coverts grey; *leucogenis* is pale grey, below becoming whitish on vent and undertail-coverts, with blackish frontal band and chin, also sharply defined large pure white oval patch around eye, tail long (128–149 mm) and rather deeply forked, female less extensive white on face, immature darker and with less distinct white patches; *salangensis* is similar to previous but considerably darker, with pale facial patch less white and not so sharply defined, whitish edges and tips of underwing-coverts, immature slightly darker and with white patches still less distinct; *innexus* is intermediate between last and *mouhoti*, has lores and ear-coverts more or less whitish and poorly defined, underwing-coverts uniformly grey, tail intermediate in length and depth of fork, bill heavier and deeper than in all other races; *stigmatops* is similar to *mouhoti* in colour, but smaller in all measurements (tail 115–126 mm, depth of fork 28–34 mm), white of lores extending slightly around eyes, iris orange-red; *phaedrus* resembles previous in colour and size, but with smaller white loral spot extending occasionally below eye; *batakensis* is similar to previous but a little darker, with lores grey or with traces of whitish, very like nominate (except for occasional white on lores) but slightly lighter, with shorter tail (114–122 mm); *periophthalmicus* is pale blue-grey as nominate, but with large white facial patch; *siberu* is similar to last but slightly darker, especially on thin and throat, and smaller in all measurements, white facial area also smaller and not extending so far behind eye. Voice. Fairly pleasant and somewhat monotonous vocalizations; sometimes silent for long periods. Songs include rapid, jumbled, chattery phrases with straight and sweet notes alternating with twangy gruff ones. In Philippines, song of nominate race consists of slow succession of rising fluty whistles and *Oriolus*-like calls. In Nepal (*longicaudatus*) a very different song, a repeated series of 3 notes, one harsh and two fluty, "trshrr tee-twuu", with few variations; on non-breeding grounds in S India an irregular succession of soft, low and monotonous short notes. Usual call notes "drong-chip, drong-chip" and "chip-chop-drong", often at frequent intervals; also assortment of musical and harsh or scolding notes e.g. "cheece-cheece-chichuck" followed by whistling "kil-kil-kil-kil", or mewing calls. Another vocalization consists of loud, strident, clear downslurred whistles given regularly in twos or threes, with possible variation of a double quick lower note followed by a single one. Non-breeder in Singapore gave 2-note whistle, reminiscent of that of a leafbird (*Chloropsis*). Described as a good mimic of other birds, e.g. imitating piping whistles of iora (*Aegithina*).
Habitat. Essentially a forest bird, mainly in mountain areas, preferring more open forest; occurs in rainforest, mixed pine, oak and rhododendron (*Pinus–Quercus–Rhododendron*) forest, mixed bamboo-jungle. In Himalayas, breeds at up to 2500 m (Pakistan) or 3000 m (India), but mainly in foothills, at edges of clearings in coniferous forest or in broadleaf and mixed deciduous forests. In NW Myanmar (Chin Hills) race *hopwoodi* breeds in quite open grassland, as well as in well-wooded areas around villages and, more rarely, in forests. In China occurs generally at 600–2500 m, but to nearly 4000 m in Yunnan (*hopwoodi*), while *leucogenis* and *salangensis* are essentially birds of cultivated and highly wooded hill country. In Malay Peninsula inhabits mangroves, beach scrub, tree plantations, including rubber (*Hevea*), teak (*Tectona*) and edges of oil palm (*Elaeis guineensis*) stands, also forest edge, wooded parkland and large wooded gardens, all at plains level. Nominate race common in open woodlands and forest edge to 3000 m in Sunda Is (to 1300 m on Lombok), and fairly common resident in secondary growth, shrubs and trees in open and cultivated areas in Palawan group (Philippines). In Borneo, *stigmatops* common throughout mountains, but may be seen at low altitude in valleys; found also in mangroves, coastal scrub, secondary vegetation, forest edge on W coast plain. In Sumatra, occurs in forest areas, roadsides and town gardens, at 600–2400 m.
Food and Feeding. Principally insectivorous; some small vertebrates also taken. Consumer of nectar, among the most regular visitors at *Bombax* and *Erythrina* blossoms, as well as introduced *Grevillea* and eucalypt (*Eucalyptus*). Insects recorded as eaten include locusts, grasshoppers and crickets (Orthoptera), dragonflies (Odonata), stick-insects (Phasmida), moths and butterflies (Lepidoptera, including pierid *Aporia leucodyce* and papilionid *Teinopalpus imperialis* in Pakistan), mantises (Mantidae), also many smaller insects, i.e. termites (Isoptera), ants (Formicidae) and other Hymenoptera (including venomous ones), beetles (Coleoptera), flies (Diptera). Occasionally eats small lizards; occasionally small birds, e.g. Old World warblers (Sylviidae) and iora (*Aegithina*). Often seen perched high on open branch at edge of forest; sallies from treetop perch to take flying insects close to ground or on tree trunks and in canopy foliage. Follows cattle, riding on back of buffalo or sheep in manner of *D. macrocercus*, and captures insects disturbed by the mammal. Reported as robbing Hoopoes (*Upupa epops*) in Pakistan. Mainly crepuscular. Hunts singly, in pairs or in small noisy parties; sometimes gatherings of 30 or more individuals, especially when feeding on winged termites, which it snaps up in acrobatic flight. In India, a few individuals of present species were reported as associated with a larger group of *D. macrocercus* and Ashy Woodswallows (*Artamus fuscus*) feeding on fire-driven insects.
Breeding. Season May–Jun in Himalayas, chiefly Apr–Jun in China and Apr in C Myanmar; Mar–May in Sumatra area, and Jan–Aug (peak Apr) on S islands (nominate race); eggs laid in Jan and Feb in Borneo; normally single-brooded. Quite territorial; aggressive towards possible predators, such as Large-billed Crow (*Corvus macrorhynchos*), approaching nest at less than 60–70 m. Both sexes take part in building nest, female doing most of construction work, male bringing materials (in earlier stages, also occasionally placing them), work taking 5–10 days, a shallow flimsy cup of vegetable fibres, e.g. rootlets, grass stems, lichens, leaves, aerial roots of banyan (*Ficus*) or seeded flower tops (China), closely interwoven, and plastered with spider webs, and a few intermingled lichen or leaves, contents often visible through bottom of nest, external measurements 10–12 cm across and 4·5 cm high (*longicaudatus*), egg-chamber 7·6 × 3 cm (*longicaudatus*), 9 × 3 cm (*nigrescens*); usually high up (often 15–20 m), sometimes lower (reported from 3 m), suspended from or partly embedded (strongly attached) in fork at extremity of slender branch, often overhanging riverbank; in Malay Peninsula, found in outer branches of mangrove tree (including *Sonneratia*), garden tree or rubber tree (6–15 m); in India and Myanmar, reported in broadleaf and pine forest but also at base of leaf stalks in palm or against tall bamboo (supported on branch of twigs at a node); also in conspicuous place, such as leafless tree. Clutch 2–4 eggs, generally richly coloured dark salmon or terracotta with dark red-brown blotches and lavender grey undermarking (*longicaudatus*), also pale pink to pale orange with dark crimson blotches underlying lavender-grey or lilac-grey spots (*stigmatops*, *leucogenis*), or varying from pure white (rare) to pale yellowish-cream to deep salmon or rosy pink, or deep terracotta (*longicaudatus*), blotched with dark reddish-brown or purple and secondary markings of lavender, lilac or pinkish-grey (*hopwoodi*), 23·6 × 18·2 mm (*longicaudatus*), 24·6 × 18·5 mm (*hopwoodi*), 25·5 × 20 mm (*leucogenis*) and 29 × 20 mm (*stigmatops*); incubation by both sexes, period 13 days; both also tend chicks, no information on duration of nestling period. Nest reported as parasitized by Indian Cuckoo (*Cuculus micropterus*).
Movements. Migratory in N of range. Mainly resident in Indonesia, but roaming widely outside breeding season. Breeding summer visitor in Himalayas (*longicaudatus*), wintering in plains from E Punjab S to S India and Sri Lanka; conspicuous spring passage in Apr in foothills and plains of E Pakistan; locally resident in lowlands of Nepal. Birds from E Himalayas and S & SW China (*hopwoodi*) migrate S to Hainan and to plains through continental SE Asia, straggling to Andaman Is; those breeding NE & C China (*leucogenis*) migrate S along Chinese coast (passage regular in Taiwan and Hong Kong) to S China (Yunnan E to Hainan; regular winter visitor Hong Kong), regular in Malay Peninsula (along E and W coastal plains), rare migrant to Korea and Japan. C Chinese race (*salangensis*) moves S to Hainan, where it arrives late Sept (vagrant in Hong Kong and Taiwan), regular in peninsular Thailand and vagrant in S Malay Peninsula (S to Singapore). Migrants coming from somewhere near presumed *salangensis–mouhoti* contact zone recorded in Malay Peninsula and Andaman Is. In Singapore, *nigrescens* occurs during post-breeding dispersal.
Status and Conservation. Not globally threatened. Generally common throughout mainland range; race *nigrescens* nowhere common within its range, and vulnerable to loss of natural habitat. Nomi-

nate race, fairly common in Philippines and Lesser Sundas: Palawan and nearby islands subject to logging, mining and agriculture following large-scale human immigration, but a network of Environmentally Critical Areas recently established (e.g. recorded in St Paul Subterranean River National Park); parts of S Sundas under threat from forest clearance, burning and shifting cultivation. Both *periophthalmicus* and *siberu*, on small islands off W Sumatra, probably under threat from habitat depletion. Race *innexus* restricted to Hainan, and linked to the remaining montane forest composing the Hainan EBA (13,000 km²); *stigmatops* confined to Borneo, where present in Bornean Mountains EBA at 500–3700 m, e.g. recorded in Kinabalu Park; *phaedrus* and *batakensis* found in Sumatra, where human pressure strong against drongo habitat, mainly through use of pesticides in tree plantations, and destruction of wooded areas.

Bibliography. 19. White-bellied Drongo

Dicrurus caerulescens

French: Drongo à ventre blanc **German**: Graubrustdrongo **Spanish**: Drongo Ventriblanco
Other common names: Indian White-bellied Drongo (*caerulescens*); Ceylon White-bellied Drongo (*insularis*); White-vented Drongo (*leucopygialis*)

Taxonomy. *Lanius caerulescens* Linnaeus, 1758, Bengal, India.
May be related to *D. leucophaeus*. On mainland, nominate race exhibits decrease in size and reduction in extent of white on abdomen from N to S; overlap in individual measurements of wing and tail, however, is c. 50%, and more than that for bill, so that determination of geographical distinctions not possible. Sri Lanka races *insularis* and *leucopygialis* intergrade. Three subspecies recognized.
Subspecies and Distribution.
D. c. caerulescens (Linnaeus, 1758) – India S from Haryana and E Gujarat, E along lower slopes of Himalayas to S Nepal, and to West Bengal and C Orissa.
D. c. insularis (Sharpe, 1877) – N & SE Sri Lanka.
D. c. leucopygialis Blyth, 1846 – SW Sri Lanka.

Descriptive notes. c. 24 cm; 39–41 g. Nominate race has frontal band and lores black and unglossed, rest of head, throat and upper breast varying from smoky blue-grey to brownish-grey, white from lower breast and flanks to undertail-coverts (extent of white variable); upperparts blackish, dully glossed slate-grey to indigo; tail black, fairly long and slender (112–130 mm) with rather deep fork (27–39 mm), end of outer rectrices curving outwards; iris brownish-red; bill and legs black. Sexes similar in plumage, male a little larger than female. Juvenile is dark brown above, brown on throat and breast with less visible distinction from white belly, traces of white barring on breast, flanks, axillaries and underwing-coverts; first-winter similar, but with slate-grey gloss above. Races differ mainly in size, intensity of dark colour above and extent of white below: *insularis* is smaller than nominate (tail 104–117 mm, depth of fork 24–26 mm), with purer and more intense black on upperparts, heavier bill, abdomen duskier and more streaked, white area not extending to flanks and starting lower; *leucopygialis* is a little bigger than previous (tail 109–120 mm, fork 26–30 mm), also darker above than nominate, white below restricted to vent and undertail-coverts and contrasting with dark uniform grey abdomen. Voice. Songs resemble chatter of small passerines such as finches (Fringillidae) or thrushes (Turdidae); excellent mimic, imitating, among others, tailorbird (*Orthotomus*), Common Woodshrike (*Tephrodornis pondicerianus*) and iora (*Aegithina*), and even mewing of a cat (observed in Sri Lanka); said to have sweeter song than that of any other drongo, with notably less harsh notes than *D. macrocercus*. Calls of nominate race include short or long dry buzzes and variety of sweet, short whistles, e.g. "dee-dee", resembling that of Old World oriole (Oriolidae) or *Turdus* thrush. Race *leucopygialis* has highly varied and prolonged but choppy songs, composed of rather harsh staccato notes mixed with sweet, short and clear ones.
Habitat. Edges of paths and shady glades in dry and moist deciduous and bamboo forests, wooded compounds in inhabited rural areas, tea or rubber plantations; breeding reported to 2000 m along Himalayas, to 1500 m in S India. In Sri Lanka, race *insularis* occurs in wooded areas and gardens, avoiding forests, in low dry zone (flatlands with annual rainfall of c. 150 cm, principally during NE monsoon), up to c. 1500 m; *leucopygialis* is found in trees of wet lowlands and nearby hills in low wet zone (area of hills to 500 m, SW of C mountains, receiving well-distributed annual rainfall of up c. 500 cm); both races occur irregularly in C hill zone (consisting of mountains reaching 2300 m, and with annual rainfall exceeding 500 cm in some parts but much less in others).
Food and Feeding. Mostly insectivorous, feeding on winged insects such as crickets and grasshoppers (Orthoptera), moths (Lepidoptera), alate termites (Isoptera) and others; sometimes takes small birds, such as Old World warblers (Sylviidae). Also fond of nectar, of e.g. *Bombax*, *Erythrina*, playing an evident role in pollination; reported as only carnivorous in Sri Lanka. Usually perches upright on branch or treetop, from which it flies out, making short looping sallies, moving with agility, and snapping up prey in the bill or claws; returns again and again to same perch or one very near. Small birds caught with claws in mid-air. Occasionally pirates food from other birds, either in surprise attack or after dogged pursuit. Highly crepuscular. Occasional nocturnal feeding observed in India, as e.g. by birds perched on wire or tree bough around electric light bulbs in front of forest rest house. Hunts singly, less often in twos or threes; often joins mixed flocks, and associates with *D. aeneus*.
Breeding. Season Mar–Jun (mostly Mar–May) in most of range; in Sri Lanka, Feb–Jun (mostly Mar–Apr) in N & SE (*insularis*) and Mar–May in SW (*leucopygialis*). Territorial; may attack crows (Corvidae), hawks (Accipitridae) or other aerial predators to drive them away from neighbourhood of nest-site. Nest built by both sexes, that of nominate a comparatively large and rather bulky cup of roots, grasses and twigs, bound with cobwebs, placed 3–9 m above ground in fork of horizontal outer branch of small or medium-sized tree, e.g. oak (*Quercus*) in mixed open forest, teak (*Tectona*) and bamboo in hilly districts, *Alnus nepalensis*, *Acacia elata* or *Acer oblongum* in deep valleys; rubber tree (*Hevea*) favoured by race *leucopygialis*, nest of which rather small and shallow (internal diameter and depth 6 × 2·5 cm), well finished, generally decorated externally with scraps of bark, lichen or moss, lined with fine grass or tendrils of creepers, the whole structure strengthened with many cobwebs, often built high above ground, up to 12 m, betrayed by head and tail of sitting bird projecting on each side. Clutch of nominate race 2 or 3 eggs, sometimes 4, pale cream or yellowish-salmon to mostly warm salmon-pink (never white), spotted with blackish-purple or reddish-brown, average 23·6 × 17·8 mm; in Sri Lanka 2–4 eggs (mostly 3), very pale cream, salmon-pink or reddish white (rarely pure white) with large or small specks of brown, brownish-red or bluish-grey, most numerous at large end, average 22 × 17·1 mm (both races), 23·3 × 17·3 mm (*leucopygialis*); 3-egg clutches of *leucopygialis* occasionally contain one bigger egg, sometimes one smaller; incubation of eggs and tending of chicks by both sexes, no information on duration of incubation and nestling periods.
Movements. Resident; in India some seasonal local and altitudinal movements, e.g. non-breeding visitor in C Gujarat.
Status and Conservation. Not globally threatened. Widespread but generally uncommon in India; locally common in Nepal from lowlands to 300 m. Recorded in Nagarhole National Park, in S India. Reported as common in Sri Lanka, but deforestation for agriculture, tree plantation or settlements could lead to local decrease of the two races. Most of the protected areas in Sri Lanka are in the dry zone, e.g. Ruhunu and Horton Plains National Parks (covering c. 1010 km²), and *insularis* is therefore better protected than is *leucopygialis*. Latter race occurs in wet-zone tropical evergreen forest, more subject to destruction but with four important reserves, including largest remaining areas of lowland and montane rainforest: Sinharaja World Heritage Wilderness Area, Peak Wilderness Sanctuary, Horton Plains National Park and Hakgala Strict Nature Reserve (covering c. 350 km²).

20. Comoro Drongo

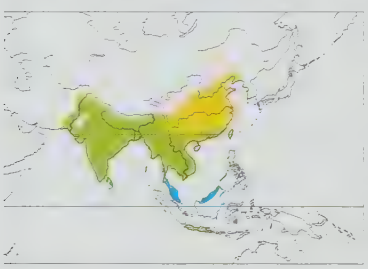
Dicrurus fuscipennis

French: Drongo de Grande Comore **Spanish**: Drongo de la Gran Comora
German: Braunschwingendrongo
Other common names: Grand Comoro Drongo

Taxonomy. *Buchanga atra* var. *fuscipennis* A. Milne-Edwards and Oustalet, 1887, Grand Comoro (Njazidja), Comoro Islands.
DNA studies indicate that this species is well differentiated, and slightly older than its closest relatives, *D. adsimilis* and *D. modestus*, suggesting that it originates from colonization by an ancient African drongo of an island of the Comoro archipelago much older than Grand Comoro (possibly Mohéli) c. 5 million years ago. Drongos from neighbouring Indian Ocean islands, *D. waldenii* (Mayotte), *D. forficatus* (Madagascar and Anjouan) and *D. aldabranus* (Aldabra), form a distinct group that separated at about the same period. Proposal that all these, along with *D. macrocercus*, form a superspecies not supported by molecular-genetic studies. Monotypic.
Distribution. Grand Comoro (Njazidja), in Comoro Is.

Descriptive notes. 26·5–29 cm. Plumage is entirely deep lustrous black, with uniformly dark dull blue gloss (turning gradually bronze on wing-coverts), except for primaries and rectrices, which unglossy reddish-brown (much clearer on undertail); in flight, gives false impression of pale underwing patch, as underside of primaries reflects light; tail relatively long (116–136 mm; two males 124–131 mm, two females 117–119 mm) and shallowly forked (13–20 mm, two males 20 mm, two females 13–17 mm), with ends of rectrices straight; iris dark brown; bill slightly curved at tip, black; legs black. Sexes identical in plumage, male slightly larger than female except for similar bill length. Juvenile is matt blackish-brown to greyish. Voice. Varied repertoire with typical harsh drongo squeaks, sharp clicks, trills, fluty whistles and grinding sounds, characterized by softer "wit wit" notes. Compared with *D. waldenii* or *D. forficatus*, song appears less harsh, more nasal, higher-pitched, with variety of liquid and melodious strophes including sturnid-like downslurs, some of them possibly imitating mynas (Sturnidae) or other species. Also gives repetitive creaks, and reported as uttering "chlew" call like that of domestic chick before attacking a goshawk (*Accipiter*). Pairs perform duets during breeding season.
Habitat. Shows preference for forest clearings and degraded areas, such as plantations and agricultural fields with few high trees and a well-developed layer of bushes and low trees. Apparently requires tall trees and open airspace to allow aerial feeding. Recorded also in cacao plantations. Present mainly at lower edge of Mt Karthala forest, between 500 m and 1000 m; recorded also at lower elevations, almost to sea-level. This species' occupancy of mainly degraded vegetation with exotics suggests that native optimal habitat may have already disappeared at lower altitudes, and that it may now be restricted to marginal habitats.
Food and Feeding. Food includes large insects. Analysis of contents of four stomachs revealed consumption of beetles (Coleoptera), grasshoppers (Orthoptera), cockroaches (Blattodea) and mantids (Mantidae); also fruits, which were main element in one of them. Forages mostly on large flying insects in sunny places; perches relatively high in trees, generally in very visible position, and sallies out to seize prey on wing. Recorded as perching on shrubs in woodland canopy 10–20 m tall (near Kourani). Observed singly, in pairs, and in family groups of up to seven individuals. Very active in morning.
Breeding. Season Sept–Dec, possibly beyond; nest probably built in Sept–Oct, as eleven adults in Aug were not in breeding condition and two pairs found with nest by mid-Oct; nest with one-week-old chicks in Nov and fledglings observed in Dec. Territorial, performing duets and displays during breeding season (three pairs displaying and singing in Nov–Dec). Very aggressive towards raptors and other potential nest predators, such as Frances's Sparrowhawk (*Accipiter francesii*), which once recorded as driven away but suspected to have returned and taken chick(s). Nest a neat substantial cup, built 7–9 m above ground on (rather than in) small fork at end of outer branch of tree. Clutch 1–2 eggs, possibly more; both parents attend nestlings, male observed to feed female at nest and she fed young. No other information.
Movements. Resident.
Status and Conservation. ENDANGERED. Restricted-range species: present in Comoro Islands EBA. Rare and uncommon within its tiny global range, estimated at only c. 150 km² on an island covering 1147 km²; extremely small population localized on flanks of Mt Karthala, an active vol-

cano. Population estimated at c. 100 birds in 1985, although there may be more. Mostly restricted to a few sites around Mt Karthala; present mainly around Nioumbadjou, but recorded also at lower elevations down to near sea-level on SW coast near Zikaledjou, Singani, the R Denga-denga bridge, Salimani and Mvouvouni; found also at Malakoff and Hantsangoma, on N side of mountain, and around Kourani, Tsinimoipanga, Boboni, Mvouni and Mlima Manda, on W side. Quality and extent of native habitats have been declining over recent decades, but species is too sparsely distributed to enable speculation on its population trends; it survives in exotic degraded vegetation and does not appear to be declining. Reasons for its scarcity largely unknown, possibly high nest predation by introduced rats (*Rattus*), which abundant in the forest, and other predators, such as lesser Indian civet (*Viverricula indica*) and small Asian mongoose (*Herpestes auropunctatus*), or scarcity of large insects, or the fact that (some of) its present distribution may be in marginal habitat. Field surveys are required to investigate the species' biology and ecology, to establish its current population, range and status, and to investigate possible limiting factors. Main threats to native habitats around Mt Karthala are clearance for agriculture, the spread of thicket-forming invasive exotic plants, commercial logging, and a road-building project to provide access to the crater (although how this would affect the species is unclear). A protected area has been proposed on Mt Karthala, extending below the native forest edge in S, in order to encompass most of species' known range. Maintaining or re-creating of habitats of appropriate structure (e.g. reforestation of grasslands on C ridge) should benefit the species. A programme aimed at increasing public awareness and influencing decision-makers is recommended, and development of ecotourism could be an alternative source of income for local communities.



Bibliography. Anon. (2008i), Butchart & Stattersfield (2004), Collar & Stuart (1985), Forbes-Watson (1969), Herremans (2001), Hornbuckle (1997), Huguet & Chappuis (2003), Louette (1988, 1999, 2004), Louette & Stevens (1992), Louette *et al.* (1988), Pasquet *et al.* (2007), Stattersfield & Capper (2000), Stevens *et al.* (1992), Vaurie (1949).

21. Black Drongo

Dicrurus macrocercus

French: Drongo royal **German**: Königsdrongo **Spanish**: Drongo Real
Other common names: (Common) King Crow, Black King Crow; South Indian Black Drongo (*macrocercus*); North Indian Black/Himalayan Black Drongo (*albirictus*); Ceylon Black Drongo (*minor*); Chinese Black Drongo (*cathoecus*)

Taxonomy. *Dicrurus macrocercus* Vieillot, 1817, Madras City [Chennai], Tamil Nadu, India.
Forms a superspecies with *D. adsimilis* and often treated as conspecific, but differs slightly in plumage and significantly in proportions and voice; close relationship between the two supported by recent DNA studies. Previously, *D. fuscipennis*, *D. modestus*, *D. waldenii*, *D. forficatus* and *D. aldabranus* thought to be part of same superspecies, but morphological and genetic differentiation considered too great to validate such a relationship. Race *albirictus* intergrades with nominate in SE Pakistan and across C India (in narrow band roughly from Kutch, in W Gujarat, E to S West Bengal) and with *cathoecus* in NW Myanmar; *cathoecus* and *thai* may intergrade in N Thailand. Seven subspecies recognized.
Subspecies and Distribution.
D. m. albirictus (Hodgson, 1836) – Himalayas from E Afghanistan and N & E Pakistan E to W & extreme N Myanmar and S China (SE Xizang), S to SE Pakistan (E from Indus Valley) and across C India (S to Gujarat, N Madhya Pradesh and West Bengal; non-breeding also S to S India, C & S Myanmar and N Thailand.
D. m. macrocercus Vieillot, 1817 – SE Pakistan and peninsular India S from Gujarat, Madhya Pradesh and West Bengal.
D. m. minor Blyth, 1850 – N & NW Sri Lanka (S, in W, to Puttalam), including Mannar I.
D. m. cathoecus Swinhoe, 1871 – breeds C, E & S China (E from Qinghai, S from Jilin; including Hainan I), Myanmar (except W & N), N Thailand and N Indochina; non-breeding S to SW & S Myanmar, S Malay Peninsula (Singapore) and S Indochina.
D. m. thai Kloss, 1921 – S Myanmar (Tenasserim), C & E Thailand, probably E Cambodia, and S Indochina.
D. m. harterti Stuart Baker, 1918 – Taiwan.
D. m. javanus Kloss, 1921 – Java and Bali.
Introduced (race *harterti*) in S Northern Marianas (on Rota I), from where colonized Guam.

Descriptive notes. c. 30–31 cm (nominate), 27–28·5 cm (*thai*), average male 27·9 cm and female 26·9 cm (*harterti*), c. 26 cm (*minor*); male 39–59 g, one female 41 g (*albirictus*), 40–51 g (nominate). Nominate race has white rictal spot relatively large at gape, matt black lores, forehead and forecrown; rest of head and body plumage deeply lustrous black, uniformly glossed with dull steel-blue, inner webs of primaries grey-brown, darkening at tips; lining of wings pale silvery brown; semi-translucent primaries visible in flight; long tail (158 mm) deeply forked (60 mm), outer pair of rectrices curving slightly outwards and rarely also slightly upwards (disappearing when in moult); iris blood-red to deep crimson; bill rather broad and short, upper mandible curved and slightly hooked, black; legs black to dark grey. Differs from very similar *D. adsimilis* in having tail longer than wing (rather than the reverse), tail fork much deeper, white spot at gape, and slightly greater amount of gloss. Sexes very similar, female on average slightly smaller than male. Juvenile has body plumage softer and browner, metallic gloss confined to upperparts, with wing and tail shorter and duller and with less gloss, underwing-coverts and undertail-coverts edged with white, rictal spot larger and conspicuous, iris reddish-brown to brownish; first-year differs from adult in being less glossy below, feathers from lower breast broadly edged with white, undertail-coverts white-tipped. Races differ mainly in size, prominence of rictal spot, and general coloration: *albirictus* is like nominate, but larger in all measurements (wing 153 mm, tail 170 mm, depth of tail fork 66 mm), with comparatively larger white rictal spot; *minor* is smallest race (wing 131 mm, tail 137 mm, fork 47 mm), white rictal spot not always directly perceptible (sometimes consisting of only a single feather), bill smaller and weaker; *cathoecus* is similar to nominate in size (slightly longer wing and bill, shorter tail less deeply forked), but differs in having wing-linings dark (instead of pale), greener gloss on wings and tail, rictal spot much smaller and concealed, and is apparently only race with dark brown eye; *thai* differs from previous in shorter wing with paler lining, shorter and somewhat less robust bill, longer and considerably more forked tail, and has rictal spot usually lacking or very small and hidden; *harterti* is similar to *albirictus* in long wing and bill lengths, but differs in having tail on average (148 mm) shorter than wing (152 mm), often with generally greener gloss (although some individuals bluer), rictal spot very small and hidden; *javanus* is bluish, rather than greenish as in neighbouring *thai*, differs from latter further in somewhat shorter and less deeply forked tail, rictal spots almost always lacking. Voice. Powerful and harsh vocalizations. Particularly noisy at start of breeding season, mainly during two hours preceding daybreak; partners frequently engage in duet of raucous 2-note calls while displaying. Songs include vehement and jarring strophes of syncopated, jangling and creaky squawks, mostly on even pitch, first often shorter and harsher, last also shorter and a few more nasal; also pleasant warbling with melodious phrases and few churrs in Orissa (E India), "tit-ti-tu-wut" in Rajasthan (W India), and combination of musical whistles and harsh sounds in Nepal (race *albirictus*). Song in Sri Lanka (*minor*) more melodious than those of congeners. Varied calls, including spaced, short, harsh, single monotonous or rising notes; also harsh double-noted "ti-tiu" like that of Shikra (*Accipiter badius*), "cheece-cheece-chichuk" call, raucous scraping or metallic sounds, also beautiful clear whistles; in Thailand, race *cathoecus* gives diverse churrs and soft nasal chatters. Accomplished mimic, especially when excited by predator such as cat or snake, imitates alarm notes of other birds.
Habitat. Mostly open country and farmland with scattered trees; very common also in villages and suburbs, parks and gardens, perching on telephone wires and poles, and on roadside trees. Race *albirictus* common and widespread in plains and openly wooded hills, e.g. with oak (*Quercus*) and rhododendron (*Rhododendron*), but not quite so exclusively an open-country bird as nominate, nesting occasionally in thin forest or well-wooded country at considerable distance from human settlements; to 2600 m in Pakistan, and to 1500 m (occasionally to 2000 m in summer) in Nepal. In Sri Lanka, common in coastal belt in open land, tobacco and pasture fields, bushy plains. In China, common in plains, where frequently seen on roadside poles, and reported particularly on willows (*Salix*) along bank of pools; to 1600 m in summer in Yunnan. Plains and hills in open country in Myanmar. In Malay Peninsula an entirely non-forest drongo, passage migrants and non-breeding visitors favouring rice fields, particularly at late-crop and post-harvest stages, also market gardens, open grassland and grass-swamp with grazing water buffaloes (*Bubalus bubalis*). In Java and Bali, and Sumatra (where rare), occurs in open spaces and agricultural land, where it follows domestic livestock.
Food and Feeding. Food predominantly insects (often agricultural pests), including locusts, grasshoppers and crickets (Orthoptera), beetles (Coleoptera), bugs (Hemiptera), termites (Isoptera), ants and bees (Hymenoptera), even ferocious rock bees (*Apis dorsata*), also moths, butterflies and larvae (Lepidopera), damselflies (Zygoptera); occasionally, mainly on Indian Subcontinent, diet reported as much more varied, including lizards, small bats, and nestlings and small birds such as flycatchers (*Muscicapa*), prinias (*Prinia*), white-eyes (*Zosterops*), ioras (*Aegithina*), swallows (Hirundinidae); cattle ticks (Ixodoidea), considered an important food resource in Sri Lanka. Reported as feeding on dead fish floating on muddy water, frequently flying to perch on nearby tree, carrying a fish c. 10 cm long in bill. Also seeks nectar (from *Bombax ceiba*, *B. insigne*, *Butea monosperma*, *Erythrina*), during which forehead and throat feathers become covered with pollen (thus helps in cross-fertilization of plants). In Gujarat (India) one individual reported as feeding on sorghum (*Sorghum vulgare*) grains; took 30 grains in ten minutes by pecking repeatedly under its feet while perched on top of the ear. Regularly reported as pirating worms (Annelida) or other prey from Hoopoes (*Upupa epops*), mynas or wagtails (*Motacilla*). Spends middle of day calmly on shady trees. Forages mainly in morning and evening hours, hunting insects attracted by electric lights as late as 2–4 hours after sunset. Perches on wires, fence posts, posts, bare treetops, earth banks or other vantage, sallying to catch prey on the wing, to seize it among herbage, or to snatch termites and other insects emerging from ground. During human activity in rice fields, perches close by on elevated posts and pounces on insects disturbed or exposed by the plough; feeds also on ground, swooping down on prey and either eating it immediately or carrying it in bill to perch. Tears larger items to pieces before swallowing them; removes wings of damselflies and other large-winged insects before consumption. Usually solitary, but will gather in numbers to feed on swarming winged termites or emerging mosquitoes (Culicidae); attracted to forest fires and areas of burning grass, where it captures escaping insects, even amid thick rising smoke. Also joins parties of Yellow-billed Babbler (*Turdoides affinis*) or Jungle Babbler (*Turdoides striata*), hawking insects flushed by the babblers, the latter (not competing for food, as near-ground foragers) benefiting from protection afforded by drongo against predators; same behaviour and benefit observed in associations with ground-feeding flocks of Jungle Myna (*Acridotheres fuscus*) and/or Common Myna (*Acridotheres tristis*). Foraging trips of present species considerably more successful when with medium-sized and large myna flocks. Associates also with mammals, mainly cattle, water buffalo or goats, catching insects disturbed by them; often uses back of cattle as mobile perch. Outside breeding season, roosts in trees or bamboo groves, dispersing at dawn to feeding areas; hardly enters closed tree cover during daytime, often foraging far from any trees.
Breeding. Season Mar–Jun in Pakistan, Mar–Aug (principally mid-Apr to end Jun, sometimes second brood Jul–Aug) in India, and Mar–May in Sri Lanka; Apr–Aug in China, but mainly Apr in Taiwan and May–Jun in Hong Kong; Apr–Aug in SE Asia, most eggs laid in Apr–May in Myanmar, Apr–Dec in Java and Bali. Cases of helpers at nest reported in India, e.g. three fledglings accepting food from parents and two additional conspecifics; also, a Red-vented Bulbul (*Pycnonotus cafer*) partaking in the feeding of three chicks in and, later, outside nest, even almost simultaneously with parents. Solitary nester, territorial; drives crows (Corvidae) and raptors out of territory, pursuing them for 200–300 m through air, and even landing briefly on back of flying Short-toed Snake-eagle (*Circaetus gallicus*) in India or Black Kite (*Milvus migrans*) of race *lineatus* in Hong Kong. Partners display by facing each other, 10–20 cm apart on perch, and indulging in rapid head-bobbing while duetting; also trios and quartet noticed in SW India (Kerala). Nest built by both sexes, taking 5–8 days (average 6 days), a flimsy-bottomed broad shallow cup, sides rather firm and thick, internally 10 cm in diameter and 4 cm in depth, made from tiny twigs, rootlets, fine grass stems and other vegetable fibres, e.g. roots of khus-khus grass (*Vetiveria zizanioides*) in India, fibres from fronds of coconut palm (*Cocos nucifera*) or twigs of gooseberry tree (*Phyllanthus emblica*), tightly woven together and plastered with cobweb, frequently lined with horsehair or fine grass, the outside often including pieces of lichen, moss, bark, spider egg sacs and the like; most often 4–7 m above ground, but up to 13 m and down to 2–3 m (even close to ground in Java or Bali), in horizontal fork at extremity of tree branch, also reported as laying on horizontal support, generally fork of strong twigs in tree, sometimes in upright fork of lower branches, or even on man-made structure (e.g. between horizontal and vertical sections of electricity pole in Andhra Pradesh, in India); nest tree often mango (*Mangifera indica*), but also *Lagerstroemia parviflora*, jackfruit (*Artocarpus integrifolia*), cashew (*Anacardium occidentale*), tamarind (*Tamarindus*), oak and many others, such as sheesham (*Dalbergia sissoo*), acacia e.g. babool (*Acacia nilotica*) or kandi (*Prosopsis spicigera*), in Taiwan also on waving branch of bamboo; chosen tree usually solitary and standing in the open, with unobstructed view of surroundings; in SW India (Calicut), nests 2·5–13 m up, on tree 5–30 m tall and usually 18–40 m from any other nesting tree, territory size 0·3–1·2 ha. Clutch 2–5 eggs, usually 3 or 4 in India (but 3–5 in Kerala), 2–3 (rarely, 4) in Sri Lanka, 3–4 and rarely 5 in E of range (race *cathoecus*), 2–3 in S (*javanus*); extremely variable, from pure white or white with sparse dark brown speckles (mostly in N) to warm pink-salmon with reddish-brown, purple-brown and burnt sienna blotches, chiefly at large end, over underlying purple markings (more in S), and all kinds of intermediates, average size 27·1 × 19·8 mm (*albirictus*),

24–27 × 18·5–20·5 mm (nominate), 24·2 × 18·1 mm (*minor*), 26·5 × 19·5 mm (*cathoectus*); up to two replacements laid if clutches lost in early stage of incubation (no re-laying if lost at advanced stage of incubation); incubation by both sexes, in some cases male taking prominent part, period mainly 14–16 days; eggs hatch asynchronously over 24–28 hours; chicks fed by both parents, nestling period mostly 16–17 days, sometimes to 20 days; fledglings dependent on parents for c. 30 days. Nests parasitized by Indian Cuckoo (*Cuculus micropterus*) in India and SE China, and by Common Koel (*Eudynamys scolopacea*) in India; also, in India and in C & S China, by Asian Drongo-cuckoo (*Surniculus lugubris*), so closely similar in shape and color that it is often mistaken for present species. Breeding success linked to availability of insects, and hence to date of first monsoon showers, which are followed by sprouting of grasses and flush of insects. Both sexes apparently breed for first time when c. 2 years old.

Movements. N populations migratory or partly migratory. Those in NW of range (race *albirictus*) winter at lower altitudes and latitudes, S to E Afghanistan and S Pakistan, C India, C & S Myanmar, N Thailand; rarely recorded in United Arab Emirates, and vagrant in Oman; in most of Pakistan except Baluchistan, *albirictus* is mainly a summer breeding visitor, arriving in Mar and departing in Oct. In China, *cathoecus* is principally a summer visitor, breeding birds present May–Sept in Henan; in Hong Kong main arrival about mid-Apr and most have left by late Oct, spring passage in loose groups of 10–20 individuals, larger groups up to 150 on autumn passage; migrates through SE China to SE Asia; resident in Hainan and partly in Yunnan E to Guangdong and Fujian. In Myanmar, majority breed in C & N late Mar/early Apr–Oct, migrating to S, where few are sedentary; seems to be less migratory in S Irrawaddy valley (where breeds in May and Jun). Race *cathoecus* also a passage migrant and winter visitor to whole Thailand and to Malay Peninsula, where observed near coast, usually in lowland (but recorded to 800 m); migration counts of this species in autumn 2003 at freshwater marsh in S Thailand totalled c. 11,300, with daily peak at 08:00–10:00 hours and a smaller peak in late afternoon, rarely after 18:00 hours (in contrast to *D. annectans*, frequently netted at night), with no significant differences related to wind direction but with heavy peak (highest single hourly count 618 birds) following two days of heavy rain throughout Thailand; passage in singles early in season, then small flocks of 5–20 individuals, sometimes across 30-m front. Regular migrant in Japan and Korea; vagrant in Mongolia (Gobi) and SE Russia. Vagrants from E Asia recorded Apr–Jun in Sumatra; regular but rare in lowland forest, mangrove, peatswamp, alluvial forest and dipterocarp forest up to 500 m in NW Borneo. In Sri Lanka, wintering birds occurring in S part of dry zone possibly migrants from India.

Status and Conservation. Not globally threatened. Common throughout range in Indian Subcontinent; race *albirictus* formerly occurred also in SE Iran. Common resident and migrant in mainland SE Asia, including E China; especially common in Hong Kong during spring and autumn passages. Migration through and in Thailand has declined in recent years; in 1920s species considered "extremely abundant" migrant in Sept, occurring in "huge noisy parties", but far fewer seen now. Resident race *javanus* widespread in Java and Bali, but now seen less often than was previously the case. Two other island races, in Taiwan (*harterti*) and Sri Lanka (*minor*), have restricted ranges but are very common and widespread in farmland and open plains; both islands, already affected by large-scale destruction of natural forest, are still subject to deforestation through firewood-gathering, clearance for permanent agriculture, shifting cultivation, tree plantations, and rapid urbanization of rural lands; most of the protected areas in Sri Lanka within the dry zone benefit the local drongo. This species, which attends ploughing operations along with several others, such as Common and Bank Mynas (*Acridotheres ginginianus*), House Crow (*Corvus splendens*) and Cattle Egret (*Bubulcus ibis*), may be considered an efficient agent in control of white grub (*Holotrichia*) in commercial crops, being economically cheaper and environmentally safer than chemicals. On the other hand, following introduction of this species in 1935 in Northern Mariana Is (to control destructive insects), it has become a serious threat to the native forest avifauna of the islands, as it preys on endemic species, notably the Critically Endangered Rota White-eye (*Zosterops rotensis*).

22. Fork-tailed Drongo

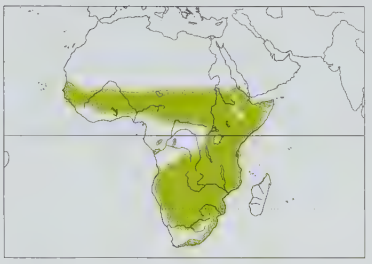
Dicrurus adsimilis

French: Drongo brillant **German**: Trauerdrongo **Spanish**: Drongo Ahorquillado
Other common names: African Drongo

Taxonomy. *Corvus adsimilis* Bechstein, 1794, Duiwenhok River, southern Cape, South Africa.

Forms a superspecies with *D. macrocercus* and often treated as conspecific, but differs slightly in plumage and significantly in proportions and voice; close relationship between the two supported by recent DNA studies. Previously, *D. fuscipennis*, *D. modestus*, *D. waldenii*, *D. forficatus* and *D. aldabranus* thought to be part of same superspecies, but morphological and genetic differentiation considered too great to validate such a relationship. Race *divaricatus* intergrades with *fugax* in N Uganda and Kenya. Four subspecies recognized.

Subspecies and Distribution.



D. a. divaricatus (M. H. C. Lichtenstein, 1823) – SW Mauritania, Senegambia and Guinea E in savanna belt to N Cameroon, S Chad, C & S Sudan, Ethiopia, Eritrea and Somalia, S to Central African Republic, N DRCongo, N Uganda and N Kenya.

D. a. apivorus Clancey, 1976 – SE Gabon and adjacent PRCongo, WC & S DRCongo, Angola, N & W Zambia, Namibia, Botswana and N South Africa (N Northern Cape E to N Limpopo).

D. a. fugax W. K. H. Peters, 1868 – Uganda, Kenya and Tanzania (including Zanzibar) S to E Zambia, Malawi, Mozambique, Zimbabwe, E Botswana, NE South Africa (E Limpopo S to NE KwaZulu-Natal) and E Swaziland.

D. a. adsimilis (Bechstein, 1794) – W Swaziland, Lesotho lowlands, and E & S South Africa (S Mpumalanga and KwaZulu-Natal S to SW Western Cape).

Descriptive notes. 23–26 cm; 34–48 g (*divaricatus*), 48–53 g (nominate). Nominate race is almost entirely black, glossed blue-green on head, upperparts, breast and flanks; upperwing black with slight greenish gloss, primaries and secondaries browner than rest of wing, inner webs of flight-feathers grey-brown (paler underside of remiges producing paler reflection in flight), primary coverts blackish with narrow glossy outer edge, belly and undertail-coverts sooty black; tail fairly long

(115–126 mm) and deeply forked (depth 19–23 mm); iris red; bill and legs black. Differs from very similar *D. macrocercus* in having tail shorter than wing (rather than the reverse), tail fork less deep, slightly less gloss, no pale rictal spot; from *D. ludwigii* and *D. atripennis*, in larger size and deeper tail fork. Sexes similar. Juvenile is dark sooty brown, with few buffish feather tips, tail fork less pronounced, iris brown, gape pale; immature resembles adult but without gloss on underparts, pale feather tips on underparts. Races differ mainly in size, in depth of tail fork and in colour of inner webs of flight-feathers: *apivorus* is large, as nominate, but has inner webs of flight-feathers pale grey-buff (as in following race), juvenile has buffy tips on body feathers, fine whitish margins on upperwing-coverts and secondaries, white tips on underwing-coverts and axillaries; *fugax* is smaller, with deeply forked tail (23–27 mm), and pale grey-buff inner webs of flight-feathers, juvenile as last; *divaricatus* resembles previous, but with shallower tail fork (8–20 mm). Voice. Very vocal; often the first bird to sing at dawn and last to be heard at dusk. Pre-dawn calls include rasping "jwaaa-jwaaa" and "jeewy-jeeerr". Extremely varied repertoire of sharp calls, short whistles and squeaky, liquid, grating and scratchy notes, given in rapid succession or between long pauses to form a song sometimes described as discordant twangy jumble, e.g. "drit-drit, woyglo-jit, drit-o, jewp-jewp, click-click, gliglaagligloo, jick-glo-jeea" and so on; rasping sounds like those made by unoiled wooden wheel. Single calls include "chyup", "tjaaa", loud "jer-woo" and whistled "jee-lu". Partners perform synchronous duets lasting c. 4–5 minutes and consisting of c. 12–20 rapidly alternating elements by each partner. Songs sometimes dominated by soft, high-pitched, nasal and scratchy sequences (especially nominate race), or by melodious whistles and chirps, grinding sounds and liquid chatters. Imitates perfectly calls of other bird species, e.g. Bocages's Bush-shrike (*Chlorophoneus bocagei*), thrushes (Turdidae), tchagras (*Tchaghra*) and bulbuls (Pycnonotidae), also raptors such as Shikra (*Accipiter badius*) and African Goshawk (*Accipiter tachiro*), and at dusk or during moonlit nights owls such as Pearl-spotted Owlet (*Glaucidium perlatum*); mimicry of mewing cat reported in Kenya. Scratchy three-syllable "my-dear-chap" given before attacking intruding raptors.

Habitat. All types of wooded habitats except dense forest, mainly from sea-level to low hills, including open woodland and savanna, moist or dry, also riverine woodland and tree plantations, agricultural land and grasslands with scattered trees, along roadsides with wires or other perches; also city parks, gardens and exotic plantations. In more dense woodland, prefers edges, glades and clearings. Equally common in semi-arid bushland, acacia (*Acacia*) woodland and moist coastal secondary woodland in E Africa, where found to 1800 m. Avoids highlands, but reaches 2200 m in Kenya.

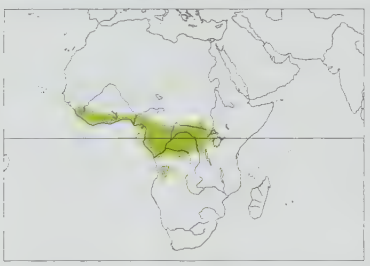
Food and Feeding. Food mostly large insects, including moths and butterflies (Lepidoptera), grasshoppers (Orthoptera), beetles (Coleoptera), cicadas (Cicadidae), also winged ants (Formicidae) and termites (Isoptera) during emergences, also bees (Apoidea); reported near hives. Small birds, such as Bronze Munia (*Lonchura cucullata*), sometimes captured and carried away in claws or bill; also captures small fish by swooping down from perch, hovering over water and dipping. Reported as probing aloe (*Aloe*) flowers, and consuming nectar. Perches in upright posture on conspicuous branch, from which it sallies out to pursue large insects, seizing them in the air, on vegetation or on ground, often returning to same branch. Occasionally forages on the ground. Holds large items with the claws and cuts them into pieces with the bill; removes wings of Lepidoptera before swallowing them. Bold and fearless; will steal food from other birds. Reported as hawking moths at night and as following ants in Tanzania. Singly and in pairs, sometimes in small groups; occasionally joins mixed-species flocks, where it catches insects disturbed by other flock-members. Associates with wild game (occasionally perching on animals) and domestic livestock; attends savanna fires, where it catches fleeing insects and other prey close to the flames.

Breeding. Season roughly Mar–Sept N of equator and Sept–Jan S of it; Apr–Jul in W Africa, Nov–Jun (mainly Feb–Apr) in Nigeria; Apr–Jun in Sudan and Mar–Sept in Ethiopia; in DRCongo, Feb–Mar in N (Uele) and Aug–Oct in SE (Katanga); Sept–Oct in Malawi and peak Sept–Nov in Zimbabwe; two and sometimes three broods in a season. Monogamous. Aggressively territorial towards other drongos; also chases and mobs nest predators, including birds of prey and crows (Corvidae), hornbills (Bucerotidae), shrikes (Laniidae) and others (will cling to back of intruder and peck it while in flight); pursues and attacks small mammals and snakes. Partners often perch together, and perform duets and displays, with bowing and bobbing of head. Nest saucer-shaped, c. 10–11·5 cm in diameter and 5 cm in depth, interior cup 7·5 across and 2·5 cm deep, made with fine plant stems, lichens, rootlets, tendrils and similar material, bound with cobweb, walls and floor so thin that eggs generally visible from outside, placed 2–12 m (usually 5–7 m) above ground, usually slung between fork of horizontal branch (often in the open), firmly fastened with rim of leaf petioles, cobwebs or lichens around top; occasionally a larger bowl of plant material and sheep wool, built on top of horizontal branch. Clutch 1–4 eggs, usually 3 (average 2·7 in Malawi, 2·8 in South Africa), very variable (five main colour types identified), some plain white, cream or pinkish-cream, others with irregular blotches of red-brown or various shades of ashy pink, usually at large end, some speckled black and charcoal-grey, average size in S Africa 24·3 × 18·2 mm; incubation 16–17 days; chicks fed by both parents, both also remove faecal sacs, nestling period 17–18 days. Exclusive host of African Cuckoo (*Cuculus gularis*); also parasitized by Jacobin Cuckoo (*Clamator jacobinus*) in South Africa.

Movements. Resident; possibly some short-distance movements in S.

Status and Conservation. Not globally threatened. Generally common to abundant and widespread in all kinds of open woodland habitats; one of the commonest birds of African savanna. Scarcer to locally uncommon in some parts of range in dry areas, including Sahel (in N) and W Karoo and Namibian coast (in SW), also in deep forest, and in grassland or highlands (e.g. Lesotho). In S Africa, 1 pair/11–30 ha in acacia woodland; and 13, 18 and 25 birds/100 ha in, respectively, mopane (*Colophospermum*), acacia and miombo (*Brachystegia*) savanna. Thought unlikely to become threatened in the foreseeable future, as it benefits from tree-cutting in dense forests and from tree-planting in grasslands.

Bibliography. Beasley (1988), Brosset & Érard (1986), Clancey (1956), Dean (1974b), Ewbank (1996), Forbes-Watson (1977), Fry *et al.* (2000), Harrison *et al.* (1997), von Helversen & Wickler (1971), Herremans & Herremans-Tonnoeyr (1997), Hockey *et al.* (2005), Maclean (1993), McCarthy (2006), Pasquet *et al.* (2007), Sibley & Monroe (1990), Skead (1962), Tarboton (1986), Tarboton & Clinning (1977), Tarboton *et al.* (1987), Thomson (1978), Underhill (1988), Vaurie (1949, 1962), Walsh *et al.* (1990), Wood (1991), Zimmerman *et al.* (1996).



23. Velvet-mantled Drongo

Dicrurus modestus

French: Drongo modeste **German**: Samtdrongo **Spanish**: Drongo Modesto

Other common names: Forest Drongo; Principe Drongo (*modestus*)

Taxonomy. *Dicrurus modestus* Hartlaub, 1849, Principe, Gulf of Guinea.
Sometimes treated as conspecific with *D. adsimilis*, but recent DNA analysis supports recognition of two distinct species; both were previously thought to be part of a superspecies with *D. fuscipennis*, *D. macrocercus*, *D. waldenii*, *D. forficatus* and *D. aldabranus*, but morphological and genetic differentiation too great to support such a relationship. Additional studies needed to clarify taxonomic position of races *coracinus* and *atactus*, which intergrade fully in SW Nigeria (Ondo and Benin provinces) and Cameroon; *coracinus* and race *divaricatus* of *D. adsimilis* behave more or less as distinct species, differing in behaviour, voice and plumage, with limited hybridization in areas of range overlap (apparent hybrids reported in Nigeria, DRCongo and Angola); *atactus* initially described as a possible hybrid between those two taxa. Proposed race *ugandensis* regarded as a synonym of *coracinus*. Three subspecies currently recognized.
Subspecies and Distribution.
D. m. atactus Oberholser, 1899 – Sierra Leone, S Guinea, Liberia, Ivory Coast, SW Ghana (S from Kintampo and Tafo), S Togo, S Benin and SW Nigeria; possibly W Cameroon, possibly also N Angola, possibly also E DRCongo.
D. m. coracinus J. Verreaux & É. Verreaux, 1851 – S Nigeria, Bioko I (Fernando Póo), S Cameroon and SW Central African Republic (Lobaye) E to extreme SW Sudan (Bengegai), W & S Uganda and W Kenya (Kakamega), S to Gabon, PRCongo, NW Angola and C DRCongo (S to Kasai and Maniema).
D. m. modestus Hartlaub, 1849 – Príncipe I, in Gulf of Guinea.

Descriptive notes. 24–28 cm; 44–53 g (mainland races). Nominate race has head and underparts deep velvety black, unglossed except for slight greenish-blue sheen on forehead and crown; mantle and back black with some faint violet-blue reflections (not much visible in field); wing browner, more blackish-brown, and with moderate gloss, looking brighter than rest of plumage, inner webs of flight-feathers dark grey-brown; tail long (male 115–134 mm, female 116–127 mm) and forked (male depth of fork 12–24 mm); iris deep red; bill strong, hook-tipped, black; legs black. Distinguished from *D. ludwigii* and *D. atripennis* by larger size, deeply forked tail and less gloss; from *D. adsimilis* by darker underside of flight-feathers, less (or no) gloss on back and underparts. Sexes alike in plumage, male slightly larger than female. Juvenile has pale barring on central belly and undertail-coverts, brown iris. Races differ in size and proportions, colour of mantle and degree of contrast with head and nape, colour and relative darkness of flight-feathers and their inner webs: *coracinus* is smaller and slightly less glossy than nominate, has thicker and more visibly velvety black mantle with bluish tinge (but virtually unglossed), contrasting bluish-glossed dark crown and nape, dark brownish wings with upperwing-coverts and tertials glossed greenish, flight-feathers tinged brownish on upper surface and greyish below, edges black with greenish gloss, underparts dull bluish-black, tail shorter (male 102–117 mm, female 105–113 mm) but more deeply forked (male depth 15–29 mm), iris orange-red to deep scarlet, juvenile lacks barring below; *atactus* is similar in size to previous, dark glossy violet-blue all over, gloss stronger on upperparts (much more visible than on nominate), back a little darker but not velvety, wings and tail glossed steely green, inner webs of flight-feathers more brownish (less blackish) than in previous race and with very glossy underside (as if covered with oil), tail length (male 104–116 mm, female 103–114 mm) and fork depth (male 14–29 mm) much as for last race, juvenile barred on lower belly and undertail-coverts. Voice. Extensive and very varied repertoire of twangy whistles and fluty notes, nasal harsh calls and scratchy sounds, including loud rasping like sound of tearing paper. Race *coracinus* described as very noisy in forests of Gabon and DRCongo. Voice more ringing and melodious than that of *D. adsimilis* and with similarities to (possibly imitations of) other drongos, e.g. "dzaa-dzaa-weet-wheep" or "dza-ti-ti-way-tea-wait" reminiscent of *D. ludwigii* in Cameroon, and rasping "jarr-jarr" and pure whistles much like those of *D. atripennis* in Gabon (where individual once observed singing while bathing). In Gabon variety of tit-like calls, e.g. "tee-ta" or plaintive churrs alternating with harsh notes; in Cameroon a very regular trisyllabic refrain, fluty and melodious, "whip-whip twuut", sometimes given in regular descending tones; in Uganda repeated nasal phrases, e.g. "chi-chi-wew-jor-chop" and "woo-titi-woo-titi-woo-tititawoo", with many variations. In Cameroon, pairs duet from songposts at forest edge with scratchy tuneless phrases, very much like those of *D. adsimilis*. On Principe, typical stereotyped vocalizations of nominate race clearly different from those of mainland races, include regular soft "weeh, yiup, yiup, yiup", or repeated "tieu wee tiuh" ending with "tieu weeeh"; various hoarse calls, including brief "krrueink", long "kchiiiir", "kchtuiiiin" or "zwuiiiin"; also a loud and hoarse call, rarely heard, described as unmusical and dissonant, unpleasant, nearly frightening, more similar to cry of a cat than to that of a bird; also, a short and monotonous plaintive cat-like call repeated between long silences.
Habitat. Wide range of habitats. On Principe, nominate race found in practically all main types of wooded habitat: patches of primary forest below 600 m (and possibly higher), mature or dense secondary forest, plantations, and sparsely wooded clearings around isolated farms; appears to have adapted to more open habitats such as coffee and cocoa plantations; often seen perched on roadside wires. Race *coracinus* mainly in lowland forests, but also to 1600 m in Cameroon, E DRCongo and Kenya, avoiding lower and dense vegetation layers, with preference for forest-edge canopies, large trees along tracks and roadsides, and gallery forest; avoids open habitats in areas where *D. adsimilis* present (e.g. Uganda, Kenya), but also where it is absent (e.g. Gabon, S Nigeria); occupies forest edges and clearings, farmland, plantations, forest–grassland mosaic, and other man-made open habitats with large trees; on Bioko present in dense forest at up to 1200 m, and also in upper canopy of cotton tree (*Bombax*) within coastal cocoa plantations. W African race *atactus* occurs in mature and secondary forests (e.g. Nigeria), glades and clearings in both lowland and montane forests (to 1100 m in Liberia), forest–grassland mosaic, gardens, parkland country and savanna, riverine forests. Original habitat high canopy of mature and old secondary forest, perching often in shade of lower canopy (mainly above 25 m in canopy in Liberia), hence well separated ecologically from *D. atripennis*, which occupies mature forest understorey where the two species co-exist.
Food and Feeding. Mainly insectivorous, feeding on grasshoppers (Orthoptera), beetles (Coleoptera), termites (Isoptera), cicadas (Cicadidae), mantids (Mantidae), moths and butterflies (Lepidoptera), and bees and wasps (Hymenoptera). Pieces of bark found in stomach contents on Principe. Insects caught mainly in air; sometimes makes circular flight to catch larger insects, also swoops to pick prey from ground, gleans from high branches and foliage, and sallies above canopy. Large prey items held with feet and dismantled with bill. Often hunts at dusk, almost nocturnally. Race *coracinus* rather shy and forages near forest openings and tracks; perches upright on tree branch 6–10 m high. Race *atactus* more noisy and lively, foraging higher in canopy (over 25 m in Liberia), hovering, gleaning, and sallying out; frequent member of mixed-species parties. On Principe, nominate race reported as less active and having less burst of speed than its continental counterparts, often perching in pairs on dry branches in treetop and remaining inactive for long periods; occasionally seen to pounce on insects from branch only 4–5 m above ground. Found singly, in pairs and small parties of 3–4 individuals; groups of up to eight reported from Principe.
Breeding. Nestlings and fledglings in May–Jun in Liberia, season Dec–Feb in S Ghana; breeds May–Jun and Oct–Nov, possibly all year, in S Nigeria; Nov–Mar (main dry season) in Cameroon, and Sept–Dec in Gabon; breeds Sept–Jan (middle of short dry season) on Principe; probably all year (recorded Jun, Jul, Nov and Mar) in E DRCongo. Territorial, and aggressive towards large birds such as hornbills (Bucerotidae) and raptors, sometimes also smaller birds such as cuckoos (Cuculidae), kingfishers (Alcedinidae) and weavers (Ploceidae); race *atactus* reported as mobbing crows (Corvidae), herons (Ardeidae), cranes (Gruidae), vultures (Accipitridae), kites (*Milvus*), buzzards (*Buteo*) and hornbills, sometimes soaring above and clinging on to back of the intruder. Displays and duets from prominent posts during breeding season, male singing and bowing from side to side while female crouches and flutters wings. Nest a shallow cup made from interlocked thin twigs and rootlets, fibres (e.g. black palm) and lichens, bound together with cobweb, placed on thin fork near end of lateral branch, in Liberia (race *atactus*) 6–18 m above ground in secondary forest and 30–40 m up in primary forest; territory 6–10 ha in Gabon (*coracinus*). Clutch up to 3 eggs. No further information.
Movements. Resident.
Status and Conservation. Not assessed. Thought not to be globally threatened. Widespread and locally common; scarce in some parts of range, as in S Benin (Pobe) and extreme SW Nigeria (*atactus*), and very rare in S Togo. Distributional limits of race *atactus* uncertain; possibly present in W Cameroon, and isolated specimens described from around rainforest in N Angola and E DRCongo (Ruzizi valley, in Uele; NW L Tanganyika). Densities of up to 10 pairs/100 ha in Liberia mature forest (*atactus*) and 10–16·7 pairs/100 ha in Gabon (*coracinus*). Nominate race, restricted to Principe I (136 km²), is widespread in open and forested habitats except primary forest on C massif, commonest in open plantations and edge habitats; numbers unknown but probably small, and taxon, when treated as a full species, is considered Near-threatened owing to its small range and various threats, such as increased use of pesticides (leading to reduction in prey availability) and reduction in tree cover following expansion of farmland. Likely niche extension by this race to man-made habitats may have partly compensated for a possible decrease in its abundance since 1950s.

24. Mayotte Drongo
Dicrurus waldenii

French: Drongo de Mayotte **German**: Mayottedrongo **Spanish**: Drongo de la Mayotte

Taxonomy. *Dicrurus waldenii* Schlegel, 1865, Mayotte (Maore), Comoro Islands.
Recent DNA studies indicate that closest relatives are *D. forficatus* and *D. aldabranus*; all three previously thought to be part of a superspecies that contains also *D. fuscipennis*, *D. macrocercus*, *D. adsimilis* and *D. modestus*, but morphological and genetic differentiation too great to support such a relationship. Monotypic.
Distribution. Mayotte (Maore), in SE Comoro Is.

Descriptive notes. 34·5–38 cm. Has uniformly deep lustrous black plumage with dark dull greenish-blue gloss; tail very long (175–206 mm) and deeply forked (58–90 mm), distal end of outer rectrices curving strongly outwards; iris red; bill strong, heavier and longer than that of *D. adsimilis* and *D. macrocercus*, black; legs black. Sexes alike, male tending to be slightly larger than female. Immature is more brownish-black and less glossy than adult, with shorter and less forked tail, remiges dull blackish-brown, underparts slightly paler, traces of white tips on undertail-coverts and underwing-coverts. Voice. Very vocal, with extensive repertoire of buzzy and scratchy calls, including loud "tyok" repeated several times, "squa-aa-kuchuk", and throaty "choo-kroo-kreech" at nest. Song includes harsh repetitive jumble of chirps and squeaks, varied whistles, twangy notes and nasal sounds; at times, one pure and melodious note repeated loudly, with long silent intervals between. Pairs perform remarkable duets throughout breeding season at different points in territory (especially in vicinity of nest), with low-pitched "wraaak" immediately followed by contrasting rolling whistles and nasal grinding notes alternated by partners; male calls "chu-chi", female responds with "chu" and male ends with "chit", all of which repeated in rhythm by both birds while displaying. Imitates calls from other bird species, e.g. Common Myna (*Acridotheres tristis*).
Habitat. Occurs mainly in summit rainforests and mixed secondary humid forest above 200 m, including those dominated by mangoes (*Mangifera*), and with maximum densities in last remnants of low-altitude natural forest (at Sohoa). Also, in much lower numbers, in adjacent degraded forest patches alternating with ylang-ylang (*Cananga odorata*) plantations, orchards, forest clearings and agricultural fields; marginally in mangroves and adjacent mature woodland. Seems to prefer wet locations, with high percentage cover of tall trees, within large forest patches at higher altitude.
Food and Feeding. Mainly insectivorous. Recorded prey include cicadas (Cicadidae) and other homopteran bugs, butterflies and moths and caterpillars (Lepidoptera), wasps (Hymenoptera), mosquitoes (Culicidae) and other flies (Diptera), grasshoppers (Orthoptera), water-beetles and other beetles (Coleoptera), also spiders (Araneae) and millipedes (Diplopoda). Cicadas (Cicadidae) represent almost half of prey, and play an essential role during breeding season. Possibly takes some small vertebrates such as small skinks (Scincidae) or chameleons (Chamaeleonidae), but this not yet reported. Exploits mostly vegetation strata between 2 m and 12 m high. Normally hunts from perch, and uses various techniques; sallies out in manner of flycatcher (Muscicapidae), glides down, hovers, and slaloms between stands of vegetation. Captures insects between ground level and more than 20 m up, half of them in flight, the rest on trunks, branches, leaves, flowers or the ground; normally catches prey with the bill, but occasionally with claws.
Breeding. Nesting observed between Sept (first eggs) and Feb (last fledglings), coinciding with Nov–Mar rainy season; only one successful brood per year. Highly territorial and extremely ag-

gressive, attacking and chasing from vicinity of nest any potential predator, such as diurnal and nocturnal raptors, e.g. Frances's Sparrowhawk (*Accipiter francesii*) and Common Barn-owl (*Tyto alba affinis*), Common Myna, brown lemur (*Eulemur fulvus*), introduced carnivores and even human observers, but also harmless birds e.g. Madagascar Paradise-flycatcher (*Terpsiphone mutata*) or Madagascar Turtle-dove (*Streptopelia picturata*). Duets and courtship displays throughout breeding season, one bird (presumably the male) offering nesting material or insects to its partner on occasion; partners, while singing, each bob head and body up and down vigorously in rapid alternation, facing and almost touching each other, in a powerful vocal and dancing display. Nest built by both parents, sometimes taking less than a week, a solid rounded cup, external diameter and depth c. 17 cm and 8 cm, internal diameter and depth c. 9 cm and 4 cm, made from intertwined vegetable fibres, placed 5–18 m (average 12·4 m) above ground on fork of horizontal branch overhanging area clear of vegetation; wide variety of trees used, such as mango, mbarabai (*Grisollea myrianthea*), sang dragon (*Pterocarpus indicus*), ylang-ylang, African tuliptree (*Spathodea campanulata*); average territory size at Combani 2·4 ha in natural mixed humid forest, 9·6 ha in surrounding semi-wooded areas with agricultural fields. Clutch 1–3 eggs (average 2·3), pinkish-cream, spotted with rufous on underlying purplish-grey, mainly at top of large end, c. 20 × 27 mm; if first attempt unsuccessful, will build new nest in different location and lay replacement clutch; incubation by both sexes, one incubating partner reported as feeding the other on occasion, period 19–21 days; nestling period 17–22 days; fledglings continue to be fed outside nest by both parents for at least one month, and remain with parents until start of next breeding season. Normally 2–3 fledglings per brood (average of 16 broods 2·1); calculated failure of individual nests as high as 75%, resulting mainly from high predation levels at either egg stage (hatching success 53 %) or chick stage (fledgling success 46%); percentage of pairs successful varies from year to year, e.g. during 2002–2003 season average productivity 1·4 fledglings per pair for sample of ten pairs, 70% of which had succeeded in raising chicks by end of season.

Movements. Resident.

Status and Conservation. ENDANGERED. Recent population estimate suggests species should be downgraded to Vulnerable. Restricted-range species: present in Comoro Islands EBA. Confined to island of Mayotte (surface area 374 km²), where present only on Grande Terre (absent from Petite Terre and other islets); the only drongo on Mayotte. Global numbers earlier underestimated at c. 100 individuals; research in 2002–2004, based on point counts and density measurements (e.g. 42·4 and 10·4 pairs/100 ha, respectively, in forest and semi-cultivated area), reassessed population size at minimum of 2500 pairs. Commonly found above 200 m around the four mountains that retain large expanses of humid natural forests in N & C of the island (Hachiroungou, Mtsapéré, Combani and Bénara), and also at lower altitude along W coast (in Sohoa forest). Occurs also, at low density, in areas of degraded habitats between mountains, and in some mangroves in NE (Dzoumonyé-Bouyouni), SW (Miréréni-Chirongui) and W (Tsingoni-Mroale-Soulou) of the island. Absent from entire S peninsula (Mt Choungui and the lowland dry forests of Dapani-Sazilé). Has suffered from continuing decline in both extent and quality of natural habitat over past decades; 6000 ha of forest (25% of the island's total) disappeared between 1949 and 2002. A network of forest reserves totalling c. 4770 ha and covering all remaining natural forests has been established, but steady human population growth on Mayotte has led to illegal clearance for cultivation of food crops and timber, and this remains a major threat to this species' future survival. Introduction of new nest predators, e.g. mongooses (*Herpestes*), monkeys, snakes and lizards, represents potentially a very serious threat. This species should continue to be monitored, and be used as a flagship for environmental programmes designed to increase the human population's awareness of the need to preserve the forests. More detailed studies on its population ecology and dynamics also desirable.

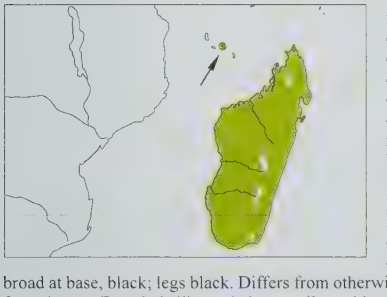
25. Madagascar Crested Drongo

Dicrurus forficatus

French: Drongo malgache **German**: Madagaskardrongo **Spanish**: Drongo Malgache
Other common names: Crested Drongo



Taxonomy. *Lanius forficatus* Linnaeus, 1766, south-east Madagascar.

Recent DNA studies indicate that this species' closest relative is *D. aldabranus*, following colonization of Aldabra from Madagascar less than 125,000 years ago, and also that it is more closely related to *D. waldenii* than to the older *D. fuscipennis*; all were previously thought to be part of a superspecies that contained also *D. macrocercus*, *D. adsimilis* and *D. modestus*, but morphological and genetic differentiation too great to support such a relationship. Two subspecies recognized.

Subspecies and Distribution.

D. f. potior (Bangs & T. E. Penard, 1922) – Anjouan (Ndzuani), in C Comoro Is.

D. f. forficatus (Linnaeus, 1766) – Madagascar and some larger inshore islands, including Nosy Bé, Nosy Komba and Nosy Boraha (I Sainte Marie).

Descriptive notes. Male 26–30·5 cm and female 18–24·5 cm (nominate), male 28·5–31·5 cm and two females 25 cm and 27·5 cm (*potior*); 39–55 g. Rather large, long-tailed drongo with strong, broad-based bill, tuft of elongated frontal feathers (20–40 mm) at base of bill forming slightly curving crest. Male nominate race has uniformly deep lustrous black plumage glossed with steely dark greenish-blue, primaries brownish-black when plumage worn; tail long (120–140 mm) and moderately forked (depth of fork 25–48 mm), outer rectrices curved outwards; iris dark reddish-brown or crimson-red; bill strong and broad at base, black; legs black. Differs from otherwise almost identical *D. adsimilis* in presence of frontal crest. Female is like male but smaller, with plumage browner and much less glossy. Immature has dark brown plumage, less glossy than adult, mixed with whitish on head, nape and neck, barred whitish or buff on underparts, and dotted with small white feathers on inner bend of wing, also has shorter and less forked tail, little or no crest, iris initially brown. Races differ only in size: *potior* is larger than nominate, with considerably heavier and longer bill, longer tail (143–153 mm) deeply forked (39–46 mm), also immature said to have varying tendency towards non-glossy black abdomen and undertail-coverts. Voice. Very vocal and noisy, with extensive repertoire. Loud calls and whistles, as well as softer whistled calls, given on Madagascar, with sometimes a 3-note monotonous "twee-too-hee", "t-seee-churr-chirr" or "kák-kák" jerky calls; also a harsh "kék" when mobbing human intruders. Song consists of succession of short strophes, such as double fluty notes or trisyllabic nasal and grinding sounds, repeated 5–10 times, developing into very rapid jingle of nasal chirps and sharp squeaks. Anjouan birds (race *potior*) reported as giving harsh "kwee-u", repeated at intervals of c. 5 seconds, and a single "quok"; found to have very similar repertoire to that of nominate race on Madagascar. Often imitates calls and songs of other birds, including Madagascar Coucal (*Centropus toulou*), Madagascar Black Bulbul (*Hypsipetes madagascariensis*), Common Myna (*Acridotheres tristis*) and Frances's Sparrowhawk (*Accipiter francesii*) in Madagascar, and even domestic animals such as cats or chickens around villages.

Habitat. Present in all wooded habitats, even with few scattered trees, from sea-level to 1875 m in Madagascar; in highlands, above 1000 m, largely restricted to natural forests. Found in all types of both primary and secondary forest (including riverine, humid, dry and spiny forests), degraded woodland and regrowth following exploitation, also in plantations of e.g. pine (*Pinus*), eucalypts (*Eucalyptus*), sisal (*Agave sisalana*), orchards, clearings with sparse trees in cattle-farming and agricultural areas, also gardens in villages and urban residential areas; particularly fond of clearings and forest edges, also perching on roofs and fences, rarely flying over large distances. Occupies similar habitats on Anjouan, including more open parts of evergreen forest above 700 m, cultivated areas with large trees, and coconut (*Cocos nucifera*) plantations.

Food and Feeding. Invertebrates, some small vertebrates; fruits. Stomach contents from Madagascar include spiders (Araneae), beetles (of families Cerambycidae, Curculionidae, Elateridae, Scarabaeidae, Tenebrionidae), robber-flies (Asilidae), grasshoppers and locusts (Orthoptera), wasps (Hymenoptera), cicadas (Cicadidae) and dragonflies (Odonata); feeds also on vertebrates such as small chameleons (Chamaeleonidae). Stomach contents from Anjouan comprised mainly insects, including beetles and to lesser extent grasshoppers and caterpillars, as well as spiders and, in one case, fruit remains. Reported as eating fruits of arofy tree (*Commiphora guillaumini*), and probably dispersing its seeds in dry forests of W Madagascar. Hunts mostly in middle and upper canopy. Frequently seen on prominent perch, from which it sallies out to capture large insects on the wing, coming back to same perch. Often flies slowly, gliding from branch and swooping up to perch, but capable of slaloming between vegetation stands and performing aerial acrobatics on occasion. After a capture, often gives short song, raises crest and flicks tail while holding prey in bill; grasps large food item with its foot, dismembering it with the bill and eating it piecemeal; large body parts of prey may be well mandibulated before being swallowed. Usually solitary, in pairs or in small family groups. In Madagascar, joins mixed-species flocks of insectivorous birds such as cuckoo-shrikes (*Coracina*), bulbuls (Pycnonotidae), tetrakas (*Bernieria*, *Xanthomixis*), paradise-flycatchers (*Terpsiphone*), sunbirds (*Nectarinia*), newtonias (*Newtonia*), white-eyes (*Zosterops*) and vangas (Vangidae), catching prey disturbed by these, and giving alarm when predators detected. In dry forests of W Madagascar, a regular member of mixed flocks (with up to 17 species) and the one exhibiting the most contrasted changes in hunting techniques: when foraging with other species, snatches or gleans vegetation or ground below 6 m to capture large slow-moving arthropods e.g. Lepidoptera larvae, Coleoptera, Orthoptera, arachnids, millipedes (Diplopoda); when hunting alone, sallies to catch small flying insects (e.g. Diptera) in air above 6 m. Benefits greatly from association with mixed flock, having feeding rates higher than when hunting alone; joins such flocks twice as frequently during non-breeding season than in breeding season. Occasionally steals food from other birds.

Breeding. Laying in Sept–Dec (likely peak Oct–Nov) in most of Madagascar, and Oct to early Feb in SE dry areas; two males with enlarged testes in Sept on Anjouan; one brood per year. Following details refer to nominate race (Madagascar); no information for race *potior* (Anjouan). Monogamous; report of males fighting over one female. Aggressively territorial; pair will vigorously drive out conspecifics entering territory, and will harass and relentlessly chase any other animal coming too close to nest, including raptors such as Frances's Sparrowhawk, Madagascar Serpent-eagle (*Eutriorchis astur*) and the huge Madagascar Fish-eagle (*Haliaeetus vociferoides*), and other large birds e.g. Pied Crow (*Corvus albus*), Hook-billed Vanga (*Vanga curvirostris*), Cinnamon Roller (*Eurystomus glaucurus*) and Cuckoo-roller (*Leptosomus discolor*), and also lemurs (Lemuriformes), cows, dogs and even humans. Nest built by both sexes, a small and shallow cup in which adult barely fits (looking as if perched on top, rather than sitting in cup), two nests had external diameter 11·5–12 cm, depth 6 cm, internal diameter 8 cm, depth 4–4·5 cm, coarsely made from intertwined fine vegetable fibres, including herbaceous stems, grasses, leaf stems or rootlets, bound together with spider webs, lined with grasses, coarse fibres or small dried branches, suspended from horizontal fork 2·5–14 m above ground at extremity of tree branch, sometimes in flat crotch or between main trunk and horizontal branch, at forest edge, above open area or stream in forest, or in lower branch of large tree in gallery forest or in mango (*Mangifera*) grove. Clutch 2–4 eggs, generally 3, white to salmon-pink, with light lilac blotches and reddish-brown and greyish spots, more numerous and blurred at larger end, 24·4–26 × 17·6–18·4 mm; incubation by both sexes, male seen to offer prey to incubating female; chicks fed by both parents; no information on duration of incubation and nestling periods; fledglings fed by both parents, period of dependence not documented.

Movements. Resident.

Status and Conservation. Not globally threatened. Nominate race rather common in most wooded regions of Madagascar except in highlands, where rarer above 1000 m (uncommon at Montagne d'Ambre; unrecorded from several forest surveys above 1260 m), and sometimes restricted to natural forests. Second commonest large passerine after Madagascar Black Bulbul at Anjanaharibe-sud (875 m), with density of 66 birds/100 ha. Formerly reported also from islets of Nosy Tanikely and Nosy Faly, both near Nosy Bé. No signs of population decline in Madagascar, where tolerant of habitat degradation; present in all man-made rural habitats and may even have benefited from human activities. Easily observed at low or middle altitudes in many reserves and national parks across Madagascar, e.g. Ankarafantsika, Andasibe-Mantadia, Ranomafana, Kirindy and Andohahela National Parks, Lokobe (Nosy Bé), Ankarana and Anjanaharibe-sud Special Reserves, Tsingy Bemaraha Strict Nature Reserve and Berenty Private Reserve. Known to host a blood parasite responsible for avian malaria (*Haemaproteus dicruri*), but this probably not a threat to the species' future survival. Anjouan race *potior* considered in 1958 to be fairly common in more open parts of evergreen forest above 700 m; in N of island, scarcer in cultivated areas, and not very common but widely distributed in forested areas down to sea-level (at Bambao and Dzindri). Little more recent information available from Anjouan, where generally considered uncommon to rare, and possibly at risk owing to small population size with low densities and its restriction to a small island (424 km²).

26. Aldabra Drongo

Dicrurus aldabranus

French: Drongo d'Aldabra **German**: Aldabradrongo **Spanish**: Drongo de Aldabra

Taxonomy. *Buchanga aldabrana* Ridgway, 1893, Aldabra Atoll, Seychelles.
Recent DNA studies indicate that this species' closest relative is *D. forficatus*, its likely origin following colonization of Aldabra less than 125,000 years ago (after the atoll's last submersion); both were previously thought to be part of a superspecies with *D. fuscipennis*, *D. macrocercus*, *D. adsimilis*, *D. modestus* and *D. waldenii*, but morphological and genetic differentiation too great to support such a relationship. Monotypic.
Distribution. Aldabra Atoll, in SW Seychelles.

Descriptive notes. 23 cm; 40–53 g. Plumage is entirely deep lustrous black with dark dull greenish-blue gloss, duller on flight-feathers and tail; long frontal feathers curving forwards and slightly upwards; tail long (128–145 mm) and moderately forked (depth of fork 26–35 mm), black in fresh plumage but browner when worn, outer rectrices curving slightly outwards at distal end; long nasal/frontal feathers; iris red; bill very strong and slightly hooked, black; legs black. Differs from relatively similar *D. forficatus* in having reduced frontal crest. Sexes alike, male tending to have longer bill tuft. Immature is distinctive, grey-brown above, with white uppertail-coverts, white-edged wing-coverts and secondaries, and most feathers with buffy terminal edges, almost completely white below with irregular amounts of buffy or brownish-grey, iris brown, also has shorter wing, shorter and less forked tail than adult. Voice. Very vocal and noisy, with very varied repertoire of calls and short phrases combining nasal and metallic squawks, melodious whistles and fluty notes, scolding chatters, harsh chuckling sounds and scratchy cries. Often sings from songpost, mainly after dawn or during early morning. During breeding season, male and female sing together in sort of duet in vicinity of nest; also exchange soft whistling and muttered calls at nest-building stage, possibly as part of courtship. Nasal and wheezy contact calls include "oink-eugh" or "eenk-yawk", and in flight high-pitched "eugh-eugh-eugh". Harsh nasal "chirrr", and alarm call of 3 musical whistles followed by 2 nasal harsh notes, "ti-ti-you caw caw" or "ti-ti-po fa fa", repeated rapidly and continuously when driving intruder from nest; after successful chase, "fa-wip" repeated several times from a branch. Distress calls reported when nest approached. Scolding chatters, reminiscent of alarm call of extinct Aldabra Brush-warbler (*Nesillas aldabrana*), possibly by juveniles begging for food.
Habitat. Present in the three main wooded habitats on Aldabra atoll (maximum elevation 17 m), i.e. dense scrub, *Casuarina equisetifolia* coastal forest, and mangroves; breeds preferentially in the two last, where taller trees probably provide better nesting sites. Uncommon or absent in open mixed scrub at E side of Grande Terre.
Food and Feeding. Mainly insects, also small vertebrates such as geckos (Gekkonidae) and lizards. Insects include beetles (of families Curculionidae, Carabidae and others), both winged and unwinged ants (Formicidae), cicadas (Cicadidae) and other homopteran bugs, grasshoppers (Orthoptera), various heteropteran bugs, and Hymenoptera (including sphecid wasps). Perches in very upright posture, tail hanging vertically below. Hawks insects on the wing while gliding from observation post, pursuing and slaloming between stands of vegetation or flycatching; flight very undulating. Prey also captured on branch or trunk of tree, by "perch-and-pounce" technique. Sometimes feeds on ground-dwelling prey; this applies especially to juveniles having not yet acquired good aerial hunting skills. Prey normally caught with the bill, occasionally with the claws. Often associates with foraging Madagascar Coucals (*Centropus toulou*), capturing insects displaced or uncovered by the latter (a relationship that may involve some form of parasitism); also with resting Aldabra giant tortoises (*Dipsochelys dussumieri*), catching flying insects attracted by their presence or their dung. Observed hunting at dusk, and also at night around artificial lights and over beach sand (where insects more easily spotted during daytime or dusk).
Breeding. Recorded mid-Sept to Nov (first nests built) and Mar–May (last fledglings), depending on year; brood-feeding coinciding with main rainy season (Dec–Mar); first laying normally Nov–Dec, clutches in Jan–Feb corresponding to replacements; one successful brood raised per year. Territorial, with stable and very precise territory boundaries throughout breeding season; extremely aggressive, driving out all intruders by mobbing, "dive-bombing", pecking at and pursuing large creatures such as crows (*Corvus*) or even humans, as well as other animals approaching too close to nest, these ranging from herons (Ardeidae), frigatebirds (*Fregata*) and boobies (*Sula*) to coucals (*Centropus*), turtle-doves (*Streptopelia*), falcons (*Falco*), bulbuls (*Hypsipetes*), terns (*Sterna*) and fodies (*Foudia*), and including migrant falcons and rollers (*Coracias*), and even fruit-bats (*Pteropus*); one bulbul reported as having been fiercely pecked at and knocked down by the drongo. In courtship, partners face each other, bills held slightly above horizontal, shaking wings vigorously and wagging tail from side to side, while uttering soft high-pitched squeaky sounds; one bird (presumed male) may pick a leaf and offer it to partner. Nest normally built by both sexes within 10–20 days, unfinished nest sometimes abandoned in event of human disturbance; a perfectly rounded cup made from intertwined fine vegetable fibres e.g. casuarina needles, wood-rush (*Luzula*) or dry monocotyledon grass leaves, bound with cobweb, nest thicker on sides and more thinly constructed at base (through which contents often visible), one nest 13 cm across and 5 cm deep externally, 8 cm across and 2 cm deep internally; generally woven in fork towards end of thin horizontal branch 2–8 m (exceptionally to 13 m) above ground, preferably in taller tree such as casuarina or mangrove tree (e.g. *Rhizophora mucronata*), also on smaller native tree e.g. fig (*Ficus*), or in *Premna serratifolia*, *Euphorbia pyrifolia* or *Mystroxylon aethiopicum* in lowland scrub habitat; average territory size 2·25 ha in casuarina woodland (on Picard), 4·5 ha in mixed scrub (Malabar; Passe Hoareau). Clutch 1–3 eggs (average 2·1), decreasing through breeding season, white to pale flesh-coloured, with dark red spots more concentrated at larger end, average of two eggs 26·2 × 19·2 mm; if contents lost, up to five replacement clutches laid (normally builds new nest at different site predation, occasionally uses same nest); incubation and chick-feeding by both parents, incubation period 16–18 days, nestling period 15–19 days; juveniles dependent for at least several weeks after fledging, remain with parents until following breeding season, then chased by parents but still tolerated at territory periphery, which they defend against neighbouring conspecifics. Breeding success appears very low owing to extremely high proportion of clutches (73% of eleven clutches in 1999/2000) suffering predation, mainly by Pied Crows (*Corvus albus*) and rats (*Rattus*), and probably Madagascar Coucals (*Centropus toulou*), herons (*Ardea*, *Butorides*) and Madagascar Bulbuls (*Hypsipetes madagascariensis*), as observed or suggested in artificial nest experiments; feral cats and Madagascar Kestrels (*Falco newtoni*) also suspected of taking chicks; annual productivity low, less than 20% of 14 pairs successful in rearing young on Malabar during 1976/77 season (0·6 fledglings per pair), and on Picard similar values in 1999/2000 (only two of ten pairs successful, 0·4 fledglings per pair) and in 2000/2001, with hatching success 29% and fledging success for hatchlings of 80% over the two seasons; only 23% of eggs laid produced a fledgling; successful nests produce up to three fledglings, but normally only one or two (average 1·6). First breeding not until at least 2 years.
Movements. Resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Aldabra EBA. Nowhere abundant, and very uncommon in open mixed scrub at E end. Confined to the four main islands of Aldabra Atoll (Grande Terre, Malabar, Polymnie, Picard) and some of their neighbouring islets, including larger lagoon islands of Esprit (where breeding reported), Moustique, I aux Cèdres, Gros Ilot and Michel. Tiny global range (154 km²) and small population size of c. 1500 individuals, putting it at risk from catastrophic events, such as disease and cyclones. No apparent decline in numbers reported. As Aldabra is a nature reserve, as well as a World Heritage Site, the species' habitat is adequately protected. High nest-predation rates may limit population size, and could be significantly reduced if introduced rats and cats were eradicated; strict control of organic waste required around settlement and camps, to prevent Pied Crow numbers increasing.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family CALLAEIDAE (NEW ZEALAND WATTLEBIRDS)

- Medium-sized to large passerines with short rounded wings, relatively long tail, sturdy legs with unusually long tarsus, distinctive orange or blue fleshy wattle below gape, and robust bill; plumage blue, or black and reddish-brown.
- 25–38 cm.

- New Zealand.
- Forest, now mostly regenerating forests on offshore islands.
- 2 genera, 3 species, 3 taxa.
- 1 species threatened; 2 species extinct since 1600.

Systematics

A small but morphologically plastic family of medium-sized to large passerines, Callaeidae is confined to the three main islands of New Zealand and its near offshore islands. Increasingly, evidence is suggesting that this family is part of an ancient radiation of birds in New Zealand that probably took place via Australia in the early Tertiary, as has been shown by the investigations of J. G. Ewen and co-workers. There are three extant species, namely the South Island Saddleback (*Philesturnus carunculatus*), the North Island Saddleback (*Philesturnus rufusater*) and the North Island Kokako (*Callaeas wilsoni*). Two further species, the South Island Kokako (*Callaeas cinereus*) and the Huia (*Heteralocha acutirostris*), are now extinct.

The species-level taxonomy is currently in a state of flux. Some ornithologists consider that the two saddlebacks are better treated as conspecific, and the two kokako are likewise often regarded as subspecies of a single species. There are good reasons, however, for recognizing two species in each of the two genera *Callaeas* and *Philesturnus*. In *Callaeas* this treatment reflects not only the phylogenetic divergence between the two kokako suggested by the results of the genetic studies of S. A. Murphy and colleagues in 2006, but also marked differences in wattle colour, minor differences in plumage, statistically significant differences in morphometrics and, moreover, documented differences in behaviour that may have led to the extinction of the South Island taxon. Although little has been written about the vocalizations of the South Island Kokako, the few details that were published, in the last two decades of the nineteenth century, do, again, suggest significant differences. The recognition of two species of kokako was the preferred treatment of W. R. B. Oliver in 1955 and also, half a century later, of R. N. Holdaway and colleagues, T. H. Worthy and Holdaway, and A. J. D. Tennyson and P. Martinson.

With the two saddlebacks, there are statistically significant differences in morphometrics and well-documented differences in breeding biology, behaviour and vocalizations between the North Island population and the South Island population. It seems likely that these two, because of their phylogeographical isolation, would have undergone genetic divergence similar to that of the two *Callaeas* taxa. In the case of the saddlebacks, however, the most significant feature supporting the recognition of two species is the juvenile plumage that is present only in the South Island Saddleback. Treatment of the saddleback taxa as representing two full species is considered appropriate and was the preferred option of Worthy and Holdaway in 2002.

The taxonomic affinities of the family have been subject to a great deal of debate. In 1872, A. H. Garrod suggested that the Huia was related to the New World blackbirds (Icteridae) and to the starlings (Sturnidae). Five years thereafter, R. B. Sharpe placed

Callaeidae is a distinctive family, confined to New Zealand. It is herein considered to contain five species in three genera: two species of kokako (Callaeas), *one of them extinct; two of saddleback* (Philesturnus); *and the extinct Huia* (Heteralocha acutirostris). *Some taxonomists consider that saddlebacks and kokako should each be regarded as single species each with two races. Notwithstanding this, differences long noted between the* ***North Island Kokako*** *and its South Island counterpart in both bare-part coloration and behaviour have now been backed up by the results of phylogenetic studies.*

[*Callaeas wilsoni*, Otorohanga Breeding Centre, North Island, New Zealand. Photo: Mark Jones/Roving Tortoise Photos]

The two saddleback species are around 25 cm in length. In the ***North Island Saddleback*** *average weight is about 80 g in males and 70 g in females, while the South Island Saddleback* (Philesturnus carunculatus) *averages slightly heavier. Saddlebacks show a strong, slightly downcurved bill, a long tail with rounded tips and a distinctive downward curve, and short, rounded wings. The plumage is mostly glossy black, with a prominent dark orange or red-brown "saddle" from the mantle to the rump. A small pendulous reddish wattle extends from the gape down to the throat. The sexes are alike in plumage, although the wattle, which increases in size, colour intensity and fleshiness in the breeding season, is larger in the male.*

[*Philesturnus rufusater*. Photo: Paddy Ryan]

the New Zealand wattlebirds in his enlarged family Corvidae, positioned between the genus *Picathartes* (Picathartidae) and the vanga genus *Falculea* (Vangidae). C. R. Stonor, in 1942, concluded that *Callaeas*, *Philesturnus* and *Heteralocha* belong in a single group. He accepted Garrod's supposed evidence for the affinity of *Heteralocha* with the Sturnidae, but it would appear that this opinion was due to Stonor's misreading of Garrod's intentions. At that time, Garrod included Icteridae within Sturnidae, and he found that icterid and sturnid skulls were morphologically similar to that of the Huia; the primary similarity which Garrod found, however, was that all three had a large M. depressor mandibulae, the primary jaw-opening muscle of birds, which is simply an adaptation for using a long bill that can be opened forcibly against resistance. For this reason, as well as the group's restricted New Zealand distribution, its very long legs, and its short rounded wing with a large tenth primary, D. Amadon, in 1943, rejected the hypothesis that Callaeidae was allied with Icteridae or Sturnidae. He preferred the idea that the New Zealand wattlebirds, sometimes referred to as "wattled crows", belonged to a group of related families that included Corvidae, the drongos (Dicruridae), the butcherbirds (Cracticidae), the birds-of-paradise (Paradisaeidae), the Old World orioles (Oriolidae), and others. Later, however, Amadon clearly changed his mind, as E. Mayr and Amadon, in their 1951 classification, placed the New Zealand wattlebirds between Grallinidae, which at that time contained the Australian species the Magpie Lark (*Grallina cyanoleuca*), the White-winged Chough (*Corcorax melanoramphos*) and the Apostlebird (*Struthidea cinerea*), and Cracticidae, consisting of the butcherbirds and allies. *Corcorax* and *Struthidea* are now treated in a separate family, Struthideidae. A few years later, Oliver, in his work *New Zealand Birds*, combined the saddlebacks and the Huia in a family Philesturnidae, but placed the kokako in a separate but closely allied family, "Callaeadidae".

More recently, C. G. Sibley and J. E. Ahlquist conducted extensive analyses, using the technique of DNA–DNA hybridization, in an innovative attempt to elucidae the interrelationships of birds. Unfortunately, they lacked DNA samples of the three New Zealand wattlebird species and were, therefore, unable to study the possible relationships of the Callaeidae with other passerines; consequently, these authors combined them as one family, which they placed after their greatly expanded family Corvidae and immediately preceding the Picathartidae.

A novel recent hypothesis regarding the systematic position of Callaeidae, proposed by F. K. Barker and colleagues in 2004, was that it grouped with the berrypeckers (Melanocharitidae) and the two satinbird genera *Cnemophilus* and *Loboparadisea*. The last two taxa are currently treated as a subfamily, Cnemophilinae, within Paradisaeidae, but are considered by some researchers to have no close affinities with this group. J. Cracraft and co-workers, in 2004, and L. D. Shepherd and D. M. Lambert, in 2007, supported this new arrangement and suggested that Callaeidae, along with Melanocharitidae and the cnemophilines, were basal members of the "parvorder" Corvida as defined by Sibley and Ahlquist, giving evidence for an origin of the oscine radiation in Australia and Antarctica. Ewen and colleagues, however, have suggested that both Callaeidae and the newly described monotypic family Notiomystidae, the latter containing the Stitchbird (*Notiomystis cincta*), are part of a largely unresolved polytomy that also includes essentially all groups of oscine passerines except the most basal lineages. They consider this New Zealand lineage as not part of the "core Corvoidea", as defined by Barker and co-workers in 2004, nor of the parvorder Passerida, as defined by P. G. P. Ericson and U. S. Johansson in 2003. A further indication that these New Zealand endemics are not part of the Passerida radiation is that neither Callaeidae nor Notiomystidae possesses an insertion in the c-myc gene, which is proposed as being a synapomorphy for this clade.

It should be noted, however, that a recent analysis of various combined data sets, undertaken by M. Irestedt and J. I. Ohlson, revealed that the phylogenetic positions for Callaeidae, Cnemophilinae and Melanocharitidae were largely dependent on which genes were combined. In this analysis, a consensus found reasonable support for a Passerida affinity of Callaeidae and the cnemophilines, contrary to previous molecular studies.

Rather remarkably in such a small family, there are two significant issues affecting nomenclature. The earliest family-group name applicable to these birds was "Callaeadides", as proposed by C. J. Sundevall in 1836, but already by the 1840s G. R. Gray was using the form "Callaeatinae"; subsequently, over the last century or so, most workers have used the form "Callaeidae". As the genus name *Callaeas* is a Latinized Greek word with an altered ending, the International Code of Zoological Nomenclature requires that its stem be formed based on the genitive of the corresponding Latinized word. There appear to be no linguistic grounds supporting use of the forms "Callaeadidae" or

*Juveniles of the **South Island Saddleback** are very different from the adults. In place of the latter's glossy black plumage and reddish-brown "saddle", the juveniles have dark brown plumage with a chestnut wash on the head and rump, and a small, pink wattle, as well, initially, as a yellowish gape-line. This distinctive appearance has given rise to a separate local name, "jackbird", for this age-group. The immature South Island Saddleback is similar to the juvenile, but with increasing amounts of black on its body feathers, although it retains the brown juvenile rectrices and remiges. The wattles become increasingly reddish-orange, and slowly grow in size. In marked contrast, the plumage of the juvenile **North Island Saddleback** differs only slightly from its adult in being mostly brownish-black, not glossy black. As in the South Island species, juveniles initially have a yellowish gape-line, and the wattles are small and pink to begin with, becoming increasingly reddish-orange as they grow. All members of Callaeidae acquire adult plumage when they are about one year old. They then undergo a complete post-breeding moult during each annual cycle, which produces successive adult plumages with no perceptible change in appearance. In all members of Callaeidae, extant and extinct, there are ten primaries, the outermost of which is comparatively long, and nine secondaries, including three tertials. The tail is long, and rounded at the tip; it contains twelve rectrices. During moult, the primaries are shed outwards, starting at the innermost primary, and up to three new primaries can be growing simultaneously.*

Below: *Philesturnus rufusater*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Peter Ryan]

"Callaeatidae", though perhaps a case could conceivably be argued for the hitherto-unused "Callaeantidae". Nevertheless, an equally good and probably better linguistic case can be made for the form "Callaeidae", and as this has been the most widely used name for the group, all the weight of the Code supports the continued use of this name.

The other major debate concerns the generic name of the saddlebacks. They have long been considered to merit a genus of their own, but there has been disagreement as to whether the correct genus is *Creadion* or *Philesturnus*. The name *Creadion* was established in 1816 by L. J. P. Vieillot, 16 years prior to I. Geoffroy Saint-Hilaire's *Philesturnus*, so there is no issue as to which of the names is older but rather as to whether or not the older name can properly be applied to the saddlebacks. Vieillot's original description included three species in his new genus, but subdivided them into two sections; he did not specify a type species. All three are still informally known as "wattlebirds" but, while the saddlebacks belong to the New Zealand family Callaeidae, the other two species are Australian wattlebirds, nowadays placed in the honeyeater family Meliphagidae. In 1827, N. A. Vigors and T. Horsfield, recognizing that the species could not all suitably be included in the same genus, erected the genus *Anthochaera* for the Australian birds, leaving the New Zealand ones to represent *Creadion*. However, the validity of this as a formal designation has been disputed, and confusion has arisen from a subsequent action of R. P. Lesson in 1837 restricting *Creadion* to the Australian wattlebirds. Due to these disagreements and the subsequent use, albeit limited, of this name for one or other group by different authors, the valid genus name for the saddlebacks is still under dispute, awaiting a clear demonstration one way or the other.

All three extant callaeids produce melodious piping or organ-like sounds, and also some flute-like vocalizations. The ***North Island Kokako*** *has one of the most haunting and beautiful songs of any forest passerine. It is the principal means of locating this shy, cryptically coloured bird. The song, given throughout year but mainly in late spring and summer, is a loud 30-second sequence of rich, slow, organ-like notes, produced by both sexes, sometimes in duet. Singing begins at sunrise, and continues for some 60–90 minutes. Apart from quiet social and contact calls, the bird is usually silent for the rest of the day.*

Morphological Aspects

The three New Zealand wattlebirds are medium-sized passerines, ranging in size from the two saddlebacks, 25 cm in length and weighing about 90–90 g, to the North Island Kokako, which is 38 cm long and weighs 200–250 g. The extinct Huia was the largest member of the family, measuring approximately 53 cm and weighing as much as 400 g or thereabouts.

These are rather attractive passerines, with plumage that varies significantly among members of the family. The kokako has the body mostly bluish-grey, whereas the saddlebacks have the base colour black but with a distinct reddish-brown to dark orange band across the upperparts; the bill, legs and feet are dark grey. The Huia was of an iridescent black, with a broad white tip on the tail, and had a pale horn bill and black feet. In all members of the family the sexes are alike in plumage. Juveniles of the North Island Kokako and of the North Island Saddleback superficially resemble the adults, but the feathers are softer and the barbs are less tightly held together, giving the plumage a soft feel and

The song of the ***South Island Saddleback*** *is heard throughout the year, and throughout the day. A loud repetitive chattering, it is given by both sexes. Although this song is indeed noisy and boisterous, it is less so than that of the North Island Saddleback* (Philesturnus rufusater). *In all three wattlebirds, components of the song can be categorized into local dialects, which may allow information about the relationships between neighbours to be expressed. Neighbouring and related saddlebacks are likely to have similar songs. In all three species, individuals countersing with their territorial neighbours and respond strongly to imitation or playback of their songs.*

[*Philesturnus carunculatus*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Tui de Roy/Roving Tortoise Photos]

All the New Zealand wattlebirds are omnivorous, but the main components of the diet vary among the species, and this is reflected in the morphology of their bills. The long, slightly decurved bills of the saddlebacks are used to forage for insects by probing, tearing and gleaning. The ***South Island Saddleback****, for example, uses its bill to pick insects off the surfaces of leaves. The bill of a foraging saddleback is held either open or closed, and the upper mandible is sometimes used as a skewer. Saddlebacks have large depressor mandibulae muscles, which enable the bill to be opened forcibly against resistance. By pushing the bill into the soil and then opening the mandibles, or "gaping", the saddleback makes an enlarged hole so that prey is easier to find and extract. In the extinct Huia* (Heteralocha acutirostris)*, the male's short, powerful, slightly decurved bill was used to break up wood; its well-developed cranial musculature also facilitated gaping. By contrast, the female Huia's long, slender, sickle-shaped bill was used for probing holes and crevices. The kokako* (Callaeas)*, with their more robust bills, show no adaptations for gaping. Saddlebacks may vary their diet seasonally, especially in late summer, when berries are available. They forage at all levels of the forest, in the leaf litter, on decaying timber, and among branches and foliage right up to the canopy. Studies of North Island Saddlebacks* (Philesturnus rufusater) *indicate that foraging heights vary seasonally, with more time spent on the ground in winter, and more spent foraging for fruits in late summer and autumn. Males and females may exploit different heights when foraging together, with males more frequently on the ground.*

[*Philesturnus carunculatus*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Tui de Roy/Roving Tortoise Photos]

*This **South Island Saddleback** is investigating the fissured and scaly bark of a tree-fern. Both saddleback species probe under and tear off chunks of bark or wood, attempting to expose the invertebrates beneath. They grasp the bark with the bill, and use their own weight to pull it away. They also probe in and around the decaying wood of branches, stumps and fallen logs. When foraging on the ground, they lift leaves and moss, and may toss leaf litter in the manner of a* Turdus *thrush. All three extant wattlebirds hold their food with their feet, in the manner of a parrot. The better-studied North Island Saddleback* (Philesturnus rufusater) *has been observed using its bill to give sharp jabs to larger prey before dismembering it.*

[*Philesturnus carunculatus*, Ulva Island Bird Sanctuary, Stewart Island, New Zealand. Photos: Tui de Roy/ Roving Tortoise Photos]

producing a scruffier appearance. The South Island Saddleback, in contrast, has a uniformly brown juvenile plumage, giving individuals of this age the name of "jackbird".

Kokako hatch with well-developed natal down, while saddlebacks are naked at this stage. Callaeids undergo a partial post-juvenile, or first pre-basic, moult to a superficially adult-like first immature, or first basic, plumage, except that the South Island Saddleback has a distinctive uniformly brown first immature plumage. All members of the family acquire adult plumage through a complete first immature post-breeding, or second pre-basic, moult, probably when they are about one year old. After acquiring this adult plumage, they have a complete post-breeding moult during each annual cycle, which produces successive adult plumages with no perceptible change in appearance. The primaries are shed outwards, starting at the innermost primary, P1, and up to three new primaries can be growing simultaneously. The moult of the rectrices and the body feathers, however, is not well known, but it is likely that the timing of the replacement of these is similar to that of the moult of the primaries.

Morphological characteristics exhibited by the members of the Callaeidae, including the extinct species, can be summarized as follows. The wings are relatively short in comparison with the body length, and are noticeably rounded at the tips. There are ten primaries, the outermost of which, primary P10, is comparatively long, and nine secondaries, including three tertials. The tail is long, and rounded at the tip; it consists of twelve rectrices. The bill varies among species. That of the kokako is rather short and robust, with a decurved upper mandible, whereas the bill of the saddlebacks is long and straight, with a compressed ridge along the culmen. Tongue morphology varies similarly, and appears to reflect diet more than it does ancestry. In the saddlebacks the tongue is lanceolate and shallowly bifid at the tip, while the kokako tongue is oblong and truncated at the tip. The extinct Huia had a sexually dimorphic bill, that of the adult female being very long and sickle-shaped, while the adult male's bill was shorter and only slightly decurved; the tongue of both sexes was narrow, tapering evenly towards the tip, which was somewhat frayed and brush-like. All callaeid species have a rather long tarsus with uniform laminiplantar scaling. The feet are moderately large and strong, with a comparatively long sharp hindclaw.

A feature of all members of this family, including both the three extant species and the two extinct ones, is the distinctive fleshy wattle at the gape, either hanging down from each side of the face or attached to the skin. This wattle, which is orange in all species except the North Island Kokako, in which it is blue, may become more prominent during courtship through vascularization.

All species are poor fliers, which glide, rather than flap, and all have a weakly developed keel on the sternum. Although not specifically investigated, the large nasal depressions of the callaeids would seem to indicate that olfaction may be important in the group. Osteologically, however, the group has been rather neglected. The kokako skull has a distinct "bridge" on the upper edge of the nasal, and large lachrymals with a thickened basal portion abutting the jugal bar. The eyes are protected by large postorbital processes and deep temporal fossae. There are two small unfused sesamoid bones, the larger of which separates the articulation of the lower mandible from the quadrate. The maxillopalatines are expanded below the vomer to form a pointed head, and the palatines are thickened, with the trans-palatine processes extending posteriorly to an acute tip. In terms of cranial details, the Huia is similar to the kokako in palate structure and postorbital processes, but it shows an articulation of the lower mandible that extends an unusual distance to the rear; it differs further in having smaller lachrymals, a distinct occipital crest, and lacking both deep temporal fossae and sesamoid bones. The skull of the saddlebacks is similar to that of the Huia, particularly in having a distinct extension of the retroarticular process of the lower mandible, but this is nevertheless relatively shorter than that of the Huia; in addition, there is no raised occipital crest, and little development of an exoccipital process. Otherwise, the skull proportions, particularly of the female, are similar to those of the Huia, although the quadrate and pterygoid are relatively smaller. Overall, the skull of the saddlebacks is apparently larger, in relation to body size, than that of the Huia.

Sometimes described as a "sequential specialist", the ***North Island Kokako*** *changes from one abundant food source to the next throughout the year. As the productive periods of one host plant species come to an end, the kokako moves on to another species that is coming into bloom, fruit or leaf. The short, robust bill with the decurved upper mandible equips the kokako for a primarily vegetarian diet of fruits and leaves, with other plant materials and invertebrates consumed less frequently. It forages throughout the day, climbing slowly up each tree while searching for food, before gliding (rather than flapping) to the next tree. It may even rummage on the forest floor. Although it is normally seen in pairs or singly, family groups may feed together outside the breeding period.*

[*Callaeas wilsoni*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Tui de Roy/Roving Tortoise Photos]

P. J. K. Burton, who investigated the head and neck anatomy of the Callaeidae, observed that, as well as similarities in plumage, osteology was instructive in elucidating relationships within the group. He found that both the Huia and the saddlebacks possess a feature which is apparently unique, a pars anterior, extending forwards from the articulation with the quadrate. Kokako show no adaptations for "gaping" (see Food and Feeding), and quite possibly did not evolve from a gaping ancestor. As Burton noted, it seems reasonable to suggest that the gaping adaptations of the Huia and the saddlebacks evolved independently of other families and in isolation, and, if this is correct, they are poor evidence for an affinity with other gaping forms.

Habitat

New Zealand wattlebirds once inhabited virtually all of the lowland and montane native forests of New Zealand. Formerly denizens of deep rainforest, they are now commonest in regenerating forests on offshore islands. While the kokako and the saddlebacks occurred on all three main islands, the Huia was apparently restricted entirely to the North Island, where, during the period of European settlement, it was commonest in the south. Significant habitat modification following human arrival, as well as predation by and competition from introduced mammals and possibly birds, has eradicated saddlebacks from all three islands, caused the extinction of the Huia and the South Island Kokako, and now restricted the North Island Kokako to a handful of isolated populations (see Status and Conservation).

The North Island Kokako is still found in the structurally complex lowland forests, preferring tall mature hardwood forest dominated by tawa (*Beilschmiedia tawa*) with emergent podocarps. On some offshore islands to which it has been transferred, the species has demonstrated a remarkable ability to adapt to unfamiliar habitats, those on Tiritiri Matangi Island, for example, occupying exotic brush wattle (*Paraserianthes*) forest. On the mainland, North Island Kokako are occasionally found also in exotic pine (*Pinus*) plantations. The South Island Kokako's habitat preferences are poorly documented, but it appears to have been commonest in the higher-altitude forests dominated by southern beech (*Nothofagus*).

Fossil evidence suggests that saddlebacks were once common in a variety of habitats throughout the largest islands. Today, translocated populations of both species occur in lowland beech forest and in mixed evergreen podocarp–hardwood forest, and populations of the North Island Saddleback can be found also in exotic pines and wattles. The North Island species' proclivity for any habitat in which it is placed, provided that it is free of rats (*Rattus*), suggests that this saddleback has always been a generalist, probably preferring seral forests and secondary growth with a high turnover of dead wood and numerous fruiting shrubs. There are indications, again from fossil evidence, that North Island Saddlebacks were able to adapt also to coastal and montane shrublands.

The Huia inhabited mainly mixed hardwood and podocarp forests, and occasionally beech forest, with a dense understorey. It was found from the forest edge to the coast.

General Habits

Kokako are shy birds with a cryptic coloration, and are most easily identified as being present in an area by their distinctive songs in the early morning. The same was said of the extinct Huia. The saddlebacks, in contrast, are considerably more forthright, constantly calling to advertise their presence and to keep in contact with the partner, and readily approaching humans to investigate them and perhaps to take advantage of any invertebrates disturbed from the forest floor.

None of the Callaeidae is particularly gregarious. All are usually seen singly or in pairs, but they may form small family groups after breeding. Foraging groups of up to ten newly independent young of the kokako and the saddlebacks have sometimes been reported in the autumn. Occasional gatherings of up to eight adult saddlebacks and up to 15 adult kokako are thought to be linked to territorial disputes.

Nectar plays a regular though minor part in the diets of all the New Zealand wattlebirds, and is eaten opportunistically. The adaptability of the ***North Island Saddleback*** *to almost any habitat in which it finds itself, including those dominated by exotic species such as pines and wattles, suggests that it has always been a generalist. However, it probably prefers habitats with a high turnover of dead wood and numerous fruiting shrubs. All the wattlebirds have suffered from introduced predators; North Island Kokako are also probably adversely affected by introduced omnivores and herbivores, which not only compete directly for the same fruits and berries, but have also altered the pattern of regeneration of forests in ways that reduce the availability of food throughout the year.*

[*Philesturnus rufusater*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Neil Fitzgerald]

All members of the family form long-term pair-bonds, often remaining paired for the life of one or other individual, and all are also highly territorial. Together, partners maintain their territory mostly by means of vocalizations, but during territorial disputes they will resort to threat displays, chasing and even, on occasion, physical fighting. The territory is an all-purpose one, generally providing all or most of what the pair requires for breeding, foraging and other aspects of its life, and is maintained from one year to the next. Territories of the North Island Kokako are generally of 4–20 ha.

Roosting normally takes place within the territory. Kokako roost in pairs, apparently near the top of a tall tree. They will sometimes change from one site to another, even regularly within a short period of time; one pair of North Island Kokako, for example, was found to utilize at least nine different roost-sites in a nine-week period. Saddlebacks roost in tree holes, beneath large epiphytes or, if no tree holes are available, in cavities in the ground. Other roost-sites used by the saddlebacks include spaces behind pendent dead leaves of large epiphytes growing on boughs or overhanging banks, downward-looping roots in hollows beneath banks, and dense vegetation on the ground, as well as crotches between large boughs. They will also make use of artificial roosting boxes provided by humans. Saddlebacks may use a single roost for several months, or even for years, but often, as with the kokako, they have several alternative roost-sites. Similarly, partners roost together within their territory, although, if no suitable sites are available, they will find one outside the territory.

Both saddlebacks and kokako bathe regularly. Saddlebacks often bathe at water-holes during the hottest hours of the day. While squatting in shallow water, they dip the head beneath the surface and then bring it up again to throw water over the back, also flapping the wings to create showers of spray. Having thoroughly wetted the plumage in this way, they then assume a more upright stance in order to help with draining of the water from the feathers. Kokako bathe by repeatedly immersing themselves briefly in water to wet the plumage, often also splashing water over the body by flapping the wings. In one case, a female North Island Kokako was seen to leave her nest and bathe in a nearby creek; she returned, quite wet, and shook her feathers to rid them of excess water, before sitting on the nest again. Later in the day, this same female repeated her bathing visit to the creek.

Preening frequently follows bathing, and is performed also at other times. In a study of the North Island Kokako at Puketi Forest, in Northland, in the early 1980s, resting and preening were observed at all times throughout the year, preening sessions lasting for 20–30 minutes. It was found, however, that kokako spent more time in these activities in the summer period, when they were moulting. Saddlebacks often pause during foraging in order to preen, and after bathing they will not infrequently devote a considerable amount of time to preening themselves on a nearby branch. Pair-members also preen each other at times, kokako indulging in such allopreening especially during courtship but also during confrontations with other kokako. Saddlebacks appear to use allopreening less often, although they do frequently preen their own dependent juveniles.

Sun-bathing has been recorded for the North Island Saddleback. During this maintenance activity, which can take place either on the ground or on a branch, the saddleback lifts one wing in order to expose its flank and underwing to the sun's rays. In addition, a possible case of anting by this species has been observed. A male saddleback, while foraging in leaf litter, was seen on several occasions to rub a small rounded-looking insect on the ground and then to rub it through the feathers of its underwing; the bird then swallowed the insect.

Voice

Vocalizations of New Zealand wattlebirds are varied, but all of the species produce melodious piping or organ-like sounds and flute-like vocalizations. The song of the North Island Kokako is described as a haunting and mournful series of loud, rich notes sounding like those produced by an organ, the whole lasting for about 30 seconds. It is often delivered from conspicuous perches and is said to be audible at up to about 1·6 km. Both sexes sing, sometimes in duet. This species sings throughout the year, but

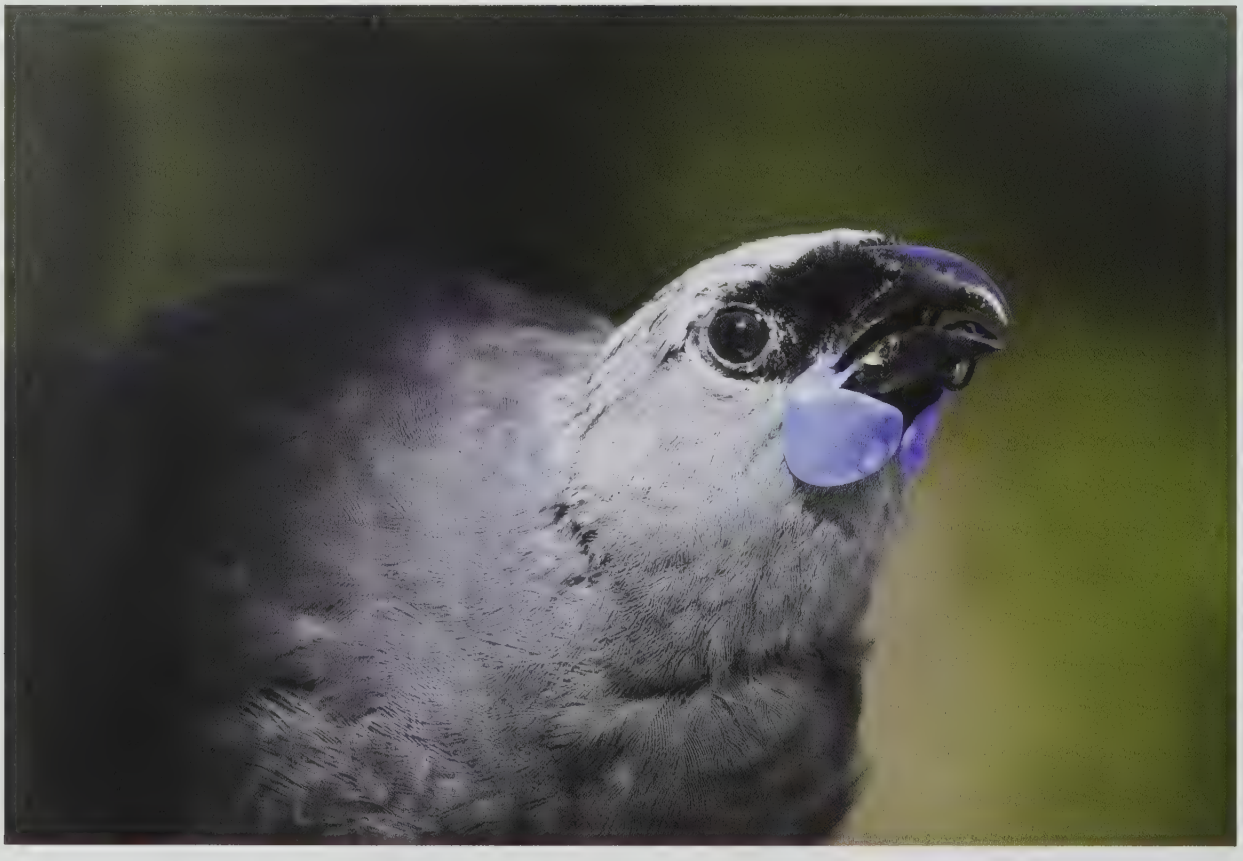
predominantly in late spring and summer. It starts at sunrise and continues for up to 60–90 minutes.

The saddlebacks are often very noisy, uttering harsher chattering or churring vocalizations. The song is either a loud, repetitive chattering, given as "cheet, te-te-te-te" for the North Island form, and with great carrying power through thick forest; or a much shorter series of softer flute-like sounds audible only at close range. Interestingly, the song of the extinct Huia was described as an array of peculiar and strange whistles. With the saddlebacks and the kokako, both sexes sing and often perform duets, and both sometimes countersing with neighbours.

In the case of the three extant species, the vocalizations exhibit significant variation from one location to another, and the components of the song can be categorized into local dialects. It is suggested that these dialects allow information about the relationships between neighbours to be expressed. All three species respond strongly to any imitation or playback of their vocalizations.

Food and Feeding

New Zealand wattlebirds forage at all levels in the forest, from the floor, where they investigate leaf litter and decaying timber, to the upper levels among branches. They search both live and dead foliage of trees and shrubs, from near the ground up to the canopy. All members of the family are omnivorous, but the main components of the diet vary among the species, and this is reflected in the morphology of their bills. The North Island Kokako, with its rather short and robust bill with a decurved upper mandible, is primarily a vegetarian; it consumes mainly fruit and leaves and, less frequently, flowers, moss, buds, nectar and invertebrates. It has been called a "sequential specialist". This means that, as the flowering, fruiting or leaf-budding periods of one host-plant species wane, the kokako move on to another species that is just coming into bloom, fruit or leaf.



Saddlebacks feed predominantly on insects gleaned from leaf litter on the forest floor or in rotting logs. The long straight bill of the two species has large muscles, allowing it to be opened forcibly against resistance. The North Island Saddleback, at least, may vary its diet seasonally, especially in late summer, with the addition of berries, and it may take other invertebrates and nectar, and occasionally buds, opportunistically. Saddlebacks most frequently employ the techniques of probing, tearing and gleaning. They probe among the dead and decaying wood of branches, the bark of trees, and in and around trunks, stumps and logs, and often tear off chunks of bark or wood from trees, exposing insects beneath. Sometimes they lift fronds, leaves, lichens or moss, and they may toss leaves in the manner typical of a *Turdus* thrush, such as a Common Blackbird (*Turdus merula*). The bill of a foraging saddleback is held either open or closed, and the upper mandible is sometimes used as a skewer. By opening the mandibles, or gaping, while the bill is inside a hole in a soft substrate, the saddleback is able to enlarge the hole to allow food to be extracted. This open-bill probing has been termed "*Zirkeln*", which in German means "using dividers". The saddlebacks utilize the bill also as a lever in order to pry bark away from tree trunks and branches. All callaeid taxa use the feet in order to manipulate and hold food.

With its bizarre specialization of differing male and female bills, the extinct Huia is of particular interest. It was considered to be a specialist predator of the larvae of the huhu beetle (*Prionoplus reticularis*), but it also consumed other invertebrates, as well as fruit. The males had a well-developed cranial musculature, and they were able to break up rotten wood by chiselling and gaping; the females utilized their longer, slender and more decurved bill for probing into the holes and crevices.

Kokako and saddlebacks forage throughout the day, usually singly or in pairs, but very occasionally in larger groups. Although kokako are not known to participate in mixed-species flocks, saddlebacks are often seen while foraging with New Zealand Fantails (*Rhipidura fuliginosa*), Silvereyes (*Zosterops lateralis*) and other small forest passerines.

Breeding

Callaeids are monogamous, forming long-term, often permanent pair-bonds. They are all solitary nesters. All breed in the austral spring and summer, the North Island Saddleback being prone to

All wattlebirds need access to water for drinking and bathing. ***North Island Kokako*** *bathe by repeatedly immersing themselves briefly in water-holes or creeks to wet the plumage, often also splashing water over the body by flapping the wings. Although territorial and generally sedentary, North Island Saddlebacks* (Philesturnus rufusater) *living on offshore islands with restricted supplies of water have been recorded traversing neighbouring territories in order to drink. In contrast to the wattles of the saddlebacks, those of the North Island Kokako are not pendulous, but follow the contour of the feathering, extending from each side of the gape and over most of the cheek, and touching or overlapping across the throat.*

[*Callaeas wilsoni*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Peter Fuller]

All three extant species perform an "Archangel Display", in which a male raises his wings and moves rapidly around opposite his mate. The ***North Island Kokako*** *generally breeds in the austral spring and summer, but when food is abundant it may also breed in autumn, and so occasionally rears three broods in a year. Unlike the mostly cavity-nesting saddlebacks, the kokako builds a substantial cup-shaped nest from coarse twigs bound together with moss and lichens, in the understorey or subcanopy. The nest is well concealed in the fork of a tree or the top of a tree-fern, or among epiphytes or lianas. On hatching, kokako chicks are covered in light down. Fledging takes 32 to 37 days, up to 10 days longer than in the smaller saddlebacks.*

[*Callaeas wilsoni*, Otorohanga Breeding Centre, North Island, New Zealand. Photo: Tui de Roy/Roving Tortoise Photos]

earlier and later clutches and the South Island Saddleback, as well as the extinct Huia, restricted to spring and early summer. They normally raise one or two broods in a season, but the North Island Kokako occasionally rears three broods, and North Island Saddleback populations newly translocated to predator-free environments may raise four.

Males of the three extant species perform what are termed "Archangel Displays", in which the male, while in a tree or on the ground, raises its wings and moves about rapidly opposite his mate. He often carries in his bill some vegetation, which he repeatedly drops. In the case of the saddlebacks, this display is associated with the drawing of the female into a chosen nest-cavity, but it has not been suggested as having such a role for the kokako. The process of pair formation and the maintenance of the pair-bond are accompanied by song, and vocalizations also play a major role in all sexual activities and all other aspects of social behaviour. Courtship feeding, which is performed in all months but increasingly as the breeding season approaches, appears likewise to be important in reinforcing the pair-bond.

Callaeids build a large, cup-shaped nest consisting of a loosely constructed base, mostly of sticks and twigs, with an inner lining of finer material. Because of the confined spaces available to saddlebacks, which are cavity-nesters, the nests of these species are generally less substantial and more compact. Typically, the female constructs the nest alone. Various nesting sites are used, but kokako generally nest among the branches of trees and shrubs at a height of 2–31 m above the ground, but mostly above 10 m, whereas saddlebacks usually nest in hollows in trees or epiphytes at lower levels and not uncommonly nest on the ground.

Eggs of New Zealand wattlebirds are oval in shape, although some kokako eggs are elliptical-ovate. The ground colour is generally pale to dark pinkish-grey or purplish-grey, but varies to white and deep beige. The eggs are marked with spots and blotches and, more rarely, streaks or lines, these markings generally being either brown or purplish-brown in colour and concentrated at the larger end. In one study of the North Island Kokako, the eggs measured 34·2–42·1 × 25·7–29·2 mm; in other studies, the mean dimensions were 38·5 × 26 mm and 39 × 26·8 mm. The average size of North Island Saddleback eggs in one sample was 28·9 × 22·3 mm, while two eggs of this species from Hen Island, off the east coast of Northland, measured, respectively, 30 × 21·4 mm and 29·8 × 22·5 mm. The eggs of the South Island Saddleback, sample means of which are 32·4 × 22·2 mm and 32·5 × 22·1 mm, are on average about 2·5 mm longer than those of the North Island Saddleback.

Clutches usually consist of two or three eggs, but both single-egg clutches and, for saddlebacks and the Huia, four-egg clutches have been recorded in what were apparently natural conditions. It has been claimed that the Huia sometimes produced clutches of five eggs, although the reliability of such reports is open to question.

The female incubates the eggs and broods the chicks, being fed on the nest by the male. Feeding of the nestlings, however, is usually undertaken by both parents. The incubation period is generally from 18 to 20 days, although the extremes of successful incubation range from 16 days to as many as 28 days. The chicks are initially semi-altricial or altricial, and nidicolous; those of the saddlebacks are naked on hatching, while kokako chicks are covered in a light down. The duration of the fledging period is dependent on relative chick size, and normally ranges from about 25 days, as with the saddlebacks, to 37 days, as for the North Island Kokako. After having left the nest, the young continue to be fed by both parents for at least a few days, and often for much longer, especially if they represent the final brood of the season. Kokako are thought to live for us to about 20 years or more.

Studies indicate that the comparatively high levels of breeding failure of North Island Kokako on the mainland are largely the result of predation, mostly by small introduced mammals such as rats, especially black rats (*Rattus rattus*) and brown rats (*R. norvegicus*), mustelids and common brushtail possums (*Trichosurus vulpecula*). On offshore islands, where introduced mammalian predators are absent, predation is also the major cause of nest failure of all three extant species, but in these environments predatory birds such as the Pacific Marsh-harrier (*Circus approximans*), the Morepork (*Ninox novaeseelandiae*) and the Weka (*Gallirallus australis*) are generally implicated.

Movements

Breeding adults of both the saddlebacks and the North Island Kokako are sedentary and territorial throughout the year, and from one year to the next. Even so, North Island Saddlebacks living on offshore islands with restricted supplies of water and ephemeral abundances of certain foods are recorded as traversing neighbouring territories in order to forage and drink.

Juveniles of the North Island Kokako disperse, generally over distances of between 1·2 km and 2·1 km, but sometimes up to 20 km, before settling into territories of their own, often close to their own natal territory.

There were some suggestions in the early literature that the Huia may have migrated altitudinally during the year. It is difficult now to assess the likelihood that this occurred, and, if it did, the extent and frequency of such altitudinal movements.

Relationship with Man

In former times, kokako were occasionally hunted for food, although they were said not to be particularly palatable. The Maori people seldom consumed kokako meat, but they did so on rare occasions. They did, however, utilize the wattles of these birds as ornaments, which they usually wore on the cheeks. It seems that all members of the family were hunted to some degree, but generally not for food.

Little information is available on the attitude of humans to the New Zealand wattlebirds and the influence that the latter had on human thinking. What is known is that there was in the past a big demand for Huia feathers and body parts, which were used as adornments by local peoples, and this species seems to have held a special fascination for all those who encountered it. The Maori fashioned elaborate wooden boxes, intricately carved, in which they kept the tail feathers of this species. It is evident that the white-tipped black rectrices had a particular importance to the Maori, who considered the Huia to be a sacred bird. The tribal chiefs wore the tail feathers as a head-dress, especially in battle, but the rectrices were also, somewhat conversely, presented as a token of respect or friendship. In addition, these feathers were placed around vessels containing preserved animal food, especially pigeon (Columbidae), as an indication that this was food fit for chiefs, a further example of the significance attached to this species by the Maori. Huia skins, the legs and wings removed, were attached to the ears as decorative pendants, and dried Huia heads were likewise worn as ornaments.

Following the settlement and spread of Europeans across New Zealand, the demand for Huia specimens for museum collections increased. Moreover, a Maori guide, when he placed a Huia tail feather in the hat-band of the Duke of York, who was on a visit to New Zealand, started a fashion which very soon led to widespread hunting of the birds for their feathers. In the first years of the twentieth century a single Huia fetched the sum of £12, this representing £1 for each tail feather; by 1915, however, a single rectrix could be sold for £5, a significant amount of money at that time. It was not long before the Huia became extinct (see Status and Conservation).

Status and Conservation

Of the three extant members of the family Callaeidae, the North Island Kokako is listed as Endangered, while the two saddlebacks, when treated as conspecific, are classified as Near-threatened. A recent reassessment of New Zealand's endangered species, undertaken by the New Zealand Department of Conservation, has not changed these ratings. The main threats have been identified as predation by introduced mammals and, as with so many threatened species in all corners of the world, habitat reduction. North Island Kokako are probably adversely affected also by competition from introduced omnivores and herbivores, which not only compete directly for the same fruits and berries as those preferred by the kokako, but also have altered the pattern of regeneration of forests in a way that reduces the availability of high-quality foods throughout the year. The saddlebacks are effectively extinct on the New Zealand mainland, and the North Island Kokako is much reduced there, but saddleback numbers are increasing as a result of translocations to offshore islands and protected mainland sites. Despite a number of successful translocations, the North Island Kokako has declined massively

*The nestlings of **South Island Saddlebacks** are fed mostly on insects. The eggs of the South Island species are slightly larger on average than those of the North Island form, parallelling the case of the birds themselves. Upon hatching, after an incubation of around 20 days, the young are naked. Saddlebacks build their nests, often in natural cavities, in the sub-canopy and understorey, and not uncommonly on the ground. Since they also have the habit of roosting on the ground, they are unable to survive in the presence of rats, and all current South Island Saddleback populations are the result of translocations to islands free of mammalian predators. The original "donor" island populations became extinct after rats were introduced.*

[*Philesturnus carunculatus*, South Island, New Zealand. Photo: Konrad Wothe]

Although the 2007 estimate for the population of ***North Island Kokako*** *was of some 1486 adult birds, the actual breeding population was more precisely 681 pairs, because differential predation has left many subpopulations with an excess of unpaired males, leading in some cases to male–male couples. This species is listed as Endangered. Rates of decline have been as high as 50% in three years in some areas, and without management of its remaining populations, the North Island Kokako would be extinct on the New Zealand mainland. Conservation strategies include translocation, large-scale predator control, and introduction of females to subpopulations with a male bias.*

[*Callaeas wilsoni*, Otorohanga Breeding Centre, North Island, New Zealand. Photo: Mark Jones/Roving Tortoise Photos]

in the last 20 years, and it is now in a position where, without high-level management of its 18 remaining natural refuges, the species would become extinct on the New Zealand mainland. Once again, however, the most recent figures indicate an encouraging recovery of numbers.

The Huia has been extinct since the early part of the twentieth century. The last confirmed sighting was made in about 1907, although there are also several unconfirmed reports, including some perfectly credible ones, up to the 1920s and perhaps even beyond. The South Island Kokako may have survived until the 1960s, but it was "officially" declared extinct by the New Zealand Department of Conservation in January 2007.

Historically, most New Zealand bird species have been adversely affected by loss or fragmentation of habitat and by introduced predators. Fossil distribution indicates that all of the New Zealand wattlebird taxa were widely distributed at the time of Polynesian colonization of the islands, in the twelfth century. Large-scale deforestation, through fire, during the pre-European period restricted kokako and saddlebacks to areas of dense forest, and the Huia was limited to dense forest in the southern part of the North Island, being absent from the South Island. The introduction of the brown rat in about 1770, followed shortly thereafter by the black rat, probably doomed the saddlebacks to extinction on the New Zealand mainland, but the introduction of mustelids in the 1880s was the final nail in the coffin for these two species. Logging and fire were less significant in the decline of the saddlebacks than they were for the other wattlebirds, probably because the saddlebacks' smaller size, combined with their habit of roosting on the ground, led to their elimination by rats before large-scale European land clearance began. Saddlebacks survive to the present day only because of the existence of natural populations on rat-free islands, and their future has been safeguarded through a widespread series of translocations to predator-free islands and to other sites, including on the mainland, where the eradication of predators or intense control operations have been undertaken.

Kokako and Huia appear to have been less susceptible to rat predation, but the arrival of cats in the early years of the nineteenth century and of mustelids in the 1880s led rapidly to the decline of the South Island Kokako. This species was said to be fast approaching extinction by 1889, while its North Island counterpart was then still comparatively common. It has been suggested that the difference in mortality was due to the South Island species' habit of spending longer periods on the forest floor. Throughout the twentieth century the range of the North Island Kokako contracted as a result not only of logging, both clear-felling and selective logging, and subsequent habitat degradation, but also of large-scale clearing and burning of native vegetation, the effects of which were, to some extent, exacerbated by hunting. The speed of this decline increased in the 1970s, and by 2006 there were only 14 natural populations and five translocated populations.

What caused the extinction of the Huia is more obscure. This species is popularly thought to have been hunted to extinction by rapacious collectors, both Maori and European, who were attempting to service the insatiable demand for Huia feathers and body parts for human adornment and for museum specimens worldwide (see Relationship with Man). Although this may have been a contributory factor in the species' demise, there is little doubt that habitat loss and predation by introduced mammals, especially mustelids, played a significant part in the extinction of the Huia.

Genus *CALLAEAS* J. R. Forster, 1788

1. North Island Kokako

Callaeas wilsoni

French: Glaucope de Wilson **German**: Graulappenvogel **Spanish**: Kokako
Other common names: Wattled/Blue-wattled/North Island Crow, Wattlebird

Taxonomy. *Glaucopis wilsoni* Bonaparte, 1850, North Island, New Zealand.
Often treated as conspecific with extinct *C. cinereus*, but differs in wattle colour (mainly orange in *C. cinereus*) and morphometrics, minor differences in plumage, also differences in behaviour and possibly vocalizations; recent genetic studies suggest that the two are better treated as separate species. Monotypic.
Distribution. Scattered localities on North I (including three small offshore islands), in New Zealand.

Descriptive notes. 38 cm; 200–250 g, male average 233 g, female average 218 g. Medium-sized to large forest passerine with short, wide downcurved bill, unusually long sturdy legs, long broad tail with rounded tip and distinctive downward curve, and broad, rounded wings, tips of which reach just past uppertail-coverts; prominent wattles extending from each side of gape and over most of cheek, touching or overlapping across throat (wattles not pendulous, but follow contour of feathering). Plumage is primarily blue-grey, with prominent black mask extending from slightly above bill to just above and behind eye and to chin; facial wattle cobalt-blue, increasing in size and in colour intensity and fleshiness in breeding season; tail blackish-brown, feathers with dark greyish-olive outer webs; wing mainly blue-grey, outer remiges olive-brown with blue-grey wash; iris dark brown, black eyering; bill black; legs black. Sexes alike, female slightly smaller than male. Juvenile is like adult, but plumage primarily sooty blue-grey and wattle small and pink; immature similar to juvenile but predominantly brownish-grey, with blue-grey wash on mantle, wattles becoming increasingly bluish on edges and turning purplish-pink and then pinkish-blue, and increase slowly in size. VOICE. Song, throughout year but mainly in late spring and summer, one of the most haunting and beautiful songs of any forest passerine and the principal means of locating the species, a loud 30-second sequence of slowly executed, rich organ-like notes, given by both sexes, sometimes in duet. Song begins at sunrise and continues for only 60–90 minutes; usually silent during rest of day, although a wide array of quiet contact and social calls recorded.
Habitat. Lowland podocarp–tawa hardwood forest with diverse understorey; from sea-level up to over 900 m. Tawa (*Beilschmiedia tawa*) an important component of nearly all current natural refuges, the only exception being Puketi (in extreme N of North I), where occurs in mixed kauri (*Agathis australis*)–hardwood forest. Occasionally found in shrublands and regenerating seral forest, and in mature exotic forests adjacent to territories. Tiritiri Matangi I (where translocated population survives) contains a small amount of established pohutukawa (*Metrosideros excelsa*) forest and large areas of shrubland, grassland and exotic brush wattle (*Paraserianthes*) forest and other exotic canopy trees, suggesting that habitat preferences of present species may be less restrictive than was previously thought.
Food and Feeding. Diet mainly leaves and fruit, with flowers, buds, nectar and invertebrates taken less frequently; has been suggested that nestling diet may be richer in invertebrates. A sequential specialist, changing from one abundant food source to the next throughout year. Forages throughout day, generally in pairs or singly, also in family groups during non-breeding period. During foraging, glides between food trees; climbs slowly up each tree while searching for food, before gliding to next tree. Often holds foliage with feet in manner of a parrot (Psittacidae) while on a stable platform such as large branch; also picks fruit or gleans insects, and even rummages about on forest floor. Occasionally recorded as balling up moss on forest floor and possibly eating capsules and foliage, but this behaviour could be a method of reaching invertebrates or water in the moss. A poor flier, preferring gliding to flapping, and rarely travelling more than 50 m through canopy in one flight.
Breeding. Breeds generally in austral spring and summer, also in early autumn but only when food abundant, with laying Oct–Mar and latest nestlings and fledglings recorded May; in a good season up to three or, exceptionally, four broods. Nest a substantial cup-shaped structure built from coarse twigs bound together with moss, lichens and similar, with inner lining of finer twigs and leaves, well supported but well concealed in fork of tree, top of tree-fern, in epiphytes or among mass of lianas, mostly in understorey or subcanopy. Clutch 1–3 eggs, usually 2 or 3; incubation by female, period on average 18 days, but successful incubation periods of 16–21 days recorded; chicks brooded by female, fed by both parents, fledging period variable, 27–42 days, mostly 32–37 days. At mainland sites, up to 42% of pairs produce one or more chicks each year when mammalian predators controlled, whereas success per pair on average 13% per season when predators uncontrolled; natural avian predators include Pacific Marsh-Harrier (*Circus approximans*) and Morepork (*Ninox novaeseelandiae*). Long-lived, probably up to 25 years.
Movements. Primarily sedentary. Juvenile dispersal generally only 1·2–2·1 km, but one individual moved at least 20·2 km.
Status and Conservation. ENDANGERED. Global population thought to number c. 750 pairs with well over 1500 adults (males predominate in population); number of immatures not known. Listed as Endangered owing to very small effective population size, which is partially due to differential predation with females very vulnerable during nesting, leaving many subpopulations with an excess of unpaired males, and often leading to couples consisting of two males. Restricted to 18 localities, including three offshore islands. Formerly more widespread in forests of North I and smaller offshore islands. Remaining populations found in Hunua Ranges, Mataraua, Kaharoa, Rotoehu, Pureora and Mapara forests, and in Te Urewera National Park (450 km^2); subpopulations entirely isolated as a result of habitat fragmentation. Populations increasing in areas where intensive conservation practised, but still declining elsewhere; now extinct in most sites where no management work undertaken. Rates of decline as high as 50% in three years in some areas. Species is entirely dependent on conservation; each population requires annual control of predators until at least 25 breeding pairs present, followed by minimum of three years of management every ten years in order to maintain population growth. Historic declines were due to large-scale habitat destruction leading to fragmentation, combined with direct effects of introduction of predators and indirect effects of introduced species as competitors. Predation by black rat (*Rattus rattus*), common brushtail possum (*Trichosurus vulpecula*), stoat (*Mustela erminea*) and feral cats are primary causes of present decline; brushtail possum also competes for serially available food items, and introduced goats and deer destroy important understorey foodplants. Majority of remaining occupied habitat is protected, and in most subpopulations brushtail possum and black rat are controlled or eradicated. All subpopulations have decreased very rapidly and fragmented further over the last 20–30 years. Unmanaged subpopulations likely to decline to extinction, at least two having been lost in the last ten years. However, intensive conservation efforts originally aimed to restore the population to more than 1000 pairs by the year 2020, and recent good results suggest target may be achieved by 2013. Recent research concentrated on cost-effective large-scale predator control. Present species introduced on three small islands; young females have also been introduced in two managed remnant male/predominantly male populations on mainland; some individuals interchanged between sites in order to maintain broad genetic base. Two small populations held in captivity.

Genus *PHILESTURNUS* I. Geoffroy Saint-Hilaire, 1832

2. South Island Saddleback
Philesturnus carunculatus

French: Créadion rounoir **German**: Südinsel-Sattelvogel **Spanish**: Tieke de Isla Sur
Other common names: Tieke, Wattled Starling(!); Jackbird (juvenile)

Taxonomy. *Sturnus carunculatus* J. F. Gmelin, 1789, Queen Charlotte Sound, South Island, New Zealand.
Genus sometimes listed as *Creadion* (see page 231). Often treated as conspecific with *P. rufusater*, but differs in details of adult plumage, morphometrics, behaviour and vocalizations, and especially in possession of a distinct juvenile plumage. Monotypic.
Distribution. New Zealand: extreme NE & SW South I (Motuara I, in Queen Charlotte Sound, and islands off Fiordland) and islands off Stewart I. Recently introduced to Erin I, in Lake Te Anau (Fiordland).

Descriptive notes. 25 cm; 61–94 g, male average 85 g, female average 75 g. Medium-sized passerine with strong slightly downcurved bill, long tail with rounded tip and distinctive downward curve, and short, rounded wings, tips of which reach just past uppertail-coverts; small pendulous wattle extends from gape over malar area and down to throat. Plumage is mostly glossy black (faint metallic blue sheen in bright light), with prominent dark orange or red-brown "saddle" from mantle to rump and extending to secondary upperwing-coverts; slightly darker lores, giving impression of mask (in bright sunlight); tail black (bluish sheen in bright light); upperwing except for secondary coverts black-brown; facial wattle reddish-orange, increasing in size, in colour intensity and in fleshiness in breeding season; iris black-brown, black eyering; bill and legs black. Sexes alike in plumage, male slightly larger and generally with larger wattle than female. Juvenile is very different from adult, has dark brown plumage with chestnut wash on head and rump, dark lores, wattle small and pink, initially has yellowish gape-line; immature similar to juvenile, but with increasingly large amounts of black on body (retains brown juvenile rectrices and remiges), wattles becoming increasingly reddish-orange and slowly growing in size. VOICE. Noisy and boisterous, though apparently less so than *P. rufusater*. Song the commonest vocalization, heard throughout year, a loud repetitive chattering, with great carrying power through thick forest, given by both sexes (apparently dimorphic in structure), apparently also dialectal in structure (neighbouring and related individuals likely to have similar songs); sings throughout day, but territorial countersinging generally heard mainly in early morning. Male, when provisioning female, calls her off nest by uttering loud "cheeet ta-chet ta-chet ta-chet" from distance of 10–20 m; quiet contact calls, whistles and pips also recorded.
Habitat. All current populations are at sites where species has been translocated. At successful reintroduction sites, available habitat almost entirely restricted to evergreen coastal forest and mixed lowland broadleaf forests, especially seral forest and second growth, and on these islands may occur at elevations of up to 152 m. In Big South Cape (Taukihepa) Group, off SW Stewart I, original habitat was dominated by *Olearia* tree daisies and southern rata (*Metrosideros umbellata*); translocated individuals on Ulva I and Breaksea I appear to prefer to establish breeding territories in coastal scrub, the dominant habitat feature of Big South Cape.
Food and Feeding. Food predominantly invertebrates and berries, occasionally honeydew, nectar of flax (*Phormium cookianum*) and fruit of the araliaceous five-finger (*Pseudopanax arboreus*). Nestlings on Solomon I fed almost entirely with grubs. On Motuara I obtained most food from the ground and five-finger, and number of prey captured generally reflected the amount of time spent on foraging substrates. Gleans items; also uses technique of gaping, and pries bark. Uses bill to pick scale insects (of genus *Ctenochiton*) off leaf surfaces, and licks honeydew from leaf surfaces while securing leaf bunches with a foot in manner of a parrot (Psittacidae).
Breeding. Timing and frequency probably density-dependent, generally breeding in austral spring and summer, with early-autumn records only when food abundant or population low; on Ulva I, breeding recorded between late Sept and late Mar, with first clutch laid in last week Sept; on Breaksea I and Motuara I, first eggs in respectively second and third weeks of Oct, and most nests contained eggs or nestlings between third week Oct and first week Jan. Nest, built by female alone, a medium-sized cup made from twigs (generally found nearby), bound together with moss, lichens and similar materials, with inner lining of finer twigs and leaves, very rarely with feathers, placed in natural cavity (54% of nests on Motuara I, 80% on Ulva I) or in flax (67% of nests on Breaksea I), generally in understorey or subcanopy. Clutch 1–2 eggs, usually 2; incubation by female, average period c. 20 days; chicks brooded by female, fed by both parents, fledging period 25–27 days. As all sites are free of mammalian predators, nest failure generally due to avian predators such as Pacific Marsh-harrier (*Circus approximans*), Morepork (*Ninox novaeseelandiae*) and Weka (*Gallirallus australis*).
Movements. Adults sedentary and territorial all year. Juvenile dispersal in general probably less than 3 km. Translocated individuals on Motuara I dispersed over 59 ha of island over a period of 8–10 months.
Status and Conservation. Not assessed. Probably Vulnerable. When treated as conspecific with *P. rufusater*, the enlarged species is considered Near-threatened. Confined to small islands off South I (including one island on an inland lake) and off Stewart I. Unable to co-exist with any rat species, including Polynesian rat (*Rattus exulans*), or any other introduced mammals, and prior to 1964 was therefore restricted to three islands in Big South Cape Group, off Stewart I. All current populations are the result of translocations. Introduced predatory mammals responsible for extinction on mainland; arrival of black rat (*Rattus rattus*) on the three islets off Stewart I in 1963 caused rapid extinction of populations. Since 1964, has been established on 16 islands, and populations on the three original "donor" island have become extinct; recently, however, rats have been eradicated from all three original islands, and it is likely that the saddleback will be reintroduced shortly. Global population has increased to over 1200 individuals, with capacity to increase to 2500 even without further reintroductions. Although populations adequate and well spread out, the threat of accidental introduction of predators on remaining islands still a concern, especially in light of recent documented outbreaks of avian pox and malaria on Long I.
Bibliography. Anon. (2008c), Bell (1978), Buller (1888), Butchart & Stattersfield (2004), Heather & Robertson (1997), Higgins *et al.* (2006b), Hooson & Jamieson (2003a, 2003b, 2004), Lovegrove (1996b), Merton (1975), Michel *et al.* (2008), Pierre (1999, 2000), Roberts (1994), Steffens *et al.* (2005).

3. North Island Saddleback
Philesturnus rufusater

French: Créadion de Lesson **German**: Nordinsel-Sattelvogel **Spanish**: Tieke de Isla Norte
Other common names: Tieke, Wattled Starling(!)

Taxonomy. *Icterus rufusater* Lesson, 1828, Bay of Islands, North Island, New Zealand.
Genus sometimes listed as *Creadion* (see page 231). Often treated as conspecific with *P. carunculatus*, but differs in details of adult plumage, morphometrics, behaviour and vocalizations, and especially in lacking a distinct juvenile plumage. Monotypic.
Distribution. North I, in New Zealand: self-sustaining populations now restricted to islands off N coast, also Kapiti I, off S coast. Attempted establishment of at least three populations within fenced mainland sites on North I.

Descriptive notes. 25 cm; 61–94 g, male average 80 g, female average 70 g. Medium-sized passerine with strong slightly downcurved bill, long tail with rounded tip and distinctive downward curve, and short, rounded wings, tips of which reach just past uppertail-coverts; small pendulous wattle extends from gape over malar area and down to throat. Plumage is mostly glossy black (faint metallic blue sheen in bright light), with prominent dark orange or red-brown "saddle" from mantle to rump and extending to secondary upperwing-coverts, saddle edged with narrow yellowish band (which becomes brighter on older males); slightly darker lores, giving impression of mask (in bright sunlight); tail black (bluish sheen in bright light); upperwing except for secondary coverts black-brown; facial wattle reddish-orange, increasing in size, in colour intensity and in fleshiness in breeding season; iris black-brown, black eyering; bill and legs black. Sexes alike in plumage, male slightly larger and generally with larger wattle than female. Juvenile is similar to adult, but with mostly brownish-black, not glossy black, plumage, less pronounced, duller mantle that lacks yellow leading edge, chestnut undertail-coverts, and weak brown barring on belly, wattles small and pink, initially has yellowish gape-line; immature similar to juvenile, but with increasingly large amounts of black on body (retains brown juvenile rectrices and remiges), wattles becoming increasingly reddish-orange and slowly growing in size. VOICE. Noisy and boisterous. Song is commonest vocalization, given throughout year, a loud repetitive "cheet, te-te-te-te", by both sexes (though dimorphic in structure), with great carrying power through thick forest; song structure dialectal, with neighbouring and related individuals likely to have similar songs; sings throughout day, but territorial countersinging generally heard mainly in early morning. Wide array of quiet contact and social calls also recorded.
Habitat. Majority of islands where this species now present are sites to which it has been translocated. At sites where successfully reintroduced, available habitat is almost entirely restricted to evergreen coastal forest and mixed lowland broadleaf forests, especially seral forest and second growth; on these islands may occur at up to 700 m. In original surviving population, most abundant in forests dominated by pohutukawa (*Metrosideros excelsa*), kanuka (*Kunzea*), and evergreen broadleaf species such as *Vitex* and *Beilschmiedia*. Translocated population on Tititiri Matangi I has even adapted to introduced brush wattle (*Paraserianthes*).
Food and Feeding. Food mainly invertebrates and berries, occasionally nectar. Nestling diet apparently richer in invertebrates. Generally forages in pairs, or in family groups during non-breeding period; larger groups occasionally recorded. Forages at all levels of forest, in leaf litter, on decaying timber and among braches and foliage right up to canopy, during most of day. Foraging heights vary seasonally, with more time spent on ground in winter and more time spent in foraging on fruits in late summer and autumn. Male and female may exploit different heights when foraging together, with males more frequently on ground. Gleans food items; also uses technique of gaping, and pries bark from branches and trunks. Fruits generally gleaned, but larger fruits may be pecked at *in situ*. Attacks prey items while actively searching on ground, lifting leaf litter; may toss leaves in manner of a *Turdus* thrush. Climbs slowly up each tree before flying/gliding or hopping to next tree. Removes bark by grasping it with bill and using own weight to pull bark away. Often holds prey with foot in manner of a parrot (Psittacidae); use bill to give sharp jabs to larger prey before dismembering them; repeatedly smashes caterpillars into branches before swallowing.
Breeding. Timing and frequency appear dependent on density, generally breeding in spring and summer, with early-autumn records only when food abundant or population low; laying Aug–Mar and latest nestlings and fledglings recorded in May; can have 3–4 broods in a good season with low population density. Nest, built solely by female, a medium-sized cup made from twigs (usually found nearby), bound together with moss, lichens or other filamentous vegetation, with inner lining of finer twigs and leaves and very rarely with some feathers, placed generally in hole or cavity in trunk or thick branch of tree in understorey or subcanopy, sometimes on ground in rock crevice or among dense epiphytes, rarely in crown of tree-fern or flax (*Phormium*), commonly in nestbox when available; sites other than nestboxes rarely reused. Clutch 1–4 eggs, usually 2; incubation by female, period on average 18 days; chicks brooded by female, fed by both parents, fledging period 23–27 days. Where Polynesian rats (*Rattus exulans*) present, few nests successful unless in secure hole or nestbox; as majority of sites free of mammalian predators, nest failure generally due to avian predators such as Pacific Marsh-harrier (*Circus approximans*), Morepork (*Ninox novaeseelandiae*) and Weka (*Gallirallus australis*) and introduced Common Myna (*Acridotheres tristis*). Long-lived for a medium-sized passerine; maximum recorded longevity 21 years, and 18–20 years common.
Movements. Adults sedentary and territorial all year. Juvenile dispersal generally less than 3 km. Translocated birds may travel 5 km before establishing territories. Birds from the Wellington Karori population have been recorded in several parts of the city many kilometres from the sanctuary.
Status and Conservation. Not assessed. Probably Near-threatened. When treated as conspecific with *P. carunculatus*, the enlarged species is considered Near-threatened. Confined to islands off North I. Although able to exist in presence of Polynesian rat, unable to co-exist with brown rat (*Rattus norvegicus*) and cannot survive with other introduced predators; prior to 1964, species was restricted to Hen I, in Hauraki Gulf. Introduced predatory mammals responsible for extinction on mainland. Since 1964, has been introduced successfully on 13 islands off North I, and global population now more than 6000 individuals, with capacity to increase to over 19,000 individuals. Although three introductions on mainland areas have been tested, only those made in two predator-fenced areas have been successful, and survival here dependent on intense management. Although current populations large and well spread out, accidental introduction of predators on the islands still a potential threat.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family NOTIOMYSTIDAE (STITCHBIRD)

- Medium-sized, rather plump passerine with fairly short and slightly decurved bill, rather long tail often held cocked, and broad rounded wings with prominent white patch.
- 18 cm.

- New Zealand.
- Forest.
- 1 genus, 1 species, 1 taxon.
- 1 species threatened; none extinct since 1600.

Systematics

The Stitchbird (*Notiomystis cincta*), known also as the "Hihi", a distinctive New Zealand endemic, has generally been treated as a honeyeater (Meliphagidae), albeit an unusual one. The main reason for including it among the honeyeaters is that it has a brush-tipped tongue and is largely nectarivorous. Recent phylogenetic analysis of both nuclear and mitochondrial DNA sequences carried out by A. C. Driskell and her colleagues, however, showed unequivocally that the Stitchbird was not a honeyeater at all. Their results, and those of a similar study by J. G. Ewen and co-workers, placed the Stitchbird in a clade that included the endemic New Zealand wattlebird family, Callaeidae, which comprises the saddlebacks (*Philesturnus*), the kokako (*Callaeas*) and the Huia (*Heteralocha acutirostris*). The affinities of this Stitchbird–New Zealand wattlebird clade were less clearly resolved. According to the DNA studies of F. K. Barker and colleagues, the New Zealand wattlebirds are part of a basal assemblage that may include the berrypeckers and longbills (Melanocharitidae) and the cnemophiline satinbirds, the latter currently placed in the bird-of-paradise family (Paradisaeidae), but many more data are required.

On the basis of DNA-clock analysis, Driskell and her colleagues estimated that the Stitchbird diverged from the New Zealand wattlebirds 28–39 million years ago. The other two endemic New Zealand species classed as honeyeaters, the Tui (*Prosthemadera novaeseelandiae*) and the New Zealand Bellbird (*Anthornis melanura*), were confirmed as being honeyeaters by these DNA studies.

Driskell and colleagues reassessed the nature of several morphological and behavioural characters that further indicated that the Stitchbird is not a honeyeater. Although brush-tipped at the end, the tongue of this species has its edge curled dorsally to form a tube for most of the length. Honeyeaters tend to have a furrowed tongue, and this, if tubular, is so for only a short part. The tongue of the saddlebacks and the kokako is fairly broad and flat. The Stitchbird also lacks the pneumatic tricipital fossa of the humerus that all honeyeaters possess. According to W. E. Boles, there are significant differences between the Stitchbird and the honeyeaters in the structure for the attachment of the toes (tarsometatarsus). In a study of the sterna of Australasian passerines, G. R. Fulton and Boles observed that most Australian honeyeaters have multiple foramina (small excavations) on the dorsal face of the sternum along the mid-line, whereas such foramina were absent in the Stitchbird and in the saddlebacks and kokako. The Stitchbird differs from the New Zealand wattlebirds in lacking the fleshy gape wattles and differs from the honeyeaters in having large rictal bristles.

In behaviour, too, the Stitchbird is quite different from honeyeaters. Unlike the latter, it nests in cavities, a habit which it has in common with the saddlebacks. Interestingly, the saddlebacks are partially nectarivorous, as is the Stitchbird. The mating system of the Stitchbird is complex (see Breeding), and not only have polyandry and polygyny been recorded but also polygynandry, both females and males having multiple partners during the breeding season. Moreover, the Stitchbird is the only species of bird known to engage in face-to-face copulation, although the sexes of this species do copulate also in the normal avian fashion.

On the combined criteria of DNA relationships, molecular-clock divergence dates and morphological considerations, Driskell and colleagues separated the Stitchbird into its own monophyletic family, Notiomystidae.

Early European settlers in New Zealand used the vernacular name "Stitch Bird", after the species' frequently heard warning call, a single or repeated "titch" note (see Voice). The Maori name of Hihi, which is widely used in the literature, also apparently refers to this call. The first published mention of the Stitchbird is a short account in 1835 by the Reverend W. Yate, who lived at the Bay of Islands, and this, as W. R. B. Oliver suggests, indicates that the birds were probably extant there at the time.

The taxonomic nomenclature of the Stitchbird is, mercifully, fairly straightforward. Originally described by du Bus de Gisignies in 1839, it was placed within the honeyeater genus *Meliphaga*, with the Latin epithet *cincta*, referring to the golden-yellow band bordering the hood of the male. As early as 1846, G. R. Gray used the generic name *Pogonornis* for this species, this name derived from a combination of the Greek *pogon*, referring to a beard, and *ornis*, a bird, a reference to the long rictal bristles. It was C. W. Richmond who, some 60 years later, erected the genus *Notiomystis* as a new name for the preoccupied *Pogonornis*. The new generic name referred to the Stitchbird's distribution and uncertain affinities, combining the Greek *notios*, meaning "southern", and *mustes*, meaning "a mystic" or "a mystery".

In 1935, G. M. Mathews proposed that the population of Little Barrier Island, in the outer Hauraki Gulf, be treated as a separate subspecies, *hautura*. This was said to be shorter-winged than other populations of the species, which were by then already extinct, and the male was apparently more yellow below the throat.

Until DNA analysis showed otherwise, the New Zealand endemic ***Stitchbird*** *was treated as a honeyeater (Meliphagidae) on the basis of its brush-tipped tongue, and its nectarivory. It is now placed in a monospecific family of its own, Notiomystidae, and has been grouped in a clade with the endemic New Zealand wattlebirds (Callaeidae). A smallish, stocky passerine, the Stitchbird is strongly sexually dimorphic. The male, shown here, has a large black hood, with conspicuous white erectile tufts.*

[*Notiomystis cincta*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Tui de Roy/ Roving Tortoise Photos]

Differences between the Little Barrier populations and those elsewhere seem, however, to be somewhat obscure, and there appears to be some overlap in measurements, at least.

Morphological Aspects

The Stitchbird is a typical, rather stocky ten-primaried passerine. It is medium-small, being about 18 cm in total length. It possesses a specialized, brush-tipped tongue and a slightly decurved and slender bill, both associated with a strongly nectarivorous diet combined with the consumption of fruit and small invertebrates (see Food and Feeding). A combination of characters superficially similar to, but convergent with, those of honeyeaters has for long been the principal basis on which the Stitchbird was placed in the family Meliphagidae (see Systematics).

This species is strongly sexually dimorphic in size and plumage, with the males larger and more colourful than the females. The mean weight of males is 37·5 g, whereas that of females is some 20% less, at 30 g. In addition, females are significantly smaller in total head length and in the lengths of the wing, tail, bill and tarsus, although there is an overlap between the sexes in all measurements. Stitchbirds are much smaller than Tuis, which are 27–32 cm in length, males having an average weight of 120 g and females one of 86 g, but they are very similar in size to New Zealand Bellbirds, which are 17–20 cm long, with average weights of about 31 g for males and about 24 g for females. Both sexes of the Stitchbird have been found to exhibit a significant increase in wing length with increasing age. There are also seasonal differences, wing length being greater in the six months immediately after the primary moult (April–September) than during the six months preceding the next moult (October–March), as the feathers become progressively worn. On Tiritiri Matangi Island, both sexes varied in weight over the year, and were heavier during the autumn and winter: the mean weight of males ranged from 37·2 g, in December, to 45 g, in April, and that of females in the same months from 30·1 g to 35·6 g.

In terms of plumage, the adult male is distinctive. It has a large black hood, bordered by a golden-yellow band extending from the shoulder downwards towards the centre of the lower breast. The rest of the upperbody merges to grey-black and olive-brown, and the underbody is dirty off-white with diffuse darker streaking. The uppertail and upperwings are blackish, but the wings are strongly patterned with a large white blaze across the base of the tertials and inner greater secondary coverts, and yellow fringes or edges on the secondary coverts and the secondaries and primaries, which combine to form pale panels on the folded wing. The yellow margins of the wing-coverts and remiges constitute a pattern that is commonly found within the Meliphagidae. Compared with the male, the adult female is a much duller and plainer bird, generally brownish-olive, although paler brownish-grey with diffuse dark streaking below. The wing pattern is similar to that of the male, including the prominent white patch, but the ground colour is duller blackish-brown and the fringes and edges of the coverts and remiges are duller, more yellow-olive. Males and females in first immature, or first basic, plumage are very similar to the respective adults.

Plumage ornamentation of the male is restricted to a pair of white and erectile tufts on each side of the nape. These nape-tufts are large, with a mean length of 13 mm, and are conspicuous against the velvety black hood; the length of the tuft increases with age. On the female, white is restricted to tiny subterminal spots on the feathers of the side of the nape, these combining to form small white spots that are considerably smaller than the tufts of the male; they have a mean length of 2 mm and in the field are usually concealed, although they are sometimes visible. Unlike any of the honeyeaters, the Stitchbird has prominent bristles around the base of the bill. These consist of four large, black rictal bristles arising at the base of the gape and several other black bristles on the chin and lower forehead.

The bare parts are unexceptional, and exhibit only slight sexual dimorphism. The bill is moderately long, about half the length of the head, and is slender and slightly decurved, most obviously towards the pointed tip; that of the male has an average length of 21·5 mm, the corresponding figure for females being 20·5 mm. The bill of the adult is black, although females often have a dark brown base on the lower mandible, and the tongue is pink. As already mentioned (see Systematics), the tongue is brush-tipped and partly tubular, adaptations to nectar-feeding, but the structure differs markedly from that found in the Meliphagidae. The eyes appear fairly large, and the irides are blackish-brown. A narrow orbital ring varies from grey-black to dark blue-grey or dark brown, and is generally inconspicuous. The legs are moderately long and slender, with holothecal (undivided) scaling, and the tibia is fully feathered. The middle toe is the longest, although the hind toe can be almost as long. The legs and feet vary from dark brown to red-brown or pinkish-brown or dark grey, and the soles are pink-buff or creamy.

Stitchbird wings are broad and rounded, with ten primaries and nine secondaries, the latter including three tertials. If the pri-

maries are numbered descendantly, from the innermost outwards, primary P6 is the longest, and several outer primaries (P5–P8) have slight emarginations on the outer webs. Unlike the two endemic New Zealand honeyeaters, namely the Tui and the New Zealand Bellbird, the Stitchbird does not have specially shaped remiges and it does not, therefore, produce loud wing noises like the ones heard from those two species. The tail is fairly long and is square-cut at the tip; it contains twelve rectrices.

Relatively little information is available on the moults of the Stitchbird. Adults undergo a complete post-breeding, or pre-basic, moult annually, with no change in appearance other than the overall freshness of the plumage. There are, however, few published details of the timing or the pattern of moults. The primaries are replaced outwards, descendantly, and this moult appears to be complete, or largely so, by the end of March; early stages of primary moult have been recorded in December. Thus, primary moult occurs late in the breeding season, but it is not known whether any individuals experience an overlap in the timing of the moult and breeding. The tail feathers are likely to be replaced centrifugally, from the central pair outwards.

Juveniles are very similar in plumage to the adult female, but are duller and browner still, with less streaking below, and have a duller, buff patch on the folded wing. The bare parts differ from those of the adult female. The juvenile has a duller, grey-black bill, with a dirty yellow or brownish-orange basal two-thirds of the lower mandible and, most obviously, prominent, swollen yellowish or orange-yellow gape-flanges. Young usually begin their post-juvenile, or first pre-basic, moult about four weeks after fledging. This moult is usually partial, resulting in an adult-like first immature plumage, although a small proportion of young appear to undergo a complete moult, resulting in adult plumage. Study is needed, however, in order to determine whether the post-juvenile moult is ever a complete one.

Most interestingly, M. Low and I. Castro and their colleagues have shown a particular aspect of the Stitchbird's morphology that is directly related to the mating system and copulatory behaviour of this species (see Breeding). Male Stitchbirds have one of the largest cloacal protuberances of any bird species, and the volume of this increases almost four-fold between the non-breeding and breeding seasons. Further, the cloacal protuberance changes its orientation seasonally by approximately 60 degrees, so that it becomes almost perpendicular to the abdomen, rather than facing posteriorly, in the breeding season. This change in orientation improves the apposition of the male and female cloacal openings during face-to-face forced copulation by this species (see Breeding). The female cloacal volume changes in much the same way as that of males, but the orientation does not.

Habitat

Before European settlement, Stitchbirds occurred throughout the North Island mainland, as well as on Great Barrier Island and Little Barrier Island, both in the outer Hauraki Gulf, and on Kapiti Island, off the south-western coast of the North Island. There is no evidence that the species ever occurred on the South Island. Towards the end of the nineteenth century, however, the species had become extinct except for a small population that survived on Little Barrier Island (see Status and Conservation).

The habitat of the Stitchbird on the North Island was dense, moist broadleaf evergreen forest, and the mature forests of Little Barrier Island where the species has managed to persist are believed to be similar to the undisturbed mainland habitats which it formerly used. The forest habitat of Little Barrier is among the most pristine in New Zealand, with negligible human impact over most of the island for some 150 years and in some areas no evidence of human impact at all.

Little Barrier Island is of volcanic origin, and has a series of central peaks that descend steeply to the coast in radiating gorges, ravines and valleys. The highest peak is Mount Hauturu, at 722 m, and the island is often capped by cloud. The combination of altitude and topography of the island produces a range of distinct forest types, each with a different suite of plant species. At least 14 vegetation communities have been recognized here.

Detailed studies on Little Barrier Island, by G. R. Angehr, showed that Stitchbirds inhabited mainly dense, moist hardwood forests but moved extensively between forest communities in order to exploit seasonal flowering or fruiting within communities, and ranged from the lowest valleys up to the ridges of the mountain summits. They appeared to prefer mixed forests dominated by tawa (*Beilschmiedia tawa*) and northern rata (*Metrosideros robusta*) in the valleys and on the lower slopes up to 300 m, where tairę (*Beilschmiedia tarairi*), kohekohe (*Dysoxylum spectabile*) and puriri (*Vitex lucens*) are also present, and forests dominated by tawa and towai (*Weinmannia silvicola*) on steep slopes at altitudes above 500 m. Stitchbirds were recorded less often in mixed forest of kauri (*Agathis australis*) and hard beech (*Nothofagus truncata*) on ridges at middle elevations, in tall regenerating forest of kanuka (*Leptospermum ericoides*) in the valleys, in wet forests dominated by tawa, towai, tawari (*Ixerba brexioides*) and miro (*Prumnopitys ferruginea*) on ridges above 400 m, and in coastal pohutukawa (*Metrosideros excelsa*) forest. They were least common in *Leptospermum* forests growing on the ridges and in stunted summit forests of *Quintinia*, tawari and southern rata (*Metrosideros umbellata*) on the highest peaks. Stitchbirds occasionally visited the garden of the single homestead on Little Barrier, where they foraged on cultivated fruits.

It is possible that *Nothofagus* beech forests represented a marginal habitat for the Stitchbird on the main North Island, as well.

All of the islands to which Stitchbirds have been translocated (see Status and Conservation) have been significantly modified from their natural state through clearing and burning and associated agricultural activities of Maori people and Europeans, and by the browsing and grazing of introduced stock, such as sheep and goats, or pest species, such as common brushtail possums (*Trichosurus vulpecula*). Compared with Little Barrier Island, all of them have a lower diversity of fruit and nectar resources, this being especially so in winter. Furthermore, as there is little or no mature vegetation, there is a shortage of natural tree cavities suitable for breeding. This, too, may continue to limit the numbers of Stitchbirds on these islands, although the provision of artificial nesting boxes can go some way towards remedying this problem. The habitats of these islands are all being managed so as to restore the native vegetation and the stock of fruit-bearing and nectar-producing plants that Stitchbirds need for their survival.

General Habits

The Stitchbird is a diurnal and largely arboreal species, although it does occasionally forage on the ground, and copulation and some displays are also performed on the ground. It is usually confiding and approachable, and quite vocal, with contact calls and some other vocalizations given throughout the year. Nevertheless, it is quieter in the non-breeding season than when breeding, and it may be harder to detect at this time (see Voice).

One of the species' more characteristic habits is its frequent cocking of the tail, to 90 degrees or a little beyond, which is typically done when it alights on a branch, and is a feature also of some displays. When alarmed or excited, the male cocks his tail and will raise the nape-tufts. In a resting posture, the tail is often cocked but the wings hang down beside the body. Stitchbirds are highly mobile and are agile and acrobatic when foraging, often hanging upside-down when searching for food or in order to reach flowers or fruit. Despite being a normally able flyer, this species appears to cross open habitats only rarely and does not usually, if ever, cross water.

In general, Stitchbirds are seen in pairs or in small groups of up to ten individuals, and they often associate with Tuis and New Zealand Bellbirds, particularly in flowering or fruiting plants. During the breeding season, which coincides with the austral spring and summer, October–March, the male Stitchbird defends a small territory of some 30–50 m around the nest-site in which it is aggressive towards and chases other males, while the female defends the nesting cavity by exhibiting aggression towards any other birds, including other Stitchbirds and even, at times, her

*The much less colourful female **Stitchbird** is significantly smaller than the male, and weighs some 20% less at around 30 g. Both sexes have prominent black bristles around the base of the bill. The wings are broad and rounded, with ten primaries and nine secondaries. The tail, consisting of twelve rectrices, is long and square-cut at the tip; it is frequently cocked, for example when the bird alights on a branch, and during displays. Remarkably, male Stitchbirds have one of the largest cloacal protuberances of any bird species. Its volume increases four-fold between the non-breeding and breeding seasons, as indeed does the female's. But the male's also changes its orientation, from posterior-facing to almost perpendicular to the abdomen, facilitating face-to-face copulation. The Stitchbird is the only species of bird known to copulate in this way, though it also copulates in the normal avian fashion.*

[*Notiomystis cincta*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Neil Fitzgerald]

own mate, that land near it. Nevertheless, during the breeding season, group size varies with the mating system of individuals (see Breeding), and groups of Stitchbirds can cluster around nest-sites and may still congregate at feeding sites.

Once they have fledged, from about December, the juveniles, accompanied by their male parents, join crèches (see Breeding). These crèches begin to disband in the autumn. In the non-breeding period, in the austral autumn and winter, Stitchbirds are often seen to congregate in small groups, again of up to about ten individuals, but typically of two to six. At this time, they are often found also in mixed-species foraging flocks with Whiteheads (*Mohoua albicilla*), North Island Saddlebacks (*Philesturnus rufusater*) and other passerines. In mid-winter on Little Barrier Island, Stitchbirds were as likely to be found in a mixed-species flock as not to be.

Stitchbirds form dominance hierarchies, with older birds typically dominant over younger ones, especially those of the same sex, and males dominant over females. The individual's position in such hierarchies, however, can vary with mating and residential status; for example, on Little Barrier Island, females are dominant over males when chicks are present in the nesting cavity. Dominance hierarchies usually form also within polygynous and polyandrous groups (see Breeding), which generally contain a dominant male or a dominant female or both.

Stitchbirds call in alarm, using different vocalizations for different levels of threat or apparent threat (see Voice), and in such situations they may raise the nape-tufts and cock the tail. It has been said also, however, that the female sometimes simply hides quietly. Stitchbirds often mob predators, including the Morepork (*Ninox novaeseelandiae*) and cuckoos (Cuculidae), although there are no published reports of Stitchbirds suffering brood parasitism by cuckoos. During mobbing, the alarm calls of one or more birds often attract others.

Little is known about the roosting habits of this species. Stitchbirds roost at night, in small groups of several individuals, and typically in tree cavities. They have been seen to roost also in clumps of *Collospermum*, in foliage or in dense lianas, and among rocks in rocky outcrops.

There has been little study of overall time-budgets of the species. During the first two weeks following the translocation of Stitchbirds to Mokoia Island (see Status and Conservation), the birds spent 70% of their time foraging, with 34% of the time feeding on nectar and fruit and 36% on invertebrates; of the remaining 30% of their time, 29% was spent in perching and 1% in other activities. Whether the behaviour of a long-established population would differ is not known, but it seems probable that it would.

Voice

The vocalizations of the Stitchbird are quite well known, and consist of a wide range of often high-pitched sounds. Both sexes call, although most of the vocalizations of males are considerably louder than those of females and are, therefore, much more readily heard; most female vocalizations are not audible beyond a few metres. Some calls, such as those used for warning and for contact, are given commonly, and throughout the year, but this species is much noisier during the breeding season. Stitchbirds vocalize least in mid-winter, although they do call at regular intervals when foraging. Seven vocalizations are unique to males, five are given only by females, and at least a further eight vocalizations are shared by the two sexes.

The frequently heard "Warning Call" is a "titch" note, this being the origin of the species' English vernacular name. The Maori name Hihi is another interpretation of the call. Such "titch"

notes can be given singly or, with increasing levels of alarm, uttered in an accelerating series, when the warning call may grade into the "Alarm Call", a series of high-pitched "yeng" notes. Other calls emitted by both males and females include a plaintive "wee" or "tseet", given singly or in pairs, which is the "Contact Call", and a soft warble, inaudible beyond a few metres, which may include mimicry of other bird species such as the New Zealand Robin (*Petroica australis*) and the North Island Saddleback. The "Aggressive Chat", somewhat similar to the warble, is given in threat (see Breeding), and a "Chase Call", consisting of rapid "pew" syllables, is uttered by an individual when it is being chased by others. A series of soft, short squeaks is sometimes heard to be emitted by individuals which are inspecting nest-cavities other than their own, and this call is uttered also by males when they are being pursued by other males. Both parents make brief high-pitched calls, known as "Parental Calls", in order to induce fledglings to move.

Male song is a loud and high-pitched whistle of two or three notes, "wee-ah-wee", "wee-ah" or "trr-ah-wee", with several variants included in a single song bout. This song, which can be given at rates of up to 120 per hour, is heard frequently during the breeding season, especially at the beginning of the season. On Kapiti Island, where there is a shortage of nest-sites, males sing throughout the year, although at higher intensity at the start of the breeding season. Other male vocalizations include the "Nest Call", "chi-ching", which is usually interspersed with song; the "Identification Chat", given whenever the male meets with its mate and comprising squeaky warbling sounds; a plaintive "Copulation Cooing"; a soft "Threat Cooing", given during the Ultimate Aggressive Display (see Breeding); and a "Metallic Call", delivered during display-flights. A quiet "pew" was once heard from a male during copulation.

Vocalizations given only by female Stitchbirds include several calls associated with copulation. Both a repeated loud plaintive "pew", the "Copulation Request Call", and a loud high-pitched warble, the "Copulation Request Warble", are given by females seeking copulation, the warble often following the copulation request call. Females also utter a rapidly repeated loud "pew", known as the "Forced Copulation Call", when being chased by males attempting forced copulation and during forced copulation itself (see Breeding). As well as these vocalizations, the female emits a short, soft, high-pitched "sweet" as an identification call from inside the nest-cavity in reply to the song of the male on his arrival at the nest; she also directs hisses towards her mate in aggression.

On Mokoia Island, novel songs were heard each year, suggesting that new songs are created regularly. Some of these songs become prevalent, which would appear to indicate that song is transmitted culturally among the Stitchbird population.

Food and Feeding

The diet of the Stitchbird consists of nectar, fruit and small invertebrates, the proportions of which vary throughout the year, largely reflecting their availability in the environment. In this regard, the diet is similar to that of many honeyeaters, and represents another convergent aspect of the species' ecology and biology that led to the Stitchbird's long treatment as a meliphagid. A habit which the Stitchbird shares with many honeyeaters is that of eating primary or secondary plant exudates that are rich in sugar or other carbohydrates, such as lerp, manna and honeydew, although the significance of these in the diet is not known as they have not been quantitatively analysed.

Stitchbirds visit a wide variety of plants in their search for food, and seasonal patterns in the use of plant species through the year are evident. Important sources of nectar include the sugar-rich flowers of *Metrosideros*; these resemble the flowers of eucalypts (*Eucalyptus*) and *Syzygium*, which are widespread in Australia and New Guinea, and all of these are members of the family Myrtaceae. *Knightia* is another main source of nectar and a member of the Proteaceae, another family of nectar-rich plants widespread in Australia. Other important nectar-producing plants that feature in the diet of the Stitchbird include the puriri, a small verbenaceous tree with scattered but nectar-rich flowers, the horopito (*Alseuosmia macrophylla*), a caprifoliaceous shrub with large crimson flowers (and berries), the lily-like New Zealand flax (*Phormium tenax*) and the cabbage tree (*Cordyline australis*). Major fruiting plants used by the Stitchbird include those of the genera *Coprosma*, *Pittosporum*, *Pseudopanax* and *Aristotelia*, of the respective families Rubiaceae, Pittosporaceae, Araliaceae and Elaeocarpaceae. These four provide both abundant nectar and fruit, as also do species of *Metrosideros*, *Fuchsia* and *Rubus*.

In studies on Little Barrier Island, important foods were found to include nectar and fruit of *Coprosma*, the fruits of which accounted for 40% of observations of feeding in one study, and nectar, and some fruits, of the haekaro (*Pittosporum umbellatum*). Equally significant was the nectar of *Metrosideros*, mainly of the pohutukawa, or "New Zealand christmas tree", which accounted for 42% of observations of nectar-feeding in one study, and of the northern rata, but also that of the scarlet rata (*Metrosideros fulgens*), the white climbing rata (*Metrosideros perforata*), the horopito, *Rhabdothamnus solandri* of the family Gesneriaceae, the puriri, and the rewarewa or "New Zealand honeysuckle" (*Knightia excelsa*).

The fruit and nectar of most of these plants are available for only part of the year. In one study on Little Barrier Island, for example, the major nectar sources over the year were the puriri in May, July, September and November, the haekaro in August–September, *Alseuosmia macrophylla* in August–October, *Knightia excelsa* in September–October, the pohutukawa in December, and the northern rata in December–January. Studies on the two islands of Kapiti and Mokoia revealed much annual variation in the timing and production of flowers and fruit, and that shortages of food may be a limiting factor in some years, particularly on the highly modified islands to which Stitchbirds have been translocated (see Status and Conservation).

On Little Barrier Island, Stitchbirds occasionally foraged in the garden of the single homestead on the island. Here, they fed from orange blossom, and took figs (*Ficus*) and the berries of houpara (*Pseudopanax lessonii*) and mahoe (*Melicytus ramiflorus*).

Small invertebrates are a further important source of food and protein throughout the year, although there are few records of precisely which species Stitchbirds consume. Insects, including beetles (Coleoptera), and spiders (Araneae) are the only items reported in the literature. Nevertheless, insects have been found to form the major component of the diet in some seasons for the natural population of Little Barrier Island and for the translocated populations studied. In addition, Stitchbirds may ingest significant amounts of pollen, but it is likely to pass through the gut largely undigested, as is the case also with the honeyeaters.

The total proportions of nectar, fruit and invertebrates in the diet vary not only seasonally, but also between the natural populations of Stitchbirds on Little Barrier Island and the translocated populations elsewhere. Moreover, there are variations within populations in the findings of different studies in which relevant data have been gathered, although these may reflect annual variation in flowering and fruiting phenology. As an example, in one study on Little Barrier Island, it was found that nectar-feeding comprised 69% of foraging observations over the year, fruit accounting for 15% and invertebrates for 16%; comparable results from a second study, albeit one with a larger sample size, were nectar 30%, fruit 31% and insects 39%. In studies of the translocated population on Kapiti Island, over the year, feeding on nectar formed 37% of observations of foraging, whereas the taking of fruit represented 23% and the eating of invertebrates 40%.

Likewise, seasonal patterns in the proportions of the three major components of the diet exhibit much variation. For example, in one study on Little Barrier Island, nectar was the main dietary component in spring and summer, accounting for, respectively, 89% and 83% of foraging observations, and was a major component also in winter, with 47%; fruit was the main component in autumn, when it figured in 50% of observations, while insects formed a maximum of 29% of observations in autumn and winter. In contrast, in a second study on Little Barrier, nectar was the main component of the diet in spring and winter, with respectively 56% and 51% of feeding observations; fruit was the

The common call of both sexes is a warning "titch", which is the origin of the vernacular English name, ***Stitchbird****. The Maori name, Hihi, is apparently another rendering of this call. The calls of the male are louder than those of the female, which are generally not audible beyond a few metres away. The male's song is a loud, high-pitched whistle of two or three notes, with several variants included in a single song bout. The song can be given at a rate of about 120 bouts per hour. The male advertises his territory by singing from within it, or at feeding areas. His persistent singing reaches its greatest intensity in the two days before the female lays, but stops almost entirely after laying. However, on Kapiti Island, where nest-sites are in short supply, males sing throughout the year. On Mokoia Island, novel songs were heard each year, suggesting that new songs are created regularly. Some of these songs become prevalent, which appears to indicate that song is transmitted culturally among the Stitchbird population. The male has seven identifiable vocalizations, and the female five. The male's calls include: the "Identification Chat", a series of squeaky and warbling sounds given at meeting with his mate; a plaintive "Copulation Cooing"; a metallic call given during display flights; and a soft "Threat Cooing" directed towards intruding males. The female's repertoire includes: the "Copulation Request" call and warble; a soft, high-pitched "sweet" given as an identification call from the nesting cavity in reply to her mate; and an aggressive hiss. Females also utter a rapidly repeated "Forced Copulation Call", when pursued or during forced copulation. At least eight further calls, including the "titch" call, and brief high-pitched calls used to induce fledglings to move, are shared by both sexes.*

*The proportions of nectar, fruit and invertebrates in the diet of the **Stitchbird** vary throughout the seasons, from island to island, and from year to year, reflecting their availability. The brush-tipped tongue has its edge curled to form a tube, and nectar is taken by probing flowers with the curved bill. Stitchbirds visit the plants which offer the most nectar, and tend to avoid those which are comparatively low in nectar. But each of these plants flowers for only part of the year, and though different species may offer nectar in succession, studies of the Stitchbird population on Little Barrier Island found that none of the major nectar sources are available between January and May.*

[*Notiomystis cincta*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Martin Grimm]

main component in autumn, with 89%, and was significant also in spring and winter, with 33% and 40% respectively; and insects were the most important component in summer, when they featured in 70% of foraging observations.

The seasonal pattern observed for the translocated Stitchbird population on Kapiti Island was different again. Nectar was the main component of the diet in winter, recorded in 73% of feeding observations, and nectar, insects and fruit formed equal proportions of the diet in autumn, each with 33% of observations; fruit, accounting for 46%, and insects, for 45%, were the main dietary items in summer, and insects formed the main component of the diet, 71%, in spring. On Mokoia Island, Stitchbirds fed mostly on nectar and fruit in winter and spring, and mostly on invertebrates in summer and autumn. Foraging for nectar comprised the main proportion of foraging time during spring and winter, 75% and 54% respectively, and invertebrates the principal component in summer and autumn, 73% and 51%; fruit was the target in a maximum of 28% and 27% of foraging time in autumn and winter, respectively.

The results of these various studies show that seasonal patterns in the consumption of nectar, fruit and insects vary both within and among islands, with no constant trends evident. It is likely, however, that the differences in the patterns of exploitation of nectar, fruit and insects are a result mainly of the differences in the floristic composition among populations, or islands, and both regional and annual variation in flowering and fruiting phenology. There may also be some effect, in part confounded by the previous factors, of competition with other birds that varies with the differing avian communities associated with each population.

On Mokoia Island, the plant species most frequently exploited for nectar tended to be those that contributed the greatest proportion of nectar in the standing crop at any one time, and the birds tended to avoid flowers that were comparatively low in nectar. This is likely to apply to other populations. In contrast, the proportion of time spent in feeding on different species of fruit bore little relation to the store of carbohydrates available in the fruits at the time.

Stitchbirds are primarily arboreal, and are agile and acrobatic when foraging in trees and shrubs. They forage actively among the foliage, twigs and terminal shoots of trees and small shrubs, often hanging upside-down in order to reach flowers and fruit and to capture invertebrates. Within trees they move from inflorescence to inflorescence by walking and clambering along branches, by jumping or making short glides; they will also spring into the air from branches to catch insects, sometimes alighting on a different branch.

On Little Barrier Island, Stitchbirds carried out most of their foraging in the middle and lower levels of the understorey, which accounted for, respectively, 27% and 29% of recorded observations, although they foraged much also in the subcanopy and in the canopy, each of which featured in 17·8% of observations. Only very rarely do they descend to the ground, but females have been seen to feed on beetles on the forest floor, and also to follow a Kaka (*Nestor meridionalis*) and catch insects disturbed by the parrot as it carved away at bark.

This species gathers nectar by directly probing flowers, and it obtains fruits by plucking them from plants. It gleans invertebrates from bark and foliage, from inside hollows and other cavities in trees, and also by probing beneath bark, and it will also make aerial sallies to catch flying insects or to pluck invertebrates from spider webs. It obtains insect and plant exudates by gleaning from foliage, twigs and shoots.

All of the important sources of nectar and fruit for Stitchbirds are commonly exploited also by the two New Zealand honeyeaters, namely the Tui and the New Zealand Bellbird. These three species, treated together as honeyeaters (see Systematics) in all existing studies of their food and feeding, partition nectar resources according to richness. When foraging together, they sometimes develop dominance hierarchies, in which Tuis and Bellbirds are dominant over Stitchbirds. The Tui, much the largest of the three, feeds on rich flowers in trees and large shrubs, which it defends. The Stitchbird is subordinate to the Tui, and may feed on peripheral flowers of the rich sources, but it tends to visit poor nectar-producers or those with dispersed flowers. The New Zealand Bellbird, in its choice of flowers, occupies a niche between these two species. All three may switch to the eating of many insects or fruits at different times of the year.

Breeding

The breeding biology of the Stitchbird is perhaps the most obvious behavioural difference between this unique species and the

honeyeater family, Meliphagidae, within which the Stitchbird was previously placed (see Systematics). Some of the most noticeable characteristics separating it from the meliphagids are its cavity-nesting habit, its typically larger clutch size, its complex and varying mating system and, uniquely among birds, its face-to-face copulation. Further, male Stitchbirds exhibit a number of morphological features found in species with highly variable mating systems and in situations when males are under intense sperm competition: they have large testes, very large numbers of sperm in their seminal glomera, and an unusually enlarged cloacal protuberance.

The species' breeding season is centred on the austral summer, with nesting recorded from September/October to February/March, although, within local populations, breeding is not synchronous and nests at various stages are recorded throughout this period. The first eggs are usually laid by mid-October, but annual variation is apparent; in two seasons on Kapiti Island, for example, first clutches were laid between 16th November and 9th December in one season and during 5th–19th December in the next. Stitchbirds begin to investigate cavities as early as August, and male displays and vocalizing begin or increase in September, before the start of nest construction and egg-laying. This species may make two or even three or four breeding attempts in a season. On Mokoia Island, females lay one to three clutches per season, although third clutches are usually laid only if second clutches fail, and second clutches do, indeed, tend to be unsuccessful. On Tiritiri Matangi Island, females can lay up to four clutches if early nesting attempts fail, but they succeed in raising only one or two broods in a season.

The displays of Stitchbirds are reasonably well known. In September–October, at the start of the breeding season, the male advertises ownership of his territory by singing persistently from within it or at feeding areas. This persistent singing continues until the time of laying, reaching its greatest intensity in the two days before the female lays, but it stops almost entirely after laying. This territorial advertising and singing probably have some function in courtship and sexual behaviour. At the nest-site, the male performs a display-flight to the female in which he glides slowly downwards from the entrance to the nest-cavity, the spread wings displaying the yellow and white colours, and the nape-tufts held raised, during which he utters a metallic call. He alights near the female, either landing on the ground or flying upwards to perch on a higher branch. Males also court females by "display-walking" on the ground, the wingtips crossed over the back and the nape-tufts raised, and uttering the warbling call. The walking display often precedes copulation. The male gives the Identification Chat each time he and his partner meet; the female within the nest gives the Identification Call after her mate sings on arrival at the site (see Voice).

Throughout the breeding season, Stitchbirds are aggressive towards conspecifics, both males and females performing threat displays. These nearly always culminate in aerial chases, which are sometimes accompanied by Chase Calls. The uttering of the Aggressive Chat is the first indication of threat, and this is followed by an "Aggressive Display" in which the bird, male or female, leans forward while holding the tail cocked vertically, the wings raised at the shoulders and the wingtips crossed over the back, and the nape-tufts raised. On occasions, individuals move the body from side to side while displaying. The Stitchbird will stop displaying whenever the antagonist moves away. Male aggressive displays are usually directed towards other Stitchbirds, such as subordinate males which are feeding nearby, or males that approach the nest-site, the young or the mate too closely. Females direct their aggressive displays mostly at other females or at juveniles, and rarely at their mate near the nest.

In extreme situations, both males and females perform an Ultimate Aggressive Display, which differs between the sexes. The female spreads her wings and moves decisively towards any bird, including her mate, near the nest, and hisses; she may also vibrate her wings. In the corresponding display of the male, the latter points his bill skywards, holding the wings spread and vibrating slightly and the nape-tufts raised, and emits low "coo" calls. The male's displays always result in chases, and usually follow repeated aggressive displays and chases when an intruding male does not leave the nest-site.

In the breeding season, threats occasionally escalate into fights if an antagonist does not leave, the two birds then grappling with their feet while pecking at one another. Such fights often start in the air, the combatants then dropping to the ground. Supposed fighting within the nest-cavity is now known to involve forced copulations. In addition, females have been seen to attack their mates near the nest, employing the bill, wings and claws for this purpose.

In response to aggression, a submissive Stitchbird sits quietly, with the plumage sleeked and the tail held downwards, and looks away from the displaying individual. Further, when it is

Foraging ***Stitchbirds*** *move from flower to flower by walking along branches, jumping, and making short glides. They hang upside-down to reach flowers and fruit, or capture invertebrates. They glean invertebrates from bark and foliage, probing into crevices and under bark. They also spring into the air to catch insects. Stitchbirds will travel several kilometres daily between feeding sites, and to visit artificial feeders. They forage in pairs, or in groups of up to ten outside the breeding season. They also join mixed flocks, often including the endemic honeyeaters Tui* (Prosthemadera novaeseelandiae) *and New Zealand Bellbird* (Anthornis melanura).

[*Notiomystis cincta*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Peter Fuller]

intruding into the territory or nest-site of another, or when a fertile female meets any male, including her own mate, the individual often freezes, and resident males appear to ignore or not to notice the still bird. In such circumstances, the intruder or the female may be able to leave the area without being threatened or attacked; if it is noticed, however, it is attacked. One female froze as if dead, closing her eyes while lying on her side on the nest-platform.

Of great interest is the mating system of the Stitchbird, which varies from social monogamy to polyandry, polygyny or polygynandry. The frequency of monogamous or polygamous breeding varies between the natural population of Little Barrier Island and translocated populations, but social monogamy is the most common system. There is variation also in the duration of the pair-bond, some individuals staying with the same mate for years, while others change partners between breeding attempts within a single season.

Regardless of the mating system involved, extra-pair copulations are common on Little Barrier and other islands. Males tend to have a strategy whereby they combine defence of a nesting site with one or more females while seeking extra-pair copulations, which occur frequently and most of which are forced (see below). Unpaired males are frequently responsible for extra-pair copulations. On Mokoia Island, it was found that 46% of 188 nestlings were the offspring of extra-pair males, and 82% of 56 broods contained at least one extra-pair nestling; of the extra-pair young, 34% were the offspring of unpaired males and the rest were sired by paired males. On Tiritiri Matangi Island, 35% of 34 nestlings were from extra-pair copulations and eight of the ten nests studied each contained at least one extra-pair young; about half of the extra-pair young were offspring of unpaired males. Further studies have shown that the level of parental care given by a male Stitchbird is linked with a number of factors, particularly the number of chicks in a brood. Males did not contribute to the feeding of broods of one, but they usually contributed to the rearing of broods of more than one, the male's effort increasing with the size of the brood.

Female Stitchbirds, during the three weeks before laying, increase their body weight by an average of 31%, from a mean of 31 g at the start to a peak weight of about 41 g two days before the first egg is laid. The males are able to determine, accurately, the fertile status of females mainly by this increase in weight, which is likely to be evaluated through changes in the female's flight. As a female's weight increases, the level of mate-guarding by her partner and attempted extra-pair copulations likewise rise.

On Little Barrier Island, Stitchbirds appear to be largely socially monogamous, but there is some variation, both polyandry and polygyny apparently occurring. In contrast to the situation on Little Barrier, in translocated populations on the islands of Kapiti and Tiritiri Matangi, and formerly on Cuvier and Mokoia Islands, where breeding density may be limited by a shortage of suitable nesting holes, the mating system varies greatly. Of 34 nests on Kapiti Island, 65% were considered to involve monogamous pairings, 12% polygynous males, 9% polyandrous females, and 3% polygynandrous individuals, and some individuals bred in more than one form of mating system, usually with different partners. Some males guarded the mate closely during the latter's fertile period, attempting to restrict the female's opportunities for extra-pair copulations, but other males did not spend much time with one female during the period from before laying to the end of incubation. On Tiritiri Matangi Island, most males were socially monogamous but some were polygynous, with usually two, and sometimes three, females in the territory of the male. On this island, during the female's fertile period, the male was more likely to be close to his mate and increased his contact with her, switched from site-specific territorial defence to defence of an area centred on his partner, and more often followed the female to communal feeding sites outside the territory. For polygynous males, these various aspects of behaviour were related to whichever of his females was fertile.

Stitchbirds copulate in two positions. They use the conventional avian method, in which the male mounts the female from behind, and also, uniquely among birds, a face-to-face position. The latter, however, is virtually restricted to forced copulations, which can occur often in most populations. Of 105 copulations observed on Tiritiri Matangi Island, half were within-pair and unforced conventional copulations, a further 27% were extra-pair and forced face-to-face copulations, and most of the rest were extra-pair conventional avian copulations, either with (10%) or without (7%) some resistance by the female. The remaining half-dozen were face-to-face copulations without apparent resistance by the female.

Normal copulation usually takes place in the mornings and late afternoons, and in the period of about nine days between the completion of the nest and the completion of the clutch, but it can start up to 17 days before laying. Display-walking by the male is often a prelude to copulation, and a female may solicit copulation by moving about while holding the feathers of the head raised, the wings crossed over her back and vibrating rapidly, and calling loudly with the copulation request call or warble (see Voice), although such female displays do not always lead to copulation. In conventional copulation, the paired male and female display, using the same posture as that of the soliciting female and emitting calls. The male then moves on to the back of the female, often mounting several times, the birds rubbing necks and touching bills before and after each copulation. This action usually takes place on the ground and within about 20 m of the nest, and only rarely is it performed on branches. Nevertheless, Stitchbirds sometimes copulate inside the nest-cavity or at foraging sites away from the nest. The act of copulation lasts for 6–30 seconds, after which the male often display-walks and sings as he moves away. The female returns to the nest, or preens or flies away with the male.

During forced copulation, a female is chased to the ground by a male, usually not her mate, which then mounts her while holding her on her back so that the two birds are face to face. The female often spreads her wings or kicks at the male, as though trying to escape, and the male also spreads his wings or points his bill upwards and extends his wings a little. After copulation, both birds fly away, separately. A female may be forced to the ground several times before copulation takes place. Repeated uttering of the forced copulation call (see Voice) by the female as she is being chased, and sometimes during copulation, can attract other males or, if the copulating male is an intruder, the female's partner, which may interrupt the act. Most forced copulations begin with the chasing of a female by a single male, but up to four more males can join in, although only the first male copulates, the others watching from within a metre and calling. The duration of forced copulations varies from 6–8 seconds to more than a minute. A male may force copulation on his mate if there are many other males in the nesting area.

Nests of Stitchbirds are almost always built in a hollow or other cavity in the trunk or branch of a mature and living tree, but dead trees are also used. On Little Barrier Island, the species commonly nests in puriri and pohutukawa, as well as in tawa and taraire, and on Kapiti Island it often utilises pukatea (*Laurelia novae-zelandiae*), rata, hinau (*Elaeocarpus dentatus*) and kamahi (*Weinmannia racemosa*) trees. Individuals recently released on the North Island mainland at Cascade Kauri Park, in Auckland, have been found to nest in kauri trees. Occasionally, pairs of this species nest in cavities among rocks in rocky outcrops, and in 1948 one pair nested in the hollow created by a kingfisher (Alcedinidae). On Tiritiri Matangi Island, Stitchbirds use artificial nestboxes, as they did formerly on Mokoia Island. On Little Barrier Island, nests have been recorded from about 1 m to 18·5 m above the ground. The mean height of nine nests over three years was 6·25 m, ranging from 1 m to 10 m. The entrances to three nests measured 4–4·5 × 4–8 cm, and that of another was 8 × 10 cm. The female will usually, if possible, begin to build in several cavities before selecting one in which to nest. On Little Barrier Island, Stitchbirds have nested without aggression close to breeding sites of the Rifleman (*Acanthisitta chloris*) and the Red-fronted Parakeet (*Cyanoramphus novaezelandiae*), both of which are hole-nesters, although on Kapiti Island there was much aggression between Stitchbirds and parakeets at nesting sites.

On Little Barrier Island, the breeding density is not limited by availability of suitable nesting holes, and the minimum dis-

Although primarily arboreal, ***Stitchbirds*** *will sometimes feed on the ground. This bird is picking up berries which have been knocked down by other feeding birds. The berries are those of* Coprosma, *a genus providing a major source of fruit and nectar for Stitchbirds;* Coprosma *berries accounted for 40% of observations of feeding in one study on Little Barrier Island. Female Stitchbirds have been seen feeding on beetles on the forest floor, and also following and catching insects disturbed by a Kaka* (Nestor meridionalis).

[*Notiomystis cincta*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Tui de Roy/ Roving Tortoise Photos]

tance between nests was about 100 m, with eight nests found in an area of approximately 20 ha. On Kapiti, the minimum internest distance was 110 m and the maximum 1620 m. On the other hand, on islands to which the species has been moved and where there are insufficient nesting sites, including Kapiti Island, up to three females have been seen to build in the same cavity, and two females have been known to share a cavity on Kapiti, and to share nestboxes on Mokoia and Tiritiri Matangi.

The nests that are built within the cavity consist of a platform of sticks and, in some cases, rootlets, supporting a cup made from fern rhizomes and bound together with spider web, and lined with scales from ferns and tree-ferns (*Dicksonia*, *Cyathea*) and feathers. The platform is typically some 15–20 cm deep, but one had a depth of 40 cm. The nests are usually level with or slightly above the entrance hole to the cavity. Nests are almost invariably built by the female, although males often take sticks inside cavities at the start of the breeding season, and there are a couple of instances of males building on Mokoia and Tiritiri Matangi Islands. On occasions when there are 2–4 females at one nest-site at the start of the season, all of these help to build the nest platform, but normally only the dominant female builds the nest-cup and only one remains in the area and stays with the nest. During the constructing of the nest, material is usually gathered within 10 m of the site and the work of building takes place at any time of the day. When the platform is being built, it is not uncommon for many sticks to be dropped, and these can pile up below the entrance to the cavity. Construction of a nest can take as little as three days, but usually takes up to two weeks, and material may still be added after the eggs have been laid.

The reuse of nesting sites appears to vary between Little Barrier Island and the islands to which Stitchbirds have been translocated. On Little Barrier, where there appears to be no shortage of suitable nesting sites, none of nine nests studied over a three-year period was reused for a second clutch in the same season, and only one nest was reused by the same pair in a subsequent season; another was reused, but by a different pair. In contrast, on Tiritiri Matangi Island, both males and females usually returned to the same nesting sites annually, and 89% of all returning females nested in the same territory, while on Kapiti Island the same cavities were used from year to year, and for both first and second clutches, although some pairs nested away from their sites of previous years.

On Kapiti Island, the average period between completion of the nest and the start of laying was 9·6 days, with a range of 1–23 days. The usual clutch consists of three to five eggs, but clutches sometimes contain as few as two eggs, and some of six eggs, presumably laid by the same female, have been reported; second clutches in a season usually contain one egg less than the first clutch. The mean clutch size on Tiritiri Matangi was 4·07 eggs. Eggs are normally laid on consecutive days, and in the morning, although laying is progressively about an hour later each morning, so that first eggs are laid between 06:30 and 07:00 hours and last eggs between 11:00 and 12:00 hours. On Tiritiri Matangi Island, in 13·5% of clutches laying was interrupted, with an interval of two days between eggs. The gaps correlated with territorial intrusions by extra-pair males in the days before laying, suggesting that harassment of the female, which involves resisted forced copulation, alters normal foraging behaviour and the process of egg-formation. While laying, the female stays in the nest-cavity for a mean of 1·4 hours.

The eggs of the Stitchbird are ovoid, and smooth and glossy. The colour varies from typically pure white without markings to pale yellowish-white with dense spotting and clouding of pale rufous-brown. Surprisingly, there are few data on the dimensions of the eggs. The length and breadth of three eggs were 21·3–21·8 × 16·7–16·8 mm, with a mean of 21·6 × 16·7 mm, which is larger than the 19 × 15·4 mm given by Oliver, and which he considered small for the size of the bird. The average weight of 26 eggs was 3·1 g. The female usually covers the eggs soon after laying with up to 2 cm of additional moss or tree-fern scales gathered from the area around the nest, fresh material being gathered daily and earlier covering incorporated into the nest lining. On Tiritiri Matangi, all females covered their first eggs and nearly half covered all except the final egg, when incubation began.

Incubation is by the female alone, and begins on the day when the clutch is completed, although some females partly incubate after the third egg has been laid. On Mokoia Island, the average length of an incubation stint by a female was just under 15 minutes, ranging from no more than about 9 minutes to about 24 minutes; the duration of absences from the nest ranged from about 3 minutes to approximately 7·5 minutes, with an average of 4 minutes 20 seconds. The average incubation period on Mokoia was 15·75 days, ranging from 13 to 19 days.

Young Stitchbirds are altricial and nidicolous. The state of the young at hatching is not properly known; they are blind, and either naked or almost so. The chicks quickly develop a light covering of down, one three-day-old individual having tufts of light grey down distributed sparsely over its head, back and lower

flanks. By the time they fledge, the young are in complete or almost complete juvenile plumage. Females undertake most or all of the brooding of the nestlings, although males sometimes assist. There are no published data on the amount of daily time spent in brooding or on whether brooding time decreases over the course of the nestling period.

Both members of the pair feed the chicks. The female, however, does considerably more feeding than the male, and in monogamous pairs the females were recorded as making three times as many visits to the nest per hour as the males. In some instances, the female contributes all of the brood-feeding. The begging call of nestlings is a loud "shh, shh, shh", audible for several metres from the nest-cavity, and given when an adult visits the nest. For the first 8–10 days, the young are fed almost wholly with small insects less than 3 mm long, and contrary to some reports that they are fed mainly or solely with nectar; thereafter, they are given a combination of nectar, fruit and larger insects. When demanding food, young nestlings stretch up towards the adult, hold the bill open and give the begging call, whereas older nestlings tend to crouch down, vibrating the wings and presenting the open bill. The adults feed them directly, by regurgitation. In experimental studies in which the effects of providing supplementary carotenoids to breeding adults and directly to nestlings were examined, it was found that nestlings had a more intense orange-yellow gape-flange and mouth colouring, which resulted in increased provisioning of the chicks by the adults. Despite the fact that both members of the pair remove faecal sacs, nests quickly become fouled and liquid often seeps from the nest-cavity. Young remain in the nest for some 26–32 days. On Mokoia Island, the average weight of chicks at hatching was 2·8 g. Some 3–4 days before fledging, this had increased to 43·8 g for males and 36·4 g for females, equivalent to 120% and 121% of the respective adult weights.

The contribution of each parent to the feeding of the fledglings, the rate at which fledglings are fed and for how long a period they are provisioned depend on whether the female makes a second breeding attempt soon after the first brood fledges. If no further attempt is made, the juveniles will be fed for up to two weeks by both parents, although most of the feeding is done by the female. If the female does attempt a second brood, however, she continues to feed the young of the first brood until the time when she begins incubation of the second clutch, while the male guards her. If the fledglings are no more than one week out of the nest when the female begins incubation of the second clutch, the male will feed them.

Whereas nestlings beg loudly, fledglings do so silently, with the bill open and the wings vibrating, while leaning towards a parent. Nevertheless, for the first two weeks after they fledge, juveniles persistently utter a high-pitched "pee-ping", possibly to maintain contact with the parents. They also give a chuckling call when they make physical contact with a parent or another fledgling. Another call given by juveniles is a persistent "sit, sit, sit...", which may be a feeding call or a contact call. Chicks also try to mimic the sounds of other bird species.

About one week after leaving the nest, the juveniles join a crèche, accompanied by adult males, although the young are not fed by their parents. Such crèches vary in size, and have been recorded from December to about March, when they begin to disband. Individuals often visit other crèches for a day or so, but they then return to their own. Crèches are thought to have an important function in social development.

Within the crèche, juveniles appear to play, indulging in both "follow-the-leader" and "pushing". In the latter game, one individual lands on a branch next to a line of other juveniles and then pushes until one of them hangs upside-down, the pushing then being repeated by other birds. Fledglings also harass each other and allopreen, and in crèches where nearby adults are actively copulating they perform mock copulations and neck-rubbing. Mock copulations take place on branches, not on the ground, and the young being mounted rolls on the branch until it is upside-down or flies away. Young Stitchbirds also rub their neck on branches and other vegetation.

There are few published observations of the parental defence of nests or young, or of the response of young to threats. Long-tailed Koels (*Eudynamys taitensis*) appear to elicit some response: a pair of Stitchbirds was seen to defend its nest and nestlings with vigour against this parasitic cuckoo, and another pair was watched as it mobbed a koel near its fledglings. Fledglings have been seen also to freeze in response to the koel, and on two occasions, when dived at by a Long-tailed Koel, they dropped from the branch on which they were perched and flew off close to the ground. A pair of Stitchbirds on Kapiti Island was seen to give alarm calls and attack a Weka (*Gallirallus australis*) that approached too close to the pair's fledglings, and a male responded to a human observer who approached a nest by raising its white nape-tufts and hopping about. Interestingly, while New Zealand Bellbirds often harass juvenile Stitchbirds, the adults rarely respond to this.

Over the course of three breeding seasons on Kapiti Island, the success for first clutches ranged from 1 to 2·3 fledglings per nest, whereas second clutches were far less successful, 80% of them failing. On Mokoia and Tiritiri Matangi, all breeding attempts in which two females have shared a nestbox, and both laid and incubated, have failed. Studies have revealed that the reproductive success of Stitchbirds increases during the first few years of life.

The causes of nesting failure are not well known. On Kapiti Island, there is much aggression between Stitchbirds and Red-fronted Parakeets around nest-sites, and in one instance interference from the parakeets may have led to the abandonment of the breeding attempt. Further, nesting cavities are sometimes taken over by parakeets a few days after the young Stitchbirds have left, which precludes the Stitchbirds from attempting a second clutch in that hollow. On Little Barrier Island, however, Stitchbirds nest near parakeets without any apparent aggression from the latter. The main natural predator of the Stitchbird is the Morepork, a nocturnal and crepuscular owl.

The sex ratio of the natural population on Little Barrier Island has not been quantified, but it is possibly male-biased. On both Kapiti and Mokoia Islands, where equal numbers of males and females were initially introduced, the sex ratio remained even for 2–3 years, before becoming female-biased on Kapiti and male-biased on Mokoia, the more numerous sex in each case outnumbering the other by two to one. The population on Tiritiri Matangi Island is strongly male-biased, with a ratio of 3:1, apparently because the survival of females after translocation is lower than that of males. The reasons for the changes in sex ratios in these translocated populations are not known.

Stitchbirds first form pairs in the breeding season after they fledge, usually when at least six months old. On Tiritiri Matangi Island, they breed for the first time at 4–16 months of age.

The longevity of this species is about seven years. Many individuals in translocated populations do not reach one year of age, which is less than the average lifespan on Little Barrier Island. On Tiritiri Matangi, Stitchbirds exhibit significant variation in reproductive performance with age, most increases in reproduction occurring between the first and second years and with a decline after the fourth year. The main influence on reproductive output was found to be the timing of breeding, those individuals that laid earlier being more likely to produce more clutches in a season, and this was the main difference between first-year birds and older ones, first-years tending to start laying later. A delay in establishment of territories by many first-year Stitchbirds also delayed breeding, and this reduced their reproductive output in comparison with that of other individuals.

Movements

Stitchbirds are sedentary, although they do undertake some short-distance movements in connection with foraging. The extent of these movements, however, is not entirely clear, but it is recorded that Stitchbirds can travel up to several kilometres in a day between preferred feeding sites or between artificial feeders.

On Little Barrier Island, individuals will move widely in response to local or seasonal flowering or fruiting of plants. Changes in the abundance of these birds indicate some movements or shifts between forest types and also altitudinally, between valleys, where the ranges appear to be centred, and slopes, ridges and summits.

*The mating system of the **Stitchbird** is highly complex. Social monogamy is commonest, but males will breed with more than one female, females with more than one male, and multiple males with multiple females. Extra-pair copulations are common. The nest, a platform of sticks supporting a cup of fern bound with spider's web, is usually built in a cavity of a tree. The usual clutch is 3–5 eggs. Incubation averages 15–16 days. The chicks are fed by both parents, with small insects for the first 8–10 days, then nectar, fruit and larger insects. They remain in the nest for 26–32 days. After the young birds fledge, both parents feed them for two more weeks, or until the female begins her next clutch.*

[*Notiomystis cincta*, Tiritiri Matangi Island Open Sanctuary, New Zealand. Photo: Tui de Roy/ Roving Tortoise Photos]

On Little Barrier, the ranges of pair-members overlap around nest-sites, but individuals appear to forage mainly in separate areas, although sometimes both foraged at rich sources of food. Females tended to remain close to the nest-sites. Earlier implications that this species is territorial throughout the year on Little Barrier Island appear not to be correct.

On Kapiti Island, small groups with overlapping home ranges occupied areas of stream catchment some 500 m wide and stretching along 3 km or so of stream. Home ranges were similar in the breeding and non-breeding seasons, but breeding individuals spent more time close to the nest-site. On Mokoia, individuals range all over the 135 ha of the island.

Relationship with Man

Stitchbirds were formerly hunted for food by Maori people, who caught them using snares, and up to 100 could be caught in a day at some times of the year. Maori also made ornamental cloaks of Stitchbird feathers, which they called *kahu-hihi*. It required an enormous number of feathers, and therefore of birds, to make one of these cloaks. Clearly, the Hihi, as the Maori call this species, was well known to the earliest human inhabitants of New Zealand.

Following the European settlement of New Zealand, the Stitchbird was one of many animal species that held a particular fascination for western scientists, to whom many of the endemic taxa were in extremely odd in one way or another. As a consequence, Stitchbirds were subjected to uncontrolled collecting by scientists and others, and this is believed to have led to a substantial drop in the numbers of this species (see Status and Conservation).

Status and Conservation

This remarkable species is one of New Zealand's rarest birds and is considered globally threatened. It is classified in the category of Vulnerable. From the mid-1880s until very recently, the Stitchbird has survived only as a remnant population on a single island that avoided the introduction of mammalian predators and did not suffer significant anthropogenic change to the vegetation. Such small offshore and outlying islands have been vital to the survival of many species of New Zealand fauna, especially birds.

Preceding the European settlement of New Zealand, in the early 1800s, the Stitchbird had survived the arrival of the Polynesians and the changes wrought on the New Zealand environment by their settlement. It was still a fairly common species on the North Island of New Zealand at the time of European settlement, and it remained so until the early 1870s, when it was found in the southern North Island and on Kapiti and Great and Little Barrier Islands. After this, however, the species underwent a rapid decline, and the last mainland record was in the Tararua Range, near the Wairarapa Valley, in February 1883. By 1885 the Stitchbird had been lost from the mainland and from Great Barrier and Kapiti Islands, surviving only on Little Barrier Island. The current population on Little Barrier Island, known also as Hauturu, is believed to be between 500 and 2000 individuals, the total having been revised downwards from earlier estimates of as many as 4000–5000 birds. Several hundred additional Stitchbirds are found in translocated populations.

There have been no verified records on the main island since 1883, despite later unconfirmed reports and rumours of individuals in the Ruahine Range and a report from Ngunguru, near Whangarei, in 1936. It was suggested that the latter, if accurate, may have involved a bird blown from Little Barrier Island.

The reasons for the extirpation of the mainland populations of the Stitchbird are not known with certainty, nor are the reasons for its fortuitous survival on Little Barrier Island. It is suspected, however, that the species' decline was caused mainly by a combination of destruction of habitat, the introduction and spread of mammalian predators, avian disease, and the excessive collecting of specimens for museums. No doubt these factors acted in concert.

Loss and modification of habitat are likely to have resulted in the isolation of populations, as Stitchbirds appear reluctant to cross open areas. Furthermore, they may have created shortages of both nesting cavities, with the loss of mature trees, and food, with the loss of the plant diversity needed to provide a sufficient year-round supply of nectar and fruit.

Throughout New Zealand, introduced mammalian predators have had a significant impact on birds, including the Stitchbird. The most destructive of these mammals appear to be feral cats (*Felis catus*), the three species of mustelid, particularly the stoat (*Mustela erminea*), and rats and mice, especially the black rat (*Rattus rattus*). The Stitchbird survived the pre-European introduction of the Pacific rat (*Rattus exulans*), known also as the kiore, which is predominantly vegetarian, and co-existed with this species on the mainland for some 1000 years, and has done so on Little Barrier Island until the present day. Stitchbirds managed to co-exist also with brown rats (*Rattus norvegicus*) on the mainland for many years following this species' introduction in New Zealand with some of the earliest European contacts. They also survive on Kapiti Island in the presence of both Pacific and brown rats. Although cats may have had a significant impact, these birds successfully co-existed with feral cats on the mainland for many years and on Little Barrier Island for more than 100 years up to 1980, when cats were eradicated.

The rapid decline of this species in the mid-1800s did, however, coincide with the introduction of black rats. As Stitchbirds roost and nest in tree-cavities, black rats readily prey on eggs, chicks and, possibly, incubating females during the breeding season and on roosting birds at any time. The mustelids were not introduced in New Zealand until after the extinction of the Stitchbird on the mainland, but they are considered a potentially significant predator and a major threat to the biosecurity of the islands on which Stitchbirds occur. They also represent a considerable obstacle to the successful reintroduction of Stitchbirds on the mainland.

Stitchbirds are affected also by avian diseases, and the species' rapid decline in the nineteenth century may have been a result, at least in part, of disease brought and transmitted with exotic birds that were introduced in New Zealand around the same time as black rats. A similar decline recorded in populations of the Tui and the New Zealand Bellbird, and a possible decline on Little Barrier Island in the absence of black rats, in the same period provide some evidence that disease may have contributed to the demise of the Stitchbird. Contemporary studies have found Stitchbirds to be particularly susceptible to at least two avian diseases, namely aspergillosis and coccidiosis. Aspergillosis from infection by the pathogenic fungus *Aspergillus fumigatus*, which is prevalent in highly modified habitats, was a significant limiting factor for the translocated population of Stitchbirds on Mokoia Island and may have a serious impact on other populations. This fungus is more prevalent on Mokoia than it is on Tiritiri Matangi Island, which in turn has a higher level than is found in the natural population on Little Barrier Island.

Together, black rats and disease were possibly the two main factors leading to the decline and extinction of Stitchbirds on the mainland and on Kapiti and Great Barrier Islands. A further factor is the collecting of specimens for scientific purposes. Although this is no longer a serious problem, this was not the case in earlier times. Following the European discovery and settlement of New Zealand, the Stitchbird was ruthlessly collected, a great many specimens being brought to Britain and elsewhere in Europe. Of the 181 specimens collected in the nineteenth century, the majority, up to 130, were taken by one Austrian collector, A. Reischek, and he undoubtedly killed more than those that have survived in collections. This scientific collecting was likely to have been a contributing factor in the decline of the species in the North Island. As early as 1892, Sir Walter Buller stated to the Auckland Institute, in relation to the Stitchbird: "An Auckland collector has recently been on a visit to the Little Barrier Island for the purpose of getting specimens of this rare bird, several of which were obtained. This is the last refuge of the species, and unless the strong hand of the Government is invoked for its protection, and that at once, the Stitchbird will soon be lost to us for ever. Let us hope that steps will be taken to save the colony from this reproach."

Conservation action for the Stitchbird has focused mainly on the translocation of individuals from Little Barrier Island to other predator-free islands, with the aim of reintroducing or establishing viable populations on these. Such translocations began in 1980. The success of these projects has varied, but, of those populations that persist, none is currently self-sustaining. Between 1980 and the present, Stitchbirds were introduced on five small islands, and in the middle of the first decade of the twenty-first century birds were reintroduced at two managed sites on the main North Island.

The first translocations were to Hen Island, a 500-ha island in the Hen and Chickens Group, with 30 individuals released in March 1980 and a further 16 in April 1981. Stitchbirds were also transferred to 195-ha Cuvier Island, where 29 were released in June 1982 and an additional 37 in April 1985. Neither of these introductions was successful, the last records being of one or two individuals on Hen Island in 1994 and a singleton on Cuvier Island in 1993.

In the same period, 30 Stitchbirds were released on Kapiti Island (1966 ha) in August 1983, 30 in August 1984, and twelve in August 1990. By August 1991, however, only four individuals could be found on Kapiti. Subsequently, 48 birds, 24 males and 24 females, were transferred from Little Barrier Island to Kapiti in August 1991, and a further 24 males and 23 females were released there in August 1992. Nevertheless, the population on Kapiti continued to decline without intervention, and supportive management of the population began in 2000. A further release was made in 2002, with the transfer of 14 of the surviving individuals from the translocated population on Mokoia Island. The Stitchbird population on Kapiti Island persists with ongoing management.

In September 1994, 40 individuals, comprising 20 of each sex, were translocated from Little Barrier Island to Mokoia Island (135 ha), in Lake Rotorua. This population survived, and was stable while under active management, but it declined when supportive management was stopped. Owing to a lack of breeding success, a shortage of resources for supplemental feeding and monitoring, and competing conservation priorities, the remaining 15 Stitchbirds on Mokoia were transferred in 2002, one going to Pukaha Mount Bruce and the rest, as mentioned in the preceding paragraph, to Kapiti Island.

The last of the island introductions has been on Tiritiri Matangi, a 220-ha island lying 4 km off the coast of the Whangaparaoa Peninsula, north of the town of Auckland. A total of 38 Stitchbirds, 20 males and 18 females, was transferred to this island in September 1995, with a further four males and nine females released there in 1996. This population has shown a constant increase with ongoing management, and it is suspected that the island may soon reach its carrying capacity for this species. The breeding population is small but expanding, rising from 14 breeding females in 1997–1998 to 42 in 2003–2004, and exists in some 30 ha of remnant and regenerating closed-canopy forest on the island.

Most recently, after more than 120 years of almost complete absence from the main North Island, Stitchbirds have been reintroduced at two carefully managed mainland sites, one at Karori Wildlife Sanctuary, in Wellington, and the other at Cascade Kauri Park, in the Waitakere Ranges, near Auckland. In February and May 2005, 60 Stitchbirds were transferred to Karori from Tiritiri Matangi Island. In early 2007, 59 individuals, mostly juveniles and again from Tiritira Matangi, were transferred to Cascade Kauri Park. By November 2007, the Stitchbirds at the latter site had bred, chicks had hatched, and at least some nests succeeded in producing fledglings. A further 60 Stitchbirds were transferred to Cascade Kauri Park in May 2008. The transfers to the mainland sites came about after intensive programmes to remove or control introduced browsing and predatory mammals, especially common brushtail possums, rats, stoats and feral cats. The removal of the possums has allowed much vegetation to recover.

Lastly, a small population, numbering some 5–12 individuals, is maintained at the Pukaha Mount Bruce National Wildlife Centre, in the southern North Island. Four transfers, totalling 16 wild Stitchbirds, have been made since 1990, one in each of 1995, 1999, 2001 and 2002. A captive-breeding programme is in place, enabling conservationists to conduct research on Stitchbirds, and to develop effective husbandry techniques for the species in order to deal with such problems as stress and disease in case of a catastrophic event affecting the population on Little Barrier Is-

Although common on New Zealand's North Island and offshore islands at the time of European settlement, by the mid-1880s ***Stitchbirds*** *survived only as a remnant population on Little Barrier Island. Habitat destruction, hunting by Maoris for food and ornament and by Europeans for museums, predation, and introduced avian diseases, probably all acted to extirpate the other populations. Translocations to predator-free islands began in 1980, but these populations rely on intensive management. Stitchbirds have also been reintroduced to two mainland sites. The natural population on Little Barrier is stable at up to 2000 birds. The Stitchbird is listed as Vulnerable. The current recovery plan aims to make five populations self-sustaining.*

[*Notiomystis cincta*, New Zealand. Photo: Robin Bush/ www.photolibrary.com]

land. In addition, it allows scientists to test methods that could assist with the establishment of new and self-sustaining populations in the wild, to produce birds for release into the wild and to improve the survival of released individuals, as well as to understand and manage relevant diseases. Pukaha Mount Bruce has produced 21 chicks for release on Kapiti Island since 2000, and it continues to breed Stitchbirds for future releases on Kapiti and elsewhere.

Current management for the Stitchbird, one of New Zealand's rarest birds, involves a recovery plan, the present one, for 2004–2009, succeeding an earlier plan (1995–2000). The main, long-term goal of the current plan is to increase the number of self-sustaining populations of Stitchbirds to five. The only self-sustaining population, however, is still that of Little Barrier Island, those on Kapiti and Tiritiri Matangi Islands and the two mainland North Island sites persisting only through active management.

The supportive management involved in the translocated populations on Tiritiri Matangi and Kapiti includes several strategies. One is the provision of nestboxes, which facilitates breeding in the absence of natural cavities, but also permits easy access for monitoring breeding and for manipulation of nests and breeding, such as the removing of infertile eggs to encourage re-laying. A second is the provision of artificial feeders in order to maintain an adequate supply of food, which assists with population-monitoring. In addition, all fledglings are individually ringed for the purposes of identification and determination of demographic parameters, and birds released as part of translocations are likewise ringed. Finally, there is intensive management of infestations of nest parasites, primarily mites (Acarina), and nestboxes are carefully cleaned after breeding attempts in order to inhibit the spread of disease within the population.

As an example, on Tiritiri Matangi Island, supplementary food is provided throughout the year in the form of *ad libitum* sugar solution (20% weight/volume) from up to nine feeding stations, which are used regularly by all adult Stitchbirds on the island. These feeding stations are needed because there can be a shortage of natural food; they were situated at the forest edges, and not within territories of individual birds. Further, as the main habitat on the island comprises young, regenerating forest, there are few natural cavities for nesting. Small groups of two or three nestboxes are placed in likely nesting areas, attached to tree trunks at a height of about 1·5 m.

Little Barrier Island, home of the last natural population of the Stitchbird, has for long been a reserve. It was formally protected in 1894, when it was purchased by the Government from its Maori owners and was designated a bird sanctuary. In 1977, the island was gazetted as a nature reserve. Little Barrier Island, however, lies in the outer Hauraki Gulf, which is subject to great human pressures through high and increasing levels of recreational and commercial use.

With the gradual maturation of the vegetation of the islands to which Stitchbirds have been translocated, it is possible that the populations will become self-sustaining. The mainland populations will, however, require continuing management of predators. Recent research on Tiritiri Matangi Island, where tourism is encouraged in part as a means of funding the ongoing species and habitat restoration programmes and public-awareness campaign, found that Stitchbirds did not avoid nesting near walking tracks and that there was no difference between the reproductive parameters of Stitchbirds nesting near paths and those nesting in areas with no public access. It appeared that, for all the monitored species on the island, any adverse effects of tourism are small and are outweighed by the benefits that tourism generates.

The New Zealand Department of Conservation, Massey University and the University of Auckland, and the Pukaha Mount Bruce National Wildlife Centre, as well as other bodies, are all involved in active research on Stitchbirds, research that has greatly increased our knowledge of the biology and ecology of this species over the last two decades. Further, there is a great deal of active and co-ordinated management of the remaining populations and programmes aimed at increasing the geographical spread of the species through translocations. Although the Stitchbird is seriously threatened, there has been significant action in New Zealand over many years to try to ensure the survival of this unique species, now recognized as the sole representative of its family (see Systematics).

Genus *NOTIOMYSTIS* Richmond, 1908

Stitchbird

Notiomystis cincta

French: Hihi de Nouvelle-Zélande **German**: Hihi **Spanish**: Hihi
Other common names: Hihi, Ihi, Kotihe, Pogonornis

Taxonomy. *Meliphaga cincta* du Bus de Gisignies, 1839, North Island, New Zealand.
Traditionally placed in the honeyeater family (Meliphagidae), but recent DNA studies, combined with morphology, indicate that it belongs in a monophyletic family of its own. Falls within a clade that includes the New Zealand wattlebirds (Callaeidae); affinities of this clade uncertain, but it appears to be a basal assemblage that may include the berrypeckers and longbills (Melanocharitidae) and the cnemophiline satinbirds (currently Paradisaeidae). Proposed race *hautura* (described from Little Barrier I) said to differ from birds in rest of species' former range in shorter wing and yellower breast of male, but some overlap in characters apparent. Treated as monotypic.
Distribution. Little Barrier I (Hauturu), in outer Hauraki Gulf, off N North I (New Zealand). Reintroduced on Kapiti I, off SW coast of North I; and at two sites on main North I, at Karori Wildlife Sanctuary, near Wellington, and at Cascade Kauri Park, near Auckland. Also introduced to Tiritiri Matangi I, in Hauraki Gulf.

Descriptive notes. c.18 cm; male 29–42 g, female 26–35 g. Medium-sized passerine with moderately long, slender and slightly decurved bill; moderately long tail, often held cocked. Male has velvet-black hood with short, erectile white nape-tuft, hood bordered by golden-yellow shoulder patch (including marginal secondary coverts) that continues as band across lower breast, where broken in mid-line; black of hood grades to grey-black on mantle, back and scapulars, and to dark brownish-olive on rump and uppertail-coverts; upperwing black, prominent white patch at base of tertials and inner greater secondary coverts, narrow yellow fringes on outer greater coverts and thin yellow tips on median coverts, yellow edges of secondaries (forming wingpanel), and thin pale yellow distal edges of primaries (in flight, wing appears blackish with golden-yellow shoulder patch on inner leading edge and conspicuous white patch at base); uppertail blackish-brown, rectrices with yellowish edges; underbody below lower breast pale brownish-grey, diffusely streaked darker; underwing buff-white with broad dark grey trailing edge and tip, underside of tail dark brownish-grey; iris blackish-brown, narrow grey-black orbital ring; bill black; legs pinkish-brown to dark red-brown or grey-black, soles cream-coloured. Female is smaller than male, also duller and plainer (lacks golden shoulder patch and breastband), being brownish-olive above, with only tiny (rarely visible) white tuft on side of nape, upperwing pattern like that of male, including prominent white patch, but ground colour black-brown, and yellow areas duller, more olive-yellow; chin, throat and underparts off-white with brownish-grey wash and diffuse dark brownish-grey streaking. Juvenile is like female, but slightly browner above and uniformly dark grey-brown to brownish-buff below, pale patch on folded wing smaller and buff, pale fringes on secondary coverts dull yellow-brown, pale edges of remiges grey-brown, bill grey-black with dirty yellow or brownish-orange basal two-thirds of lower mandible, and gape swollen, yellow to orange-yellow; immature very similar to adult of corresponding sex, but retains juvenile remiges, primary coverts and alula; immature male sometimes distinguishable in close view by duller and browner greater primary coverts and alula with narrow yellowish edges (these wholly black in adult male), and in the hand retained juvenile plumage of immature female slightly duller and browner than adult female's. Voice. Range of mainly high-pitched vocalizations, some given throughout year, others only in breeding season. Male has seven identifiable vocalizations, female five (most female calls quiet, audible only within a few metres); at least eight further calls shared by sexes. Common call of both sexes is warning call, a "titch" note, given singly or (with increasing alarm) in accelerating series, when may merge into alarm call, which a series of high-pitched "yeng" notes. Contact call (both sexes), heard often and throughout year, a high-pitched and plaintive single or double "wee" or "tseet", usually answered by another. Other calls by both sexes include, among others, a soft warble, "Aggressive Chat", high-pitched parental call directed at fledglings, and squeaks. Male song a loud, melodious high-pitched whistle of 2–3 notes, e.g. "wee-ah-wee", "wee-ah", or "trr-ah-wee", mainly or most frequently during the breeding season. Other male vocalizations include "chi-ching", given only near nest; "Identification Chat", a series of squeaky and warbling sounds given at meeting with mate; two cooing calls; and metallic call during display-flight. Female vocalizations include several calls associated with copulation or when being chased by males attempting forced copulation; short, soft, high-pitched "sweet" as identification call from nesting cavity in reply to mate; and hisses in aggression.
Habitat. Dense native forests, with some movement between forest types to exploit seasonal flowering or fruiting. On Little Barrier I prefers mature, moist, hardwood forest, particularly mixed forests of tawa (*Beilschmiedia tawa*) and northern rata (*Metrosideros robusta*) in valleys, and tawa with towai (*Weinmannia silvicola*) on steep slopes at higher elevations; found less often in kauri–hard beech (*Agathis australis–Nothofagus truncata*) ridge forest, regenerating valley forests of kanuka (*Leptospermum ericoides*), wet ridge forest of tawa, towai, tawari (*Ixerba brexioides*) and miro (*Prumnopitys ferruginea*), or coastal pohutukawa (*Metrosideros excelsa*) forest; least common in *Leptospermum* forest on ridges, and in stunted summit forests. Extinct population on North I originally inhabited broadleaf evergreen forest; mature forest of Little Barrier I thought to be very like undisturbed habitat of mainland North I formerly used by this species. Requires mature forest for breeding. On Little Barrier I recorded at all altitudes from lowest valleys to high summits (highest point 722 m), but mainly in valleys and lower ridges to c. 300 m.
Food and Feeding. Diet nectar, fruit and small arthropods. Arthopods mainly insects, including beetles (Coleoptera), but also spiders (Araneae). Proportions of main items in diet vary seasonally, geographically (between natural population on Little Barrier I and various translocated populations) and, where data exist, among different studies within populations; variation probably due mainly to availability. Differences between islands probably relate to differences in floristic composition and in flowering and fruiting phenology of respective flora. Invertebrate and plant exudates such as lerp, manna and honeydew also consumed. Takes fruit and nectar from wide variety of plants. On Mokoia I, nectar usually taken from plant species contributing greatest proportion of nectar standing crop at the time, and tended to avoid flowers comparatively low in nectar; proportion of time spent in feeding on different species of fruit not related to available store of carbohydrates in fruit. Forages at all levels, including occasionally on ground, but mainly in trees and shrubs; in one study on Little Barrier I, foraged mostly in middle and lower levels of understorey, but also often in subcanopy and canopy. Most foraging carried out among fine twigs, leaves and terminal shoots of trees and small shrubs; sometimes in canopy of trees, especially among flowering and fruiting mistletoes (Loranthaceae). Agile and acrobatic when foraging, often hanging upside-down to reach flowers and fruit. Nectar taken by probing flowers; invertebrates and plant and insect exudates obtained mainly by gleaning from foliage or branches, also by probing beneath bark, and sallies into air to catch flying insects. Usually in pairs or, particularly outside breeding season, in small groups of up to ten individuals. Sometimes associates with meliphagids, i.e. Tui (*Prosthemadera novaeseelandiae*) and New Zealand Bellbird (*Anthornis melanura*), and often part of mixed-species feeding flocks. Will travel several kilometres daily between preferred feeding sites, and known to visit artificial feeders up to 1·5 km apart during same day.
Breeding. Recorded Sept/Oct–Feb/Mar, but not synchronous within populations; first eggs usually mid-Oct but annual variation (e.g. on Kapiti I first clutches laid 16th Nov–9th Dec in one year, 5th–19th Dec in next); up to two or, occasionally, four breeding attempts in a season. Nest almost invariably built by female alone, a platform of sticks and rootlets supporting a cup made from fern rhizomes, cup bound together with spider web, lined with fern scales and feathers, almost always

placed in hollow or other cavity in trunk or branch of mature living tree, sometimes in dead tree or cavity in other site, and on islands where translocated artificial nestboxes used; on Little Barrier I nests c. 1–18·5 m (mean for nine nests 6·25 m) above ground. Clutch 3–5 eggs, sometimes 2, exceptionally 6, second clutch in season usually one egg fewer than first clutch; eggs laid at one-day intervals, in morning, laying 1 hour later each morning; incubation by female only, beginning with completion of clutch, period 13–19 days (mean 15·75 days); chicks brooded by female, male sometimes assisting, fed by both sexes, female doing considerably more of provisioning than male, both adults remove faecal sacs (but nest quickly becomes fouled), nestling period 26–32 days; young fed by parents for up to 2 weeks after fledging, contribution of each adult and rate at which young fed (and for how long) dependent on whether female making another breeding attempt. Juveniles join crèches c. 1 week after fledging.

Movements. Sedentary. Individuals move widely within home ranges, up to several kilometres daily, to exploit seasonally available nectar or fruit.

Status and Conservation. VULNERABLE. Restricted-range species: present in North Island of New Zealand EBA. Rare. Natural population confined to Little Barrier I, where current estimated population 500–2000 individuals; formerly estimated as high as 4000–5000 birds. Translocated populations on Kapiti I (c. 100 birds) and on Tiritiri Matangi I (c. 150 birds); reintroduced populations established on main North I at Karori Wildlife Sanctuary (translocation of 60 individuals in 2005, population estimated at 37 birds in Oct 2006) and at Cascade Kauri Park, in Waitakere Ranges, near Auckland (59 birds translocated in 2007 and a further 60 in May 2008). Unsuccessfully translocated to Hen I (in Hen and Chickens Group) and Cuvier I (Repanga I); also to Mokoia I (in L Rotorua), and that population later transferred to Kapiti I. Formerly widespread on North I and several adjacent offshore islands, but by mid-1880s natural population confined to a single island, Little Barrier I, in outer Hauraki Gulf. Causes of rapid decline and extinction on mainland and on Kapiti I and Great Barrier I not certainly known; suspected that main reason was a combination of loss of habitat, introduction and spread of mammalian predators, especially black rats (*Rattus rattus*), avian disease, and excessive collecting of specimens for museums, these factors having no doubt acted in concert. No translocated populations self-sustaining, but those on Kapiti I and Tiritiri Matangi I increasing through intensive and ongoing management. Translocated populations reliant on supplementary feeding, provision of nestboxes and, in the case of mainland population, intensive predator control. A small captive population is held at Pukaha Mount Bruce National Wildlife Sanctuary.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family GRALLINIDAE (MUDLARKS)

- Medium-sized passerines with small head, longish slender bill, long legs and fairly long tail; plumage distinctively black and white.
- 20–30 cm.

- Australia, New Guinea and Timor.
- One species near upland streams, the other in open habitats with water source.
- 1 genus, 2 species, 3 taxa.
- No species threatened; none extinct since 1600.

Systematics

The family Grallinidae comprises only two species, the Torrent-lark (*Grallina bruijni*) of New Guinea and the Magpie-lark (*Grallina cyanoleuca*) of Australia. Not long after it was first described, in its present genus, the Torrent-lark was placed in a different genus, *Pomareopsis*. The separation of the two species at the generic level, however, was not supported in an early list of bird species published by the British Museum, nor in later publications, although it persisted into the 1960s.

The relationship of the two species to other avian taxa has been the subject of considerable speculation. The Magpie-lark was originally named, in 1801, *Corvus cyanoleucus*, suggesting a perceived affinity with the crow family (Corvidae). In the 1870s, however, the British Museum placed both the Torrent-lark and the Magpie-lark in the Prionopidae, a family that now comprises the helmet-shrikes. This classification was still accepted by some authors until the middle of the twentieth century, but it, as well as an affinity with the crow family, was questioned or ignored by some researchers.

In the same period, the Magpie-lark was placed in its own family, Grallinidae, in some publications and, in a list of Australian birds published in 1946, this was positioned next to the monarch-flycatchers (Monarchidae), which were then treated as a subfamily of the Old World flycatcher family Muscicapidae. Furthermore, the Magpie-lark was referred to as being "merely a ground-living flycatcher" and, together with the Torrent-lark, was considered closely related to the monarch-flycatchers in a major publication on the birds of New Guinea, contributed by T. Iredale, in 1956.

At about the same time, it was suggested, on the basis of perceived similarities in their skeletons and their nests, that the two species were in fact closely related to the White-winged Chough (*Corcorax melanoramphos*) and the Apostlebird (*Struthidea cinerea*) of Australia. Subsequently, most authors included all four species in the Grallinidae, although the extent of the differences among the species were sometimes noted and two subfamilies were generally recognized. These were the Grallininae, for the Magpie-lark and Torrent-lark, and the Corcoracinae or Struthideinae, for the other two. Some taxonomists preferred to treat these as two full families, Grallinidae and Corcoracidae/Struthideidae. It was also suggested, on the basis of an examination of skulls, that the family Grallinidae was related to the butcherbirds and currawongs (Cracticidae) and the woodswallows (Artamidae) and, from a comparison of egg-white protein, to the crows in the family Corvidae.

With the advent of comparative studies of DNA in the 1980s, an affiliation with the crows was emphasized. The principal researchers using these relatively modern genetic techniques placed many Australasian species, including the Torrent-lark and the Magpie-lark, in a greatly expanded family Corvidae. They aligned both of these species with the monarch-flycatchers and, more distantly, with the fantails (*Rhipidura*) and drongos (*Dicrurus*), all of which they placed in a subfamily Dicrurinae. Further, the results of their analyses strongly indicated that the two *Grallina* species were not closely related to the White-winged Chough or the Apostlebird. Other researchers have preferred to accord this assemblage the status of a full family, rather than maintaining it as a subfamily of the Corvidae, and have thereby included *Grallina* within the family Dicruridae. The close relationship of *Grallina* to the monarch-flycatchers has been supported by a study of skull morphology, and some recent taxonomists have united them in the family Monarchidae.

Despite the results of DNA studies, and notwithstanding similarities in some features of external morphology, there are marked differences in behaviour and nest structure between *Grallina* and the monarch-flycatchers. Moreover, it is true to say that the allocation of genera and species to families still involves an element of subjective judgement. These factors suggest that, for the time being, the family Grallinidae perhaps should be maintained, although the close relationship to the monarch-flycatchers appears to be extremely probable.

Although it is widely distributed in mainland New Guinea, the Torrent-lark is a monotypic species, presenting no obvious differences among the various populations. The Magpie-lark, too, has often been treated as monotypic, but those individuals in north Australia are distinctly smaller than those in the south. These smaller birds, which have a proportionately shorter tail and longer bill, were described in 1912 as a subspecies, *neglecta*. Most subsequent authors considered the differences in size between the two to be clinal in nature, but other, more recent authors maintain that they are sufficient to warrant the recognition of this race. Indeed, the wing and tail lengths of male *neglecta* are significantly shorter than those of the southern populations of the species, and the former weigh less than the latter. It is worth noting, however, that the two subspecies intergrade in the region from central Northern Territory eastwards to west and north-central Queensland.

*The two members of Grallinidae, the **Magpie-lark** of Australia and the Torrent-lark* (Grallina bruijni) *of New Guinea, are similar in appearance, with distinctive black and white plumage. Both species show sexual dimorphism. The male (left-hand bird here) has white lines above the eye, and large white patches from the ear-coverts down to the side of the neck. The female Magpie-lark's forehead and throat are white, with a broad black band extending from the crown down the side of the face to the chest, and a broad white area extending from below the rear crown to meet the white of the underparts.*

[*Grallina cyanoleuca cyanoleuca*, Grey Range, Queensland, Australia. Photo: Graeme Chapman]

Too little is known about the Magpie-larks occurring on Timor and in south New Guinea for their subspecific identity to be determined. They may represent one or more further subspecies, but for the time being their taxonomic position remains a matter for speculation.

Morphological Aspects

Both the Torrent-lark and the Magpie-lark are medium-sized passerines, but they are large in comparison with the monarch-flycatchers, their closest relatives (see Systematics). The Torrent-lark is about 20 cm in length, while the Magpie-lark is bigger, with an average measurement of approximately 26 cm.

Adult male Magpie-larks are heavier than the females. In one sample, males of the nominate race had an average weight of 91·6 g, whereas the average for the females was 81·3 g. The corresponding figures for the smaller subspecies *neglecta* were 82·8 g and 75·4 g. Very few data are available for the Torrent-lark, but these indicate that males weigh around 40–41 g and females 38–40 g.

*Both grallinids have a small head and a long tail. The wings are long, broad and rounded. **Magpie-larks** are relatively slow fliers, and spend much of their time walking on the ground in open feeding areas. In connection with this, their legs are long and sturdy. This species is sedentary, with a longest recorded movement of just 15 km. However, it apparently arrived only recently in East Timor, suggesting it is capable of long-distance flight.*

[*Grallina cyanoleuca cyanoleuca*, Waikerie, South Australia, Australia. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

The two grallinids have a smallish head, with a fairly long and slender bill. The wings are long and rounded and the tail is quite long. The legs are long and sturdy, as would be expected for birds which are largely terrestrial (see General Habits, and Food and Feeding).

The Torrent-lark and the Magpie-lark are similar in appearance, both having distinctively black-and-white plumage. The adults' bare parts, too, are of contrasting colours, the bill and iris being whitish and the legs black. Adult males and adult females can be distinguished in the field by differences in the pattern of the head, throat and breast. Juveniles have the bill and eyes dark, in addition to which the black parts of the plumage are tinged brown. Aggression occurs mainly between members of the same sex, at least in the case of Magpie-larks, and the sex-related plumage patterns enable rapid identification of rivals. The plumage of juveniles, which features a combination of adult male and adult female markings, may also may serve to inhibit aggression from adults.

Adult Magpie-larks have a complete post-breeding moult, in which the shedding of the primaries begins in November or December and continues until the last primary is replaced, in April or May. The tail feathers are replaced during approximately the same period and over a slightly longer time scale, sometimes starting in September and terminating in May. The body feathers are replaced over a protracted period, which apparently commences before the first of the primaries are shed and does not end until after all of the flight-feathers have been renewed. The post-juvenile moult is evidently partial, including all of the body feathers but only some of the wing-coverts and few or no remiges. For some juvenile Magpie-larks, moult into adult plumage begins six to seven weeks after leaving the nest, and while they are resident within their parents' territory. Most juveniles, however, start to moult about ten or eleven weeks after fledging and shortly after leaving their parents' territory. The complete moult takes three to four months. No comparable data are available for the Torrent-lark.

Habitat

Torrent-larks live close to small, fast-flowing streams bounded either by forest or by grassland in hills and mountains throughout mainland New Guinea. They have been observed at altitudes

Shy, possibly scarce, and certainly little-studied, the ***Torrent-lark*** *lives in hills and mountains throughout mainland New Guinea, close to small, fast-flowing streams, bounded either by forest or by grassland. It is usually seen singly, in pairs, or in groups of up to four birds, which may be family parties. Mainly found between 400 m and 2300 m, it has been recorded up to 2800 m in the Snow Mountains. Although it is widely distributed, the Torrent-lark is considered monotypic, with no obvious differences among the various populations. It is smaller than the Magpie-lark* (Grallina cyanoleuca) *and apparently weighs about half as much. Both grallinids are, however, large in comparison with the monarch-flycatchers (Monarchidae), which DNA indicates are their closest relatives. Despite some external similarities, the grallinids differ markedly from the monarch-flycatchers in behaviour and nest structure.*

[*Grallina bruijni*, Crater Mountain, EC New Guinea. Photo: William S. Peckover]

ranging from about 400 m to 2300 m, and sometimes higher, reaching 2800 m in the Snow Mountains. The species is occasionally sighted in forest distant from water, but it is assumed that such observations relate to individuals or groups travelling between streams.

Water also is a key component of the habitat of the Magpie-lark. Early records suggest that, at the time of European colonization in Australia, Magpie-larks occurred only close to rivers, lakes and other wetlands. They appear to have spread with the colonists as the latter cleared land for agriculture and created artificial watering sites to supply sheep and cattle. Magpie-larks are now found over much of mainland Australia, occurring in a variety of open or lightly wooded habitats, including grassland, farmland and even built-up areas, from sea-level to about 1000 m, occasionally to 1200 m. The species' main requirements are the availability of water, the presence of trees for roosting and for providing nest-sites, and a clayey soil suitable for building the nest (see Breeding). Relatively open vegetation is another key feature of suitable habitat, as Magpie-larks catch most of their food on the ground (see Food and Feeding). They do not occur in rainforest, wet eucalypt (*Eucalyptus*) forest, scrub and other dense vegetation, although they do exploit the edges of such habitats where there is more open vegetation, and they will visit these places after a fire, again when the habitat is open. They are common in farmland, inland pastoral areas, cities and towns.

The introduced population of Magpie-larks on Lord Howe Island, to the east of Australia, occurs primarily in open grassy paddocks and in open forest. It is absent from areas of denser forest, but can be found in the ecotone between lowland forest and paddocks.

Over much of their present range adults appear to be resident wherever there is permanent water. They are absent only in arid desert areas of western central Australia and the Nullarbor Plain, where there is no surface water for considerable periods of time. Elsewhere, they become relatively scarce around Darwin, in far northern Australia, during the tropical wet season and, in eastern Australia, they move away from high altitudes on the Great Dividing Range when snowfields are present in winter. These movements may be in response to extreme conditions. Flocks, which consist predominantly, if not entirely, of young birds, are more mobile, but they may still require water as part of their habitat.

General Habits

Almost nothing is known about the habits of the Torrent-lark. This species is considered to be scarce and relatively shy, but conspicuous because of its plumage and vocalizations. It is usually seen singly, in pairs, or in small groups of up to four individuals, which may be family parties. Torrent-larks spend much of the day in searching for food on rocks and gravel and in very shallow water associated with streams. They walk about actively on the ground, constantly moving the tail from side to side. It is presumed that they roost in trees. Male Torrent-larks perform a display in which the head is raised, with the bill pointing upwards, and the wings are opened and held vertically, showing the black undersurfaces when viewed from the front; this is accompanied by a nasal buzzy call. The wings also may be spread on landing.

In contrast, Magpie-larks are very common on the Australian mainland and have been studied in detail. Their general habits appear to be strongly influenced by the availability of important ecological resources. In agricultural areas of the south-west of Western Australia, adult Magpie-larks have lifelong pair-bonds and pairs maintain permanent territories. The territory may be abandoned if one partner dies or, among newly established younger pairs, following breeding failure. Adults may live for more than ten years, although there appears to be relatively high mortality among adults and a subsequent acceptance of new partners. The territories at three locations ranged in size from 5 ha to 25 ha, and the average size varied from about 13 ha to 19 ha. Most of the territories contained a permanent source of water,

*Most **Magpie-lark** territories contain permanent surface water, and the birds appear to bathe regularly. Birds have been watched bathing belly-deep in the water of a creek, either walking in from the bank, or jumping from a low rock. The birds plunged their heads beneath the surface, and rapidly beat their wings for less than one second. After this, they walked to shallower water or onto the bank, or jumped back onto the rock, where they proceeded to fluff up the plumage and preen. This procedure was repeated four times in a minute. In agricultural areas of Western Australia, adult Magpie-larks have lifelong pair-bonds, and maintain permanent territories of up to 25 ha. A pair will roost at night in a particular tree within the territory. The birds call from the tree before sunrise, before moving to another tree, where they preen and continue to call. They then fly down to the ground, and spend most of the day walking about, foraging. They may also patrol the boundaries of their territory during the first two hours of the day, when aggression is most likely to take place. Intruders, or pairs holding adjacent territories, are chased or dived at. There is a peak in aggression between neighbours early in the winter nesting season. Non-breeding Magpie-larks gather at roosts that may contain hundreds of birds. At daybreak the flocks break up into pairs, or small parties that may be families. Juveniles within these flocks feed and associate with individuals of the opposite sex, while being aggressive towards their own sex. This can lead to pair formation, when the birds either leave the flock to establish a territory, or take up a territory within the area occupied by the flock.*

[*Grallina cyanoleuca cyanoleuca.*
[Above: near Brisbane, Queensland, Australia
Photo: Brian J. Coates.

Below: Melbourne, Australia.
Photo: Rohan Clarke]

Aggressive towards their own species, ***Magpie-larks*** *will also tackle predators like this Little Eagle* (Hieraaetus morphnoides). *Magpie-larks perform at least 13 displays. In one of the commonest, the "Sculling" display, which is given in flight, the bird beats its wings several times and then glides, often calling simultaneously. This display is believed to be primarily for maintenance of the pair-bond, but perhaps has the secondary function of advertising and defending the territory.*

[*Grallina cyanoleuca cyanoleuca*, Innamincka, South Australia, Australia. Photo: David Stowe]

such as a farm dam, and all contained water in the nesting season. These sources also provided the mud that is needed for nest-building. It is thought that the maintenance of permanent partners and territories provides an evolutionary advantage by enabling Magpie-larks to start nesting as soon as rainfall creates appropriate conditions.

In the grounds of the Australian National University, in Canberra, which feature parklands with cultivated trees and lawns, the territory sizes are much smaller, covering only 1–2 ha in area. Further, pair-bonds appear to be weaker in this "urban" context, and more than 30% of observed pair-members separated after fewer than four months together. In some areas where climatic factors are extreme, such as Darwin, in Northern Territory, in the summer wet season, adults may abandon their territories and flocks will move away from the region.

At night, Magpie-larks roost in trees with reasonably dense foliage, including eucalypts, figs (*Ficus*) and mangroves, and exotic willows (*Salix*) and pines (*Pinus*). They will also use the introduced jacaranda tree (*Jacaranda mimosifolia*), which is considered an invasive species in several parts of Australia. The members of a pair will roost in one of several specific trees within their territory, and the partners typically call from that tree before sunrise. They then fly to another tree nearby, where they will preen and continue to call for a period of time, before flying down to the ground and starting to forage; they also "patrol" the boundaries of their territory during the first hour or two of the day. They spend most of the rest of the day in walking about on the ground, actively searching for food. At sunset, the birds fly back to the roost tree and give a few calls, before settling down for the night.

Each pair of ***Magpie-larks*** *has a signature call. One bird begins to give loud metallic notes at intervals of about one second, and its partner joins in during the intervals, creating a highly synchronized sequence of alternating calls, known as "antiphonal calls". Each pair has a repertoire of calls distinct in tone and components from other pairs, even within the same region, though differences are most pronounced between birds from different regions. Antiphonal calls are usually given when the pair members are together, but during the nesting season, they may call while one bird is brooding and the other foraging.*

[*Grallina cyanoleuca cyanoleuca*, Geelong area, Victoria, Australia. Photo: Peter Fuller]

Many observations of communal roosting have been recorded. Indeed, mobile flocks of non-breeding Magpie-larks regularly roost together in trees, particularly during the non-breeding season. Such roosts often contain hundreds of individuals, and one roosting flock in fig trees was estimated to number something in the region of 3000 individuals. Although the birds leave the roost at daybreak in pairs or in small parties, the latter thought to be families, there are also some reports of huge flocks leaving en masse.

Territories are defended by means of aggression and vocal behaviour. Most aggression occurs in the first two hours after sunrise, and is directed both at intruders and at pairs holding adjacent territories. It typically occurs along the common boundary of their territories and varies seasonally, with a peak in frequency and duration early in the winter nesting season. Aggressive behaviour comprises mostly chasing, diving at or flying rapidly towards opponents. Males are involved in more aggressive interactions than females, and individuals tend predominantly to attack members of the same sex. The main function of this intraspecific aggression appears, therefore, to be that of mate protection in the context of territory maintenance.

The Magpie-lark is known to use at least 13 different displays. Two of these are performed when the bird is in flight, and the remainder while it is perched. Six of the perched displays involve wing movements, and five involve a change in body posture with no wing movements. By far the most common displays are the "Sculling" display, the "Wing-flash" and the "Bow-flick". In the first of these, given in flight, the bird beats its wings several times and then glides, often calling simultaneously; this display is believed to be primarily for the maintenance of the pair-bond, but perhaps with a secondary function of advertising and defending the territory. The other two are performed on a perch. In the wing-flash, the individual repeatedly opens and raises one wing or both wings upwards and outwards, away from the body, while repeatedly calling; this display is strongly associated with antiphonal calls (see Voice), and the partner usually gives the same display. In the bow-flick display, performed throughout the year, the Magpie-lark bows forwards with its tail lowered and fanned, and then quickly tilts upright while flicking the tail upwards, usually uttering song while in the upright posture; this display, as with the previous one, is strongly associated with antiphonal calls, and is normally given by both partners. It is believed to have the same functions as the aerial sculling display.

Ten of the displays of the Magpie-lark are usually given in the presence of a partner, but three, termed the "Wing-waving", "Dropped-wings" and "Flat-wings" displays, are performed in other social contexts. Most of the displays are accompanied by calls. The dropped-wings and flat-wings displays occur mostly during aggression between individuals of the same sex, and may be appeasement displays.

Immature Magpie-larks, after having left their parents' territories, join together in flocks, which range in size from small numbers to thousands of individuals. These include birds in juvenile plumage, young birds that are moulting or have recently acquired adult plumage, recently paired young adults, second-year pairs, and one or more older pairs from territories that overlap with the area being used by the flock. The number of individuals within a flock increases markedly in the period immediately following the nesting season, and declines as the subsequent nesting season approaches.

The flocks tend to remain in a limited geographical region and to occupy areas that are mostly outside, but overlap parts of, the territories of adults. Within the flock, the juveniles roost together but tend during the day to feed close to individuals of the opposite sex and to call and associate with them, while exhibiting aggressive behaviour towards individuals of the same sex. The associations eventually lead to the formation of pairs within the flock. Such pairs leave the flock in order to establish a territory, or they become increasingly aggressive towards other Magpie-larks and establish a territory within the area occupied by the flock.

Pairs acquire territories by occupying and defending areas that are on the edges of existing territories, rather than by exhibiting persistent aggression against the original owners. They may also occupy areas in which one of the former resident pair of Magpie-larks has died. Some young paired birds in their first year will not be successful in establishing a territory and in breeding, and these may rejoin a flock in their second year.

Magpie-larks are conspicuous birds, they are relatively slow fliers, and they spend much of their time in feeding in open areas on the ground, often in the proximity of families of Australian Magpies (*Cracticus tibicen*). The latter usually detect and attack predators, and this may benefit the Magpie-larks, which also are aggressive but are less bold. There are records of predation on Magpie-larks by the Black-breasted Buzzard (*Hamirostra melanosternon*), the Whistling Kite (*Haliastur sphenurus*), the

Both members of Grallinidae feed mainly on invertebrates, though they occasionally take small vertebrates like frogs and lizards. ***Magpie-larks*** *forage mainly on open ground, including the edges of wetlands, exposed tidal flats, and even lawns in urban areas. They often scratch at the ground, then move backwards to snap up prey thus uncovered. They will also flush and pursue prey in grass, and sally into the air from the ground or a perch to catch flying insects. The foraging techniques of Torrent-lark* (Grallina bruijni) *are very similar. While foraging, it persistently wags its tail from side to side, and fans its wings.*

[*Grallina cyanoleuca cyanoleuca*, Brisbane, Queensland, Australia. Photo: Ian Fisher]

*During the hot hours of the day, **Magpie-larks** need to drink; they may also drink in the early and late hours. They have been seen drinking from garden ponds, and also from taps. They tend to be resident wherever there is permanent water, and are absent only from Australia's arid deserts, though in northern Australia they may become scarce during the tropical wet season. Magpie-larks will wade in the muddy margins of pools and streams while foraging, and both species of grallinid will snatch prey items from the surface of the water. On very wet mud, Magpie-larks employ the technique of "foot-trembling" to bring items to surface.*

[*Grallina cyanoleuca cyanoleuca*, Geelong area, Victoria, Australia. Photo: Peter Fuller]

Collared Sparrowhawk (*Accipiter cirrocephalus*), the Grey Falcon (*Falco hypoleucos*) and the Barking Owl (*Ninox connivens*).

As already mentioned, Magpie-larks often preen very soon after leaving the roost in the morning. One female was seen to preen for up to 20 minutes in the early morning. In addition, pairs often rest and preen in the early part of the afternoon.

Magpie-larks appear to bathe fairly regularly. On two occasions they were watched while bathing in the shallow, belly-deep water of a creek, into which they either walked from the nearby mudbank or jumped from a low rock. The birds plunged the head beneath the surface and rapidly beat the wings for less than one second, after which they walked to shallower water or on to the bank, or, alternatively, jumped back on to the rock, and proceeded to fluff up the plumage and preen. This procedure was repeated four times within the space of a minute. A single individual, standing 1 m from the bank, was observed to dash into the water and then immediately dash out of it, return to its original standing position, and begin to preen; it repeated this behaviour on three or four occasions while the observer watched. On one occasion, a Magpie-lark landed briefly on the surface of the water in a tank and fluttered its wings, splashing water over its plumage.

This species has been observed also to indulge in sun-bathing. One individual was watched as it sat on the ground in the full sunlight, with its back facing the sun and its wings held slightly out from the body, allowing the sun's warm rays to penetrate its plumage. Anting, too, has been recorded. A Magpie-lark picked up in its bill, three times, an ant of the species *Froggattella kirbyi*, which it rubbed beneath its right shoulder; it repeated this action on the left wing, before apparently eating the ant.

Voice

Only a few calls made by Torrent-larks have been described. One call, given in flight, has been described as a harsh, rasping, buzzy note that is easily heard above the sound of water. In addition, a male Torrent-lark was recorded as giving a nasal, buzzy "k-zaaat" call during a raised-wing display.

Far better known are the vocalizations of Magpie-larks. This species has fascinating vocal behaviour that is often associated with visual displays. Its vocalizations are of three main types. The first of these is termed solo calls, as when one individual utters a call and usually repeats it, at regular intervals of about one second, a variable number of times. The second type is antiphonal calls, when one member of an adult pair begins to call as with the solo call but its partner calls during the intervals in the series, the result being a highly synchronized sequence of alternating calls. The third main type of vocalization is termed rapid calls, whereby one individual repeats a high-pitched "pee" at a rate of about four per second in a relatively long sequence.

A large number of solo and antiphonal calls have been identified, but these are variants of a smaller series of basic call types. The calls are delivered most often in association with displays, particularly antiphonal calls with the wing-flash and bow-flick displays and solo calls with sculling displays (see General Habits).

The antiphonal calls of paired Magpie-larks are possibly the most pronounced and complex calls of this type of any species of bird. They are most often described as a sequence of repeated "ptowit, deedee", or a variant of this. Each adult pair, however, has a repertoire of antiphonal calls that differ noticeably in tone and/or components from equivalent calls given by other pairs. These differences, although most pronounced among birds from different geographical locations, are also evident among individuals living in one and the same area. This fact has enabled researchers to identify pairs by their calls alone. Each adult pair of Magpie-larks delivers a particular antiphonal call at dawn from its roost tree. This call is given only in this context and, because it differs from one pair to another, it is known as the pair's signature call. Most antiphonal calls are given in the first two or so hours from dawn, and most often when the pair-members are together in a tree or other elevated position with no other Magpie-larks nearby. During the nesting period, however, antiphonal calls are often emitted when the partners are separated, as one may be sitting on the nest while the other is in the process of foraging some distance away.

The contexts in which Magpie-larks employ antiphonal calls strongly suggest that the primary function of those calls is that of maintaining the bond between partners. These calls also "advertise" to other Magpie-larks that a territorial area is occupied by a pair of this species.

*Ten of the displays of the **Magpie-lark** are usually given in the presence of a partner. In the "Wing-flash" display, a bird repeatedly opens and raises one or sometimes both wings, while repeatedly calling. This display is strongly associated with antiphonal calling, and the partner usually gives the same display. Like the aerial "Sculling" display, wing-flashing is believed to help maintain the pair-bond. Magpie-lark breeding appears to be influenced by rainfall and daylength. Most egg-laying occurs in the austral spring and summer, but there are records for all months. In southern parts of Australia, breeding normally commences following the onset of winter rain in June, when a lasting source of mud for nest-building is available.*

[*Grallina cyanoleuca cyanoleuca*, Grey Range, Queensland, Australia. Photo: Graeme Chapman]

Interestingly, solo calls seldom elicit responses from birds other than the partner of the caller. The primary function of these calls appears to be that of maintenance of contact between pair-members when they are apart within their territory and, especially, when they are separated visually. As a result, the number of solo calls increases during the nesting season, when the partners are often apart.

Rapid calls are usually emitted during aggressive interactions between adjacent territorial pairs, between a pair and intruders into its territory, and between a pair and potential predators. These vocalizations are an important component of the aggressive behaviour of the Magpie-lark, and there is less noticeable variation among individuals and less geographical variation in this type of call. As aggressive interactions can occur at any time, the frequency of rapid calls, unlike that of solo and antiphonal calls, is not related to the time of day. The number of rapid calls given by a pair, however, increases during the nesting season.

The ability of Magpie-larks to identify the antiphonal, solo and rapid calls of their partners, and to distinguish them from those of their neighbours, has been demonstrated in field experiments, using playback of recorded calls.

Food and Feeding

Both members of this family feed predominantly on invertebrates that they catch on the ground. Both have been recorded catching and eating small vertebrates, the Torrent-lark occasionally consuming lizards and Magpie-larks sometimes eating frogs. In addition, Magpie-larks occasionally eat small seeds and grain. Both species appear to feed opportunistically, as a considerable variety of food items has been recorded in their diets. Among others, these include insects, molluscs, millipedes (Diplopoda), spiders (Araneae), worms (Oligochaeta) and crustaceans.

Grallinids are terrestrial in their foraging habits. Torrent-larks forage on exposed rocks and gravels of streams and roads, and they also take food items from the surface of water. Magpie-larks forage on open ground in natural areas, including on the edges of wetlands, on exposed tidal flats and on lawns in urban areas. The preference for feeding on the ground is probably the reason why Torrent-larks are restricted in their distribution to the vicinity of streams in dense forests, and why Magpie-larks occur mainly in farmland and relatively open vegetation.

The foraging techniques of the mudlarks are relatively simple. For example, the Magpie-lark walks along on the ground or wades in muddy waterside margins and gleans any suitable items which it finds. It will often stop and scratch a few times at the ground, and then move backwards a few centimetres in order to snap up a prey item thus uncovered. It has also been seen to flush and pursue prey in grass, and to employ the technique of "foot-trembling" on very wet mud in order to bring worms and other items to the surface. Both of the mudlarks will seize aerial prey by sallying briefly into the air, usually from the ground but sometimes from a low perch.

Magpie-larks drink water during the hot hours, and sometimes also do so in the early and late hours of the day. They have been observed drinking from garden pools and ponds, and from taps.

Breeding

Information on the breeding of the Torrent-lark is limited. Nests have been recorded from July to early January, which would indicate that breeding takes place at least from the middle of the dry season until the early wet season. Torrent-larks construct a cup-shaped nest from mud and rootlets, which they site on the branch of a tree or bush near a stream. There appear to be no published descriptions of the dimensions of the nest, nor any details of this species' nesting behaviour. The clutch is stated in some publications to consist of only one egg, but groups of up to four individuals have been sighted and it is thought that they may represent family parties. The eggs are described as being identical in colour and markings to those of Magpie-larks.

Far more information is available about the breeding habits and biology of the Magpie-lark, which is comparatively well known. The following details refer to that species.

For Magpie-larks, the onset of breeding appears to be influenced by rainfall and by daylength, or the total number of hours of daylight. This species begins to build its nest when sufficient

When sufficient rain has fallen to create long-standing pools, ***Magpie-larks*** *take mud from the margins, and combine it with strands of vegetation to build their nests. The nest is cup-shaped and relatively large, about 15 cm in diameter, and 8 cm deep. It is placed 5–20 m above ground, occasionally higher, usually on the outer part of a tree branch, though sometimes on a man-made structure such as a telegraph pole or fence post. Both partners work on the nest, but the male devotes more time to it. Each bird carries the nesting material in its beak, and places it in position by rapidly vibrating the head from side to side. It will also press its breast against the soft mud walls to shape the inside of the bowl. The finished nest is lined with fine stands of vegetation and small feathers. Nest construction may take anything from a few days to three weeks, and the nest may be used for second and subsequent broods, or alternatively a new one may be built. Mating takes place near the nest, during or shortly after the time in which the nest is lined, and the first egg is laid five to six days after the nest is completed. Clutches are of one to six eggs, which are pearly white marked with reddish and grey spots. Both sexes incubate the eggs during the day, for about 25 minutes at a time, but only the female sits on the nest at night. Incubation takes 17–19 days. Torrent-larks* (Grallina bruijni) *also construct a cup-shaped nest from mud and rootlets, siting it on the branch of a tree or bush near a stream. There appear to be no published descriptions of the dimensions of the nest, or indeed any details of the Torrent-lark's nesting behaviour. Nests have been recorded from July to early January, from the middle of the dry season to the early wet season. The clutch is probably of one to four eggs.*

[*Grallina cyanoleuca cyanoleuca*, Port Willunga, South Australia, Australia. Photo: Stewart Roper/ Lochman Transparencies]

*Both **Magpie-lark** parents brood and feed the chicks. There is a single report of co-operative breeding, where one male and two females occupied a single territory and bred several times over a period of more than two years. All three contributed to the tasks of nest-building, incubating the eggs, and feeding and brooding the young. In general, nests may be parasitized by several species of cuckoo (Cuculidae). Breeding success is moderate to rather low, with more than 50% of young dying as nestlings, or within a few weeks of fledging. In one survey, 405 out of 761 eggs hatched, and 227 young fledged. In another survey, 743 of 1099 nests produced at least one young, and the remaining failed, with predators a primary cause.*

[*Grallina cyanoleuca cyanoleuca*, Geelong area, Victoria, Australia. Photo: Peter Fuller]

rain has fallen to create durable surface water within its territory. The surface water provides a source of mud, which is used, together with strands of vegetation, to construct a relatively large cup-shaped nest about 15 cm in diameter and 8 cm deep.

Throughout the species' range, most egg-laying occurs in the austral spring and early summer, but there are records for all months. In southern parts of Australia, breeding normally commences following the onset of winter rain in June. In the south-west part of Western Australia, nest construction begins in July, and the first clutch is laid and incubation commences in August, about a month after the peak in winter rainfall. In south-east Australia, on the other hand, the winter is colder and nesting is delayed. In Canberra, for example, nest construction begins in late August, but most nests are started in September. Breeding can continue until December or even early January, several broods being raised. Heavy rain may initiate breeding at other times, and nests with chicks have been recorded in south-west Western Australia in April, after very heavy rainfall in February.

In the tropics of far north Queensland, the hours of daylight are relatively constant and rain may fall during most months but is least plentiful during the "winter". In this region, one observer recorded nesting in every month except April and June, over a period of 15 years. In inland Australia, where rainfall is episodic and may not occur at all during extended periods, Magpie-larks typically live only near persistent sources of water, such as billabongs (stagnant pools associated with temporary rivers), and troughs associated with water bore-holes. Nesting in these areas appears to take place in winter and spring, presumably because food items are more abundant in these seasons.

Magpie-larks are monogamous, having long-term, usually lifelong pair-bonds. There is a single report of co-operative breeding, in Melbourne, where one male and two females occupied a single territory and bred several times over a period of more than two years. All three individuals contributed to the tasks of nest-building, the incubation of the eggs and the brooding and feeding of the nestlings, and the provisioning of the fledglings. When one of the females was thought to have died, the remaining female and the male continued to maintain the territory.

Nests are usually situated towards the end of a branch, relatively high in a tree that is within 25 m of water and where mud is available. The majority of nest trees are located in the central area of a territory, but some are sited close to a boundary. Sometimes, mainly in areas lacking trees, artifical sites are utilized, examples being the tops of telegraph poles, windmills and the like, and, more rarely, airport towers, posts, the tops of streetlights, and poles supporting electricity cables. Both members of the pair construct the nest, but males devote more time to the task. They work mostly during the morning. Each bird collects mud and fibrous plant material and carries this in its beak to the nest, where it places it in position by rapidly vibrating its head from side to side. It then smoothes the mud by stroking the underside of its beak over the area. The outside of the nest is smoothed in the same way, and each partner presses its breast against the newly built mud walls in order to shape the inside of the bowl. Finally, the completed structure is lined with fine strands of vegetation and small feathers. The task of nest-building may be completed in a few days or over a period of more than three weeks. Second broods are relatively common, the adults either using the same nest or constructing a new one, and up to four broods have been recorded.

Mating usually takes place near the nest and occurs during, or shortly after, the time when the nest is being lined. The first egg is laid generally five to six days after completion of the nest, and a further egg is laid each day, the average interval being 1·2 days, until the clutch is complete. The clutch size ranges from one to six eggs, which have a pearly-white ground colour marked with reddish and grey spots. Incubation begins with the second egg, and lasts for 17–19 days. Both sexes incubate during the day, each sitting for about 25 minutes at a time, but the female sits on the nest through the night.

Young Magpie-larks are almost naked on hatching, having no more than a minimal amount of dark down along the main feather tracts. They remain within the nest for a period of some 19–23 days, and are brooded and fed by both parents throughout the day, the female again sitting during the night-time. The chick's first primary quills appear at 3–4 days, and the primary sheaths open at 7–8 days; by 14 days of age the chick is well feathered, and three days later its primaries are two-thirds out of the sheaths and the chick is able to flutter its wings while standing on the rim of the nest.

The adults, in order to encourage the young to leave the nest, often land some distance from it, while carrying food, and then call and display there. Eventually, one chick flies to join the parents, which feed it, and the other chicks soon follow. The young remain in trees or other vegetation for several days before first coming to the ground and following their parents for brief periods. Thereafter, they accompany the parents closely and beg for food, most often following the parent of the same sex. They continue to be fed for a further two weeks, before they start to catch food for themselves on the ground. After a further three weeks, the young, now about eight weeks of age, catch all of their own food and are no longer fed by the adults. They remain within the natal territory, but the parents become aggressive towards them, chasing and attacking the young if they approach, and the young begin to feed and roost separately. The offspring generally leave the territory and join juvenile flocks when about nine to eleven weeks old. Those leaving earliest tend to be the young of parents that have started to incubate the eggs of a second brood. In urban areas some young may remain in their parents' territory until the start of the next breeding season.

More than half of the young die either as nestlings or in the first few weeks after fledging, and for each breeding attempt generally only one or two young survive for long enough to leave the parents' territory.

Breeding success is moderate to rather low. Of 761 eggs in 216 nests throughout the Magpie-lark's Australian range, 405 hatched, and 227 of these hatchlings survived to the fledgling stage. In a sample of 1099 nests at which the outcome was known, 743, or 67·6%, produced at least one young and the remaining 356 failed. Predators are a major cause of nest failure. In particular, birds of prey such as the Red Goshawk (*Erythrotriorchis radiatus*), the Brown Falcon (*Falco berigora*) and others take chicks from nests, as do butcherbirds and, occasionally, Laughing Kookaburras (*Dacelo novaeguineae*), and snakes sometimes raid the nests. Young fledgling Magpie-larks fall prey to domestic cats and one was even caught and eaten by a dog, while another was captured by a Whistling Kite. In addition, nests are parasitized by Pallid Cuckoos (*Cuculus pallidus*), Channel-billed Cuckoos (*Scythrops novaehollandiae*) and Common Koels (*Eudynamys scolopacea*).

Movements

Virtually nothing is known about the movements of Torrent-larks, but the adults of this species are thought to be sedentary.

Adult Magpie-larks likewise are sedentary, and maintain permanent territories throughout much of the range of the species in Australia. Young disperse from their parents' territories and join flocks usually only a short distance away. There is a turnover of individuals within any flock, and it is assumed that birds leave and join other flocks nearby. The young form pairs within the flock, and a new pair will either establish a territory in the area used by the flock or leave the area, presumably to establish a territory elsewhere. It is not known how far such pairs may travel.

The longest recorded movement for the species is only 15 km, for an eight-month-old youngster. Magpie-larks are, however, regular non-breeding winter visitors to islands in the Torres Strait, between north-east Australia and south New Guinea, and occasional visitors to Tasmania. Moreover, they apparently arrived relatively recently in East Timor, and there is also a record of a single individual that turned up on Lord Howe Island in 1913. These records suggest that the species is capable of long-distance movements.

Very large flocks of Magpie-larks form in the dry season, from April to December, in northern Australia. The size of these flocks decreases as the wet season approaches, and Magpie-larks are absent from the region from December to the end of March. It is not known to where the birds go, but they may disperse southwards, to beyond the limits of the heavy seasonal rain.

*Young **Magpie-larks** are almost naked on hatching, with a thin dusting of dark down along the main feather tracts. The first primary quills appear at three to four days, and the primary sheaths open at seven to eight days. By 14 days, the chick is well feathered, and three days later its primaries are two-thirds out of the sheaths, and the chick is able to flutter its wings while standing on the rim of the nest. The juvenile has a black crown and a white stripe above the eye like an adult male, but a white throat and white area from the eye to the shoulder, like a female. Some begin the moult into adult plumage six to seven weeks after leaving the nest, while they are resident within their parents' territory. Most, however, start to moult ten or eleven weeks after fledging, shortly after leaving their parents' territory. The complete moult takes three to four months.*

[*Grallina cyanoleuca cyanoleuca*,
Beerwah, Queensland,
Australia.
Photo: Graeme Chapman]

*To encourage the young to leave the nest, adult **Magpie-larks** carrying food will land some distance away, and begin calling and displaying. Eventually, one chick will fly to the parent to be fed, and the rest soon follow. The young stay in the trees for several days after leaving the nest, before they descend to the ground and begin following their parents. They continue to be fed for a further two weeks, before they start to catch food for themselves. By eight weeks old, they are no longer fed by the parents. Although they remain in their parents' territories, the parents themselves are aggressive towards them. The young birds begin to feed and roost separately before, at nine to eleven weeks, they leave to join a juvenile flock.*

[*Grallina cyanoleuca neglecta*, Cairns, Queensland, Australia. Photo: Atsushi Matsui]

On the eastern side of Australia, the species leaves the high altitudes on the Great Dividing Range when cold temperatures and snow produce difficult and unsuitable conditions in the winter.

Relationship with Man

Torrent-larks inhabit rainforest and are considered to be scarce. They presumably, therefore, have little contact with humans. Nevertheless, there is a reference in the literature to the fact that some tribal people in New Guinea are wary of Torrent-larks, as they believe the birds to be associated with witchcraft.

In Australia, Magpie-larks have benefited from the extensive agricultural development that followed European settlement (see Status and Conservation). Historically, this grallinid has, in turn, been considered to be beneficial to agriculture, as it consumes a variety of invertebrate pests. The most important of these pests is a freshwater snail which is the intermediate host for a liver fluke that affects sheep and cattle. Unsuccessful attempts were made to introduce Magpie-larks in New Zealand, Hawaii and Fiji in the hope of reducing snail populations and the associated parasites there.

Status and Conservation

Both of the members of this family are considered not to be at any risk, at least in the immediate future. There is no suggestion in the literature that Torrent-larks are in decline or are in any way threatened as a result of human activities. They occur over a very large part of New Guinea in hill and mountain areas, and the remoteness and rugged nature of much of the terrain are likely to provide reasonably safe habitat for this species. The Torrent-lark seems to be fairly common throughout most of its range, but it has been said to be locally uncommon, at least in the eastern half of the island.

The Magpie-lark is a common and protected species over much of mainland Australia, where it is one of the most familiar birds in towns and on farms. It has benefited from the extensive agricultural and pastoral development that has occurred over much of Australia following colonization by Europeans. Historical reports suggest that, at the time when the first British settlers arrived, the species was restricted to habitats close to natural wetlands. Its populations then increased as the species dispersed into areas newly cleared for agriculture and where artificial sources of water and mud were provided. Thus, agricultural conversion and the clearing of natural vegetation, activities that have reduced the populations of many other species, as well as reducing species diversity in many areas, have enabled the Magpie-lark, conversely, to achieve a noticeable expansion of range and increase in numbers. The species has bred once in Tasmania, in 1903, but it is otherwise only a vagrant on that island.

Elsewhere in its range, the Magpie-lark is apparently numerous but local near the Bensbach River, in the Trans-Fly region of south New Guinea, but it seems not to have spread further afield. It is also resident in Timor, but no information is available on its numerical status there, although it seems to be locally common. The species is thought to be a relatively recent immigrant in these two areas.

In 1913 a Magpie-lark was recorded as a vagrant on Lord Howe Island, where the species was later introduced, in 1924, and is now well established and widespread on the island. Other attempted introductions, on the North Island of New Zealand, in Hawaii in 1922 and 1929, and in Fiji, have all been unsuccessful.

Finally, there are early records of the Magpie-lark from the small island of Luang, to the east of Timor, and from Tayandu Island, which lies about 200 km south of the western end of New Guinea. The Tayandu record was in 1899 and the Luang one was in 1905. The provenance of these individuals is uncertain, and there have, so far as is known, been no further records of the species from either island.

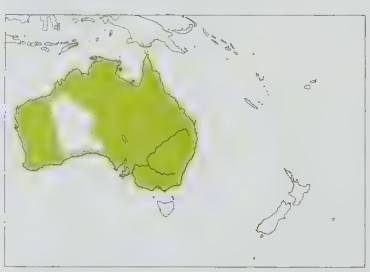
PLATE 14

inches 4
cm 10



Genus *GRALLINA* Vieillot, 1816

1. Magpie-lark

Grallina cyanoleuca

French: Gralline pie **German**: Drosselstelze **Spanish**: Grallina Australiana
Other common names: Australian Magpie-lark, Little/Murray Magpie, Mudlark, Pied Grallina

Taxonomy. *C[orvus] cyanoleucus* Latham, 1801, Sydney, New South Wales, Australia.
Proposed and formerly widely used name *picata* is a synonym of nominate race by first revision (both names were simultaneously published for same taxon). Relationships of genus disputed; has in the past been thought to be closely related to the two species of Struthideidae, but genetic analyses indicate no such relationship; on basis of recent genetic studies, has been placed in drongo family (Dicruridae) or in monarch-flycatcher family (Monarchidae), and apparent close affiliation with latter supported by details of skull morphology; has also been suggested as being related, on basis of examination of skulls, to butcherbirds and currawongs (Cracticidae) and woodswallows (Artamidae) and, from comparison of egg-white protein, to the crows (Corvidae). Although many modern taxonomists favour placement of present genus with Monarchidae, and despite some similarities in external morphology, the two differ markedly in behaviour and nest structure. For the time being, it is considered best to retain the present family as a separate entity, although close relationship to Monarchidae appears very probable. Smaller race *neglecta* intergrades with nominate in N Australia (in broad band from C Northern Territory E to W & NC Queensland); was for long considered not worthy of recognition, but recent study suggests that biometric differences significant. Birds of this species on Timor and in S New Guinea of unknown racial identity; study needed. Two subspecies recognized.
Subspecies and Distribution.
G. c. neglecta Mathews, 1912 – N Western Australia (Kimberley) E to N Queensland (Cape York).
G. c. cyanoleuca (Latham, 1801) – W, C, E & S Australia.
Also (race unknown) on Timor, in E Lesser Sundas, and (possibly *neglecta*) in S New Guinea (Bensbach R area, in Trans-Fly region).
Introduced (nominate race) on Lord Howe I.

Descriptive notes. 25–30 cm; male 63·9–118 g and female 70–94·5 g (nominate), male 71–102 g and female 60–90 g (*neglecta*). Male has broad white line above eye, large white patch from ear-coverts down to side of neck; rest of head, and throat and upper breast glossy black; hindneck to rump glossy black, bases of scapulars white, uppertail-coverts white; tail white (appearing mostly black from above), broad black subterminal area (broadest on central feather pair, decreasing outwards, variable amount of black on outermost rectrix), tip white; upperwing black, most of secondary wing-coverts white, bases of inner secondaries white, tertials tipped white; underparts below upper breast white; iris white to pale straw-yellow or pale greyish; bill ivory-coloured to creamy, with blackish nasal groove and distal half of culmen; legs dark bluish-grey to blackish. Female differs from male in having forehead and throat white, a broad black band extending from black crown down side of face to chest, and behind this a broad white area from eye down to shoulder and meeting white of underparts. Juvenile appears to have mixture of features of male and female adults, with black crown and white stripe above eye (like male) but white throat and white area from eye down to shoulder (like female), also black parts of plumage dull, rather than glossy, iris dark brown (not white) and bill dark grey to black (not ivory with black tip). Races differ mainly in size: *neglecta* is smaller than nominate, with wing and tail of male significantly shorter than those of nominate, bill proportionately longer, also tends to have more black in outer tail (but this matched by some nominate). Voice. Loud and metallic vocalizations, of three main types: solo call, a monosyllabic or disyllabic note given by single individual, usually repeated a variable number of times at intervals of c. 1 second; antiphonal call, in which one member of pair gives solo call and its partner calls during the intervals in the series, producing highly synchronized sequence of alternating calls; third type is rapid call, in which individual repeats high-pitched "pee" or similar at rate of about four per second in relatively long sequence.
Habitat. Open vegetation, farmland, parks and gardens; requires surface water supply, and consequently is sparse in arid zones. In New Guinea, found beside rivers and lakes and in savanna. Lowlands, in Australia locally to 1000 m, occasionally to 1200 m.
Food and Feeding. Mainly invertebrates, including insects, spiders (Araneae), worms (Oligochaeta) and crustaceans; also small frogs, occasionally some seeds. Forages mainly on open ground, including edges of wetlands, exposed tidal flats, and lawns in urban areas. Walks along on ground or wades in muddy margins, opportunistically gleaning items; often stops and scratches a few times at ground, then moves backwards a little and snaps up prey thus uncovered. Seen to flush and pursue prey in grass, and to employ technique of "foot-trembling" on very wet mud in order to bring items to surface. Will seize aerial prey by sallying briefly into air, usually from ground but sometimes from low perch. Very active, constantly calling and fluttering about. Singly or in pairs; young form flocks of variable size.
Breeding. Timing related to rainfall, availability of mud for nest construction, daylength and probably temperature: in SW Western Australia commences nest-building in Jul, egg-laying Aug, but unseasonal heavy rain known to initiate nesting in Apr; in SE of country (Canberra, where winter wet and cold) building late Aug, laying Sept; in tropical far N Queensland (dry winter, wet summer) nesting recorded in all months except Apr and Jun; second broods common, and up to four broods recorded. Monogamous, with long-term pair-bond; single report of co-operative breeding (in Melbourne), with male and two females, all three contributing to nest-building, incubation of eggs, brooding and feeding of nestlings, and provisioning of fledglings. Solitary nester, pair maintains permanent territory. Nest constructed by both partners, an open cup or bowl made from mud and fibrous plant material, lined with fine strands of vegetation and small feathers, placed 5–20 m above ground, occasionally higher, usually on outer part of tree branch, sometimes on man-made structure (e.g. telegraph pole, other pole, lamppost); nest reused or new one constructed for subsequent brood. Clutch 1–6 eggs; incubation by both sexes, period 17–19 days; chicks brooded and fed by both parents, leave nest at 19–23 days; young fed by both adults until c. 14 days after fledging, fed less thereafter, and independent c. 5 weeks after fledging; young remain within natal territory, but parents attack them if they approach, and offspring generally leave and join juvenile flocks when c. 9–11 weeks old. Nests parasitized by Pallid Cuckoo (*Cuculus pallidus*), Channel-billed Cuckoo (*Scythrops novaehollandiae*) and Common Koel (*Eudynamys scolopacea*). Breeding success moderate to rather low, and more than 50% of young die as nestlings or within few weeks of fledging; of 761 eggs in 216 nests throughout Australian range, 405 hatched, and 227 young fledged; of 1099 nests at which outcome known, 743 (67·6%) produced at least one young and remaining 356 failed; predators a primary cause of nest failure. Age at first breeding 2 years. Lifespan 10 years or longer.
Movements. Mainly resident, with some local movement; partly migratory in some areas. Adults usually sedentary within territories over most of range. Seasonal occurrence in tropical N Australia (absent in wet season) and at high altitudes (absent in winter); observations suggest that most, if not all, individuals (including adults) leave area around Darwin, in Northern Territory, before or soon after onset of wet season, but extent of movements unknown. Young disperse from parental territories and form flocks nearby, from which pairs disperse; distance travelled by new pairs seeking territories unknown. Regular non-breeding visitor to islands in Torres Strait, and occasional visitor to Tasmania. Capable of long-distance movements, as occasionally recorded on islands distant from mainland Australia; apparently colonized Timor from Australia, and single individual recorded on Lord Howe I (600 km off E Australia) in 1913. Old records from Luang I (E Lesser Sundas) in 1905 and from Tayandu I (SE Moluccas) in 1899 presumably refer to vagrants.
Status and Conservation. Not globally threatened. Common to abundant over much of Australia, where one of the most familiar birds in towns and on farms; locally common in S New Guinea; no recent information on status in Timor, but thought to be locally common. Has benefited from extensive agricultural and pastoral development over much of Australia following colonization by Europeans. When first settlers arrived, this species was apparently restricted to habitats close to wetlands; it then dispersed into areas cleared for agriculture and where artificial sources of water

were provided, enabling it to achieve a noticeable expansion of range and increase in numbers. Has bred once in Tasmania, in 1903. Introduced on Lord Howe I in 1924, and now well established and widespread there; attempted introductions in New Zealand (on North I), in Hawaii and in Fiji all unsuccessful.

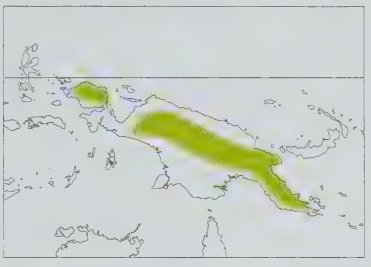
2. Torrent-lark

Grallina bruijni



French: Gralline papoue **German**: Trugstelze **Spanish**: Grallina Papú

Taxonomy. *Grallina bruijni* Salvadori, 1876, Arfak Mountains, north-western New Guinea.

Relationships of genus disputed; has in the past been thought to be closely related to the two species of Struthideidae, but genetic analyses indicate no such relationship; on basis of recent genetic studies, has been placed in drongo family (Dicruridae) or in monarch-flycatcher family (Monarchidae), and apparent close affiliation with latter supported by details of skull morphology; has also been suggested as being related, on basis of examination of skulls, to butcherbirds and currawongs (Cracticidae) and woodswallows (Artamidae) and, from comparison of egg-white protein, to the crows (Corvidae). Although many modern taxonomists favour placement of present genus with Monarchidae, and despite some similarities in external morphology, the two differ markedly in behaviour and nest structure. For the time being, it is considered best to retain the present family as a separate entity, although close relationship to Monarchidae appears very probable. Present species has in the past sometimes been placed in a different genus, *Pomareopsis*, but no apparent justification for generic separation from *G. cyanoleuca*. Monotypic.

Distribution. Hills and mountains of New Guinea.

Descriptive notes. c. 20 cm; male 40–41 g, female 38–40 g. Male has white line above eye, large white patch from ear-coverts down to side of neck; rest of head, upperparts to rump, and throat and breast black; uppertail-coverts and undertail-coverts pale buff, tail buffy white basally with broad black subterminal band; upperwing black, most of secondary wing-coverts white; lower underparts white, undersurface of wing black; iris dark brown; bill lead-grey to pale blue-grey, tip whitish; legs blue-grey. Female differs from male in having black head with white band extending from base of bill through and above eye and expanding onto side of neck; breast and underwing-coverts white; flanks and lower abdomen pale buff. Juvenile is similar to female, but has area between base of bill and eye black, and remaining dark areas of plumage very dark brown (instead of black). Voice. Loud, penetrating, buzzy call notes "jjirrreee" or "bzzzeee", or series of notes, often considered harsh and unpleasant, also upslurred calls, far-carrying and clearly audible against background noise of streams. Male recorded as giving nasal, buzzy "k-zaaat" during raised-wing display.

Habitat. Near small, fast-flowing streams in rainforest and open grassland, mainly between 400 m and 2300 m; to 2800 m in Snow Mts.

Food and Feeding. Invertebrates; small lizards occasionally caught and eaten. Forages on ground, mostly at edges and on exposed rocks and gravels of streams and on roads; mainly in shallows of streams, searching among boulders and fallen trees in and beside rushing water; takes items from surface of water. Sometimes captures aerial prey by sallying briefly into the air, usually from ground but sometimes from low perch. Very active, constantly calling and flying about; persistently wags tail from side to side, also fans wings. In pairs or small parties.

Breeding. Few observations. Nests recorded Jun–Jan, predominantly dry season. Nest cup-shaped, made from mud and rootlets, placed on branch of tree or bush close to stream; clutch probably 1–4 eggs. No other information.

Movements. Very little information. Adults believed sedentary, juveniles presumably dispersive; some altitudinal movement possible. Individuals or groups travel between streams.

Status and Conservation. Not globally threatened. Fairly common throughout most of range; perhaps locally uncommon, at least in E half of range. Distributed over large part of New Guinea in hill and mountain areas, and habitat likely to be reasonably secure owing to remoteness and rugged nature of terrain. Considered not to be at any risk, at least in immediate future.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family STRUTHIDEIDAE (AUSTRALIAN MUDNESTERS)

- Medium-sized, largely terrestrial passerines with shortish, rounded wings and long, sturdy legs; dull plumage.
- 29–50 cm.

- Eastern Australia.
- Open woodland.
- 2 genera, 2 species, 4 taxa.
- No species threatened; none extinct since 1600.

Systematics

The type specimen of the White-winged Chough (*Corcorax melanoramphos*) was collected in New South Wales, in east Australia, and was described by L. J. P. Vieillot in 1817 as a roller (Coraciidae). The description does not specify the precise locality where the bird was taken, but it was probably near Sydney. Two years later, J. R. C. Quoy, on his way to Bathurst from Sydney, reported that "on the heights one finds the black chough with white wings, a stupid animal, armed with sharp talons". In 1820, C. J. Temminck, presumably unaware of Vieillot's description, placed it in the same genus as the Alpine Chough (*Pyrrhocorax pyrrhocorax*), a member of the crow family (Corvidae), and gave it the name *Pyrrhocorax leucopterus*, which led to the common vernacular name of White-winged Chough. In 1830, R. P. Lesson considered that this bird merited its own separate genus, and the species received a third name, *Corcorax australis*, and was placed in the family Corvidae.

It was not until twenty years after Vieillot's original description of the White-winged Chough that the Apostlebird (*Struthidea cinerea*) was collected for the first time, again in New South Wales, when the Blue Mountains were penetrated and the inland plains reached. The first specimen was described by J. Gould in 1837 as having come from the interior of New South Wales, and it had probably been sent to him by Mrs Gould's brothers, Stephen and Charles Coxen, who had settled in the Hunter Valley. The earliest field description is that of J. Gilbert, who was surprised to see a *Struthidea* approach and sit on what he had presumed to be a magpie-lark (*Grallina*) nest; this was also the first record of the use by *Struthidea* of a mud nest.

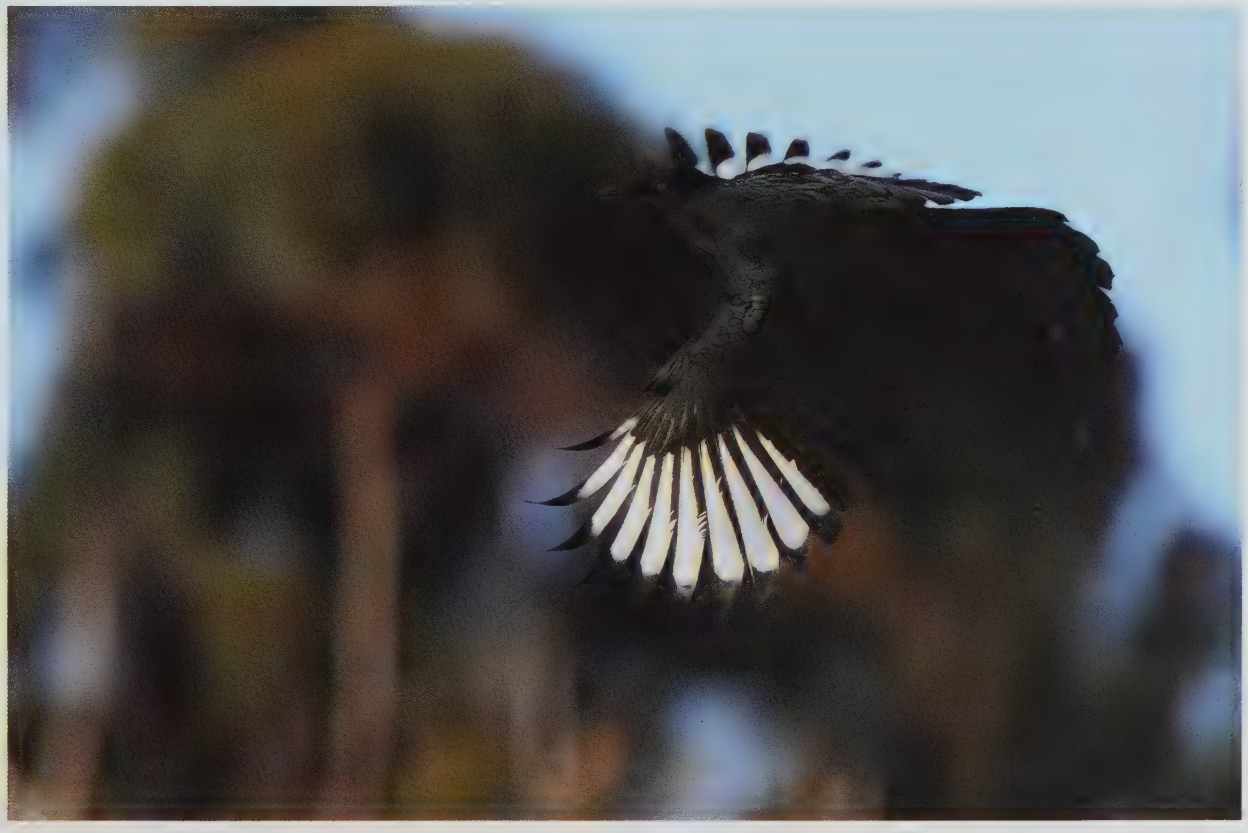
Three Australian bird species build mud nests. These are the White-winged Chough, the Apostlebird and the Magpie-lark (*Grallina cyanoleuca*), and this shared trait has confused the systematic position of the three genera concerned. The family affiliations of the three species were uncertain from the time of their description until, in the latter part of the twentieth century, DNA studies shed some light on their probable relationships. Although Lesson placed *Corcorax* in the Corvidae, Gould was not prepared to assign *Corcorax*, *Struthidea* and *Grallina* to known families and, in his 1865 *Handbook*, he listed each one with the note "Family ?". For many years, *Corcorax* and *Struthidea* were included in the Corvidae, but later authors did not recognize the similarities between the two groups and placed them in separate families. The authors of the 1926 checklist of the Royal Australasian Ornithologists Union placed *Corcorax* in the Corvidae, *Struthidea* in a monotypic family Struthideidae, and *Grallina* on its own in the Grallinidae. Soon thereafter, G. M. Mathews, in his 1931 list of the birds of Australia, had three families for the mudnesters: Corcoracidae, Struthideidae and Grallinidae. Two decades later, however, D. Amadon placed *Corcorax* and *Struthidea* together with the Magpie-lark in the family Grallinidae on the basis of the substantial bowl of mud which all three genera build for the purpose of nesting.

Initial genetic evidence from DNA studies undertaken by C. G. Sibley and J. E. Ahlquist suggested that *Corcorax* and *Struthidea* were elements of an old corvoid lineage, each the closest relative of the other, but quite divergent, and both more distant from *Grallina*, which appeared to be a monarch-flycatcher (Monarchidae). These authors placed *Corcorax* and *Struthidea* in a subfamily Corcoracinae of a greatly expanded family Corvidae. Later DNA studies have supported the finding that *Corcorax* and *Struthidea* are related genera in a separate lineage of the core Corvoidea, and current usage in Australia treats them as constituting one of a number of core corvoid families. Their closest relatives appear to be the birds-of-paradise (Paradisaeidae) and the butcherbirds (Cracticidae).

The name of the family consisting of *Corcorax* and *Struthidea* alone has normally been listed as "Corcoracidae", but in fact the name "Struthideidae" has priority. Both names were coined by Mathews in the 1920s, but the latter is older by one year and is therefore the valid name for the family thus constituted.

Mathews, in 1912, described three subspecies of the White-winged Chough and three of the Apostlebird. Since then, however, most authors have not recognized any races of either species. Nevertheless, R. Schodde and I. J. Mason, in *The Directory of Australian Birds*, published in 1999, recognized two subspecies of each of the struthideids. In the case of the White-winged Chough, the nominate race is found in most of the species' range, but is replaced in southern South Australia by the subspecies *whiteae*; the two intergrade in the region of the the Mount Lofty Ranges. There appear to be no differences between the two northern populations of the Apostlebird, although they occupy discrete ranges, one in the north part of the Northern Territory and the other in the southern Cape York Peninsula, in Queensland.

*The **White-winged Chough** and the Apostlebird* (Struthidea cinerea) *are medium-sized passerines, with drab plumage and no sexual dimorphism. In the past, they were grouped with the mudlarks* (Grallina) *in the family Grallinidae, on the basis that all three genera build substantial mud nests. The White-winged Chough and the Apostlebird are now recognized as each other's closest relations, well distanced from* Grallina. *Their closest relatives appear to be the birds-of-paradise (Paradisaeidae) and the butcherbirds (Cracticidae). The name of this family as constituted herein has normally been given as "Corcoracidae", but in fact "Struthideidae" has priority and is thus the valid name.*



[*Corcorax melanoramphos melanoramphos*, Lara, Victoria, Australia. Photo: Peter Fuller]

Both are therefore included in the subspecies *dalyi*, which intergrades with the nominate race in an area running from north-east to south-west in north-central Queensland, more or less along the low divide between the northern and inland rivers.

Northern populations of the Apostlebird have sometimes been referred to as race *swainsoni*, but this is inadequately described and may possibly be based on an intermediate specimen. Not only are the description and measurements of the type specimen ambiguous, but the type locality, given as north Queensland, is insufficiently precise and could refer to a place within the zone of intergradation between the two subspecies. Although *swainsoni* was first described by Mathews in 1912, eleven years earlier than *dalyi*, it is therefore deemed an invalid name.

Morphological Aspects

Both the White-winged Chough and the Apostlebird are medium-sized typical passerines, with drab plumage and no external sexual dimorphism. The White-winged Chough is the larger of the two

*The **White-winged Chough** is the larger of the two species, with an average overall length of about 47 cm and a weight of around 350 g. The struthideids have relatively short, rounded wings and are not strong fliers. The tail is long and bulky, and rounded at the tip. Adult White-winged Choughs have entirely matt black plumage, except for a glossy sheen on less worn feathers of the head, wing and tail; and a white wingpanel across all ten primaries, only visible when the bird is flying or displaying. The primaries do not reach their maximum size until the bird is in its fourth year.*

[*Corcorax melanoramphos melanoramphos*, Lara, Victoria, Australia. Photo: Peter Fuller]

*The bill of the **Apostlebird** is short and deep, resembling that of a finch (Fringillidae). The smaller of the struthideids, at 29–33 cm and 110–155 g, its plumage is mostly grey, with brown wings, and a blackish tail with a greenish gloss. The rather pointed feathers on the head and neck, with paler tips, give a shaggy appearance. The bill, gape, legs and feet are black. Both struthideids are birds of relatively open habitat, such as eucalypt woodland, shrubland and open-canopy forest, in temperate, tropical and semi-arid areas. The Apostlebird is found only west of the mountains of Australia's east coast, extending well into arid areas. It becomes bold and tame around modified habitat such as farms and picnic grounds.*

[*Struthidea cinerea dalyi*, Chillagoe, Queensland, Australia.
Photo: Rohan Clarke]

species, about the size of a *Corvus* crow, with a typical length of 47 cm and an average body mass of approximately 350 g. The Apostlebird is smaller, having a maximum length of 33 cm and a mean body mass of about 130 g. Both species show the morphological characteristics generally found in birds that forage mainly on the ground, having long, sturdy legs, with feathered tibia, and relatively short, rounded wings. They are not strong fliers.

The two species are similar in body proportions, with a similar ratio of wing length to tarsus length, that of White-winged Choughs being 3·9 and that of Apostlebirds 3·8. The White-winged Chough has a tarsus length of 61 mm and a wing length of 237 mm, with ten primaries and eleven secondaries. In the case of Apostlebirds, the tarsus length is 39 mm and the wing 148 mm, and there are ten primaries and nine or ten secondaries. The tip of the folded wing reaches just past the uppertail-coverts. The tail is long and bulky, and rounded at the tip, and consists of twelve graduated rectrices. That of the Apostlebird, at 153 mm, is relatively longer than that of the larger White-winged Chough, at 205 mm.

*Both struthideids live in groups which travel, feed and roost together. A group of **White-winged Choughs** may forage over a home range of 10 km^2. Encounters between groups are infrequent, but when they occur, the birds threaten and display at each other, giving loud piping calls. In the "Wing-wave Tail-wag" display, the bird spreads its wings, making the white patches conspicuous, and fans its tail, moving both tail and wings up and down about once per second. At the same time, the conjunctiva of the eye becomes engorged. Displays do not last long, and groups may then feed in sight of each other.*

[*Corcorax melanoramphos melanoramphos*, Hattah-Kulkyne National Park, Victoria, Australia.
Photo: Rob Drummond/ Lochman Transparencies]

Ringing studies have shown that social groups of struthideids are formed largely by young birds remaining within the family for several years after they have become independent foragers. Both species are sedentary, with a core area of about 20 ha which they defend against other groups while breeding, and a much larger home range once the young are fledged. ***Apostlebird*** *home ranges extend to 3–4 km², and groups vary from three to 19 individuals. Groups break up at the death of the senior male or female. The remaining breeding bird, accompanied by immatures of less than four years, will join a lone bird of the opposite sex to form a new group. Individuals or coalitions from different groups may also come together to form a new group.*

[*Struthidea cinerea cinerea*, Hattah-Kulkyne National Park, Victoria, Australia. Photo: Dean Ingwersen]

In contrast to the features revealing similarities between the two members of the family, the bills of the two species are very different, reflecting differences in the mode of feeding. The White-winged Chough's bill is long, 49 mm, slender and decurved, with a pointed tip, whereas the Apostlebird has a short, deep bill 26 mm in length and resembling that of a finch (Fringillidae).

Although the Struthideidae share many skeletal features with other corvoids, they have several characteristics of the skull that are distinctive. For example, *Corcorax*, the White-winged Chough, has a weakly ossified upper mandible with the naris extensively aperturate and the nasal bars narrow, and there is a large nasal vestibule as the maxillo-palatine processes are long and thin and extend over the vomer, which is dorsoventrally compressed. The ectethmoid plate is fused laterally to the frontal, and the temporal fossa is very broad and shallow, and with its processes greatly reduced. In addition, *Corcorax*, as it reaches adulthood, acquires a sclerotic ring around the outer edge of the iris; when the bird is excited, or when it is in an aggressive mood, this ring becomes bright red as blood flows into it. The Apostlebird, *Struthidea*, likewise has a sclerotic ring, but in this case it is greatly reduced. It differs further from *Corcorax* in having, among other characteristics, a much more heavily ossified skull, with a more cylindrical vomer bordered by thickly crested maxillo-palatine processes, and a foreshortened palatal cavity with a broader palatine shelf.

Adult White-winged Choughs have an entirely black plumage apart from a white wingpanel across all ten primaries. This panel, the size of a tennis-ball, is visible only in flight. The dark plumage appears matt black, except for a slight bluish-green sheen on less worn feathers on the head, the tip of the tail and the wing. The entire plumage becomes browner with wear. The bill, legs and feet are blackish, and the inside of the mouth is dark grey. The eye colour of White-winged Choughs changes with age, until the fifth year is reached. From observations of individuals of known age that were recaught and photographed, I. Rowley determined an age scale based on the colour of the iris at the middle of each year. Thus, in the first year the iris is entirely brown; in the second year it is brown with an orange outer ring, being more brown than orange; the third year is indicated by an orange iris with a brown inner ring, the iris being more orange than it is brown; fourth-year individuals have an orange iris with brown flecks in a yellow inner ring; and in the fifth year and subsequently the iris is orange and red. Juvenile White-winged Choughs exhibit two rows of buff supraorbital down on the head, these persisting for the first 65 days of the bird's life; after that, the young are indistinguishable in the field from other choughs, except for the colour of the eyes.

Apostlebirds are predominantly grey, with paler tips on the feathers of the head and neck and some streaking over the rest of the body. The wings are brown, with paler fringes on most of the feathers, and the dark tail has a greenish gloss. The bill, gape, legs and feet are blackish. Juveniles appear similar to adults, but the feathers of the head and body are softer, with a looser texture, and the streaking is less marked. As with the White-winged Chough, eye colour changes with age, and G. Chapman showed that for the Apostlebird the main development takes three years: for the first year the iris is brown; in the second year it is grey; and in the third year a thin pearly outer ring develops. This outer ring becomes larger as the individual ages further. When an Apostlebird is excited, the iris becomes reddish-brown.

Adult White-winged Choughs have a complete post-breeding moult, which takes place from late spring to mid-autumn. Juveniles of this species replace their body feathers and wing-coverts in a partial moult about two months after fledging; the resulting immature plumage is less glossy and slightly browner than that of adults. At about one year of age, at the time of the adult post-breeding moult, immatures moult into the adult plumage, and are then distinguished from the adults only by eye colour. Immatures do not achieve their full dimensions until they are three or four years old. Bone growth, as measured by tarsus length, is completed early, but the bill continues to grow for two years. After the first moult the new tail feathers are longer than those which they have replaced, but thereafter the length of the rectrices remains constant. The primaries do not reach their maximum size until the bird is in its fourth year, and the body mass does not stabilize until it reaches adulthood, at more than four years of age.

The Apostlebird undergoes a complete post-breeding moult over a period of about four months at some time between late spring and early autumn. The primaries and the tail are moulted

White-winged Choughs *rest and roost together, generally in the canopy of a large tree, perching side by side and facing into the wind. As well as preening themselves, both White-winged Choughs and Apostlebirds* (Struthidea cinerea) *preen each other, especially those parts of the head, neck and underwing that are hard for the individual to reach on its own body. This social preening, or allopreening, is an important part of the group's social behaviour. On some evenings White-winged Choughs will dust-bathe, using the bill to collect fine dust and deposit it at the bases of the body feathers. All members of the group dust together, becoming very excited.*

[*Corcorax melanoramphos melanoramphos*, Stanthorpe, Queensland, Australia.
Photo: Graeme Chapman]

outwards. Young of this species fledge in a juvenile plumage, which is replaced by an adult-like immature plumage some months after fledging. Only the eye colour distinguishes them from adults.

Habitat

The two species of the family Struthideidae are birds of relatively open habitats. White-winged Choughs live in areas of eucalypt (*Eucalyptus*) woodland or dry eucalypt forests with a sparse understorey of shrubs or grass. Most of this species' range lies within temperate, subtropical and semi-arid areas, reaching the tropics in the north and the arid zone in the western and south-western limits. The nominate race of the White-winged Chough is often found in plantations of exotic pines (*Pinus*), in well-wooded farmland and in suburban areas with well-established parks and large gardens, as well as in uncleared forest and woodland.

Apostlebirds are found only west of the mountain ranges of the east coast, from temperate to tropical regions, where they extend farther into the arid areas. They occur in a variety of habitats, including arid acacia (*Acacia*) woodlands and shrublands, and semi-arid cypress-pine (*Callitris*) or eucalypt woodlands.

Both members of the family are tolerant of some habitat modification. They can be found in parks, in camping areas and on the modified fringes of towns, although they generally do not enter smaller suburban gardens.

General Habits

One of the striking features of the Struthideidae is the fact that both species live in groups and breed co-operatively. They travel around, feed and roost together in small parties. In Rowley's study of White-winged Choughs near Canberra, in the south-east of the species' range, groups consisted of 2–14 individuals, with a mean of six, although groups of up to 20 have been recorded. In two studies of Apostlebirds in similar habitats in mid-western New South Wales, groups were found to contain, respectively, 3–19 individuals, with a mean of nine, and 3–17 individuals, with a mean of 7·6. Ringing studies of both species reveal that the social groups are formed largely through the retention of progeny within the family for several years after they have become independent foragers, and even after they reach sexual maturity. In the breeding season, these additional birds assist in nest-building, incubation, brooding, and the feeding of nestlings and fledglings. With both species, groups may include more than one adult of each sex, although, in most cases, only one pair breeds. The studies made by R. G. Heinsohn showed that it takes four years for individual White-winged Choughs to become efficient enough at foraging to have the spare capacity to feed young.

Groups break up at the death of the senior male or female. When this happens, the remaining breeder, accompanied by immatures less than 4 years old and of either sex, then join a lone mature adult of the opposite sex to form a new group. In the case of Apostlebirds, groups may be created also by the amalgamation of individuals or coalitions from different groups. A phenomenon noted for both species was that, on rare occasions, dispersing individuals formed simple pairs.

Both members of the family are sedentary, remaining resident in the same area from year to year. Each group maintains a territory of approximately 20 ha, which it defends against the members of other groups during the breeding season. Once the young are fledged and mobile, the group is less restricted and may forage over a much larger home range, extending to about 10 km² for White-winged Choughs and 3–4 km² for Apostlebirds; a group's foraging range may overlap with those of other groups.

Several groups may accumulate into a large flock, sometimes of up to 100 individuals, at an especially good food source, such as an oat stubble in the case of the White-winged Chough. Within such flocks the constituent groups maintain their identity and, if disturbed, they fly off as separate groups. Local movements within the home-range areas are probably influenced by the availability of food sources and the occurrence of water, the latter being necessary for the building of a mud nest (see Breeding), as well as for drinking. In the heat of summer, several groups of Apostlebirds may congregate close to a permanent water supply. Sometimes the birds drink twice in a day.

White-winged Choughs are weak fliers. Indeed, they resort to the air only for travelling and for escape. They forage on foot, covering 5–6 km in a day. They drink at least once in the day, flying to water, but approaching the water warily on foot; one

individual always remains alert, with the head raised, acting as a sentry. On some evenings White-winged Choughs will indulge in dust-bathing, for which they insert the bill into narrow ditches and extract a billful of fine dust, which they deposit at the bases of their body feathers. All members of the group dust together, becoming very excited in the process. White-winged Choughs also roost together, generally in the canopy of a large tree, where they perch side by side and facing into the wind.

Similarly, Apostlebirds spend most of their active time on the ground, foraging in noisy groups. As they walk or run, the long tail sways from side to side; they also hop, the tail then flicking up and down. They travel longer distances to or from cover or a perch by flying with active wingbeats interspersed with gliding. Apostlebirds have not been reported as dust-bathing, but a smell of ants is common to many captured individuals of this species, and behaviour suggestive of anting has been observed. Apostlebirds are very cautious when going to roost, usually not settling until after dark, when they perch together in a dense shrub, side by side, usually in bodily contact with one another. During the hot part of the day they often rest in a huddle formation, pressed tightly against one another.

As well as preening themselves during periods of rest, in the middle of the day or before going to roost, both White-winged Choughs and Apostlebirds preen each other, especially in those parts of the head, neck and underwing which are hard for the individual to reach on its own body. This social preening, or allopreening, is an important part of the group's social behaviour.

Encounters between groups of White-winged Choughs over their large, overlapping foraging ranges are infrequent. When they do occur, however, the two groups threaten and display at each other and give loud piping whistle calls. In the full display, named the "Wing-wave Tail-wag" (WWTW) by Rowley, the bird partly spreads its wings and fans the tail, moving both up and down about once per second; the white wing patches are then highly conspicuous. At the same time, the conjunctiva of the eye, the membrane covering the outer surface of the cornea, becomes engorged and the two protruberant scarlet eyes enhance the threat. When two groups first meet, the two primary males may advance towards each other and perform an early stage of this threat display, with the head held lowered, the tail raised and partly fanned, and the eyes engorged. Later, the whole group may face the intruders, giving the full display accompanied by very noisy piping whistles. Displays do not persist for long, and the opponents will often then feed within sight of each other. Groups which approach one another but do not quite meet may enter into a battle only of sound, consisting of loud piping whistles.

So important to a group's reproductive success is the presence of helpers that groups may even kidnap recent fledglings from another group. Heinsohn, who observed this phenomenon during his detailed studies of White-winged Choughs, described the way in which recently fledged, highly dependent young, in the course of aggressive display battles between groups, transferred from one group to the opposing one during the encounter. The kidnapped young were enticed away from their own group and herded away by the marauders, this even before the young were able to fly. Some of the kidnapped young returned to their own group within a few days. Others, however, remained with their captors, and were later watched as they helped to feed the unrelated young in their new group.

The WWTW display has been recorded in many other contexts. If an incubating adult was slow to come off the nest when a relieving individual arrived, the latter would embark on a WWTW display that provoked the sitter to rise from the eggs and respond. As soon as it did so, the relieving individual poked its head under the sitter's body and replaced it on the nest. The display can be given by an adult to an unsated youngster after it had been fed, or to an individual rejoining a group after having lagged behind. The Wing-wave Tail-wag is also incorporated into a display apparently given only when the group is attacked by the very aggressive Australian Magpie (*Cracticus tibicen*). Australian Magpies hold group territories of about 4 ha, which they defend throughout the year. In the course of a day's foraging, a group of White-winged Choughs is likely to infringe upon many magpie territories, where it is subjected to vigorous attack. Choughs are heavier than Australian Magpies, but they are also slower, less agile fliers, and a single chough is no match for a magpie, whose main form of attack is a repeated rapid swooping on its victim. Chough groups employ a method of defence that Rowley named the "plum-pudding" display. In this, the members of a group on which the magpies are swooping run together and form a large clump; they then face in the direction of the attack and perform the Wing-wave Tail-wag display, which increases their apparent

Apostlebirds *spend most of their active time on the ground, foraging in noisy groups. This group-living is indeed the origin of their vernacular name. Outside the breeding season, at a particularly good food source, several groups may accumulate into a large flock of up to 100 individuals. Within such a flock the groups maintain their identity, and fly off separately if the flock is disturbed. Several groups of Apostlebirds may also congregate close to a permanent water supply. Encounters between groups tend to provoke a threat display, with arched neck, spread tail, and spread and lowered wings. When Apostlebirds walk or run, the long tail sways from side to side.*

[*Struthidea cinerea cinerea*, Sturt National Park, New South Wales, Australia. Photo: Dave Watts/ Lochman Transparencies]

size and shows off their white wing patches and engorged red eyes, while at the same time they call loudly. Magpies do not press home an attack against such a large and noisy clump of choughs, whereas they will easily drive a lone individual out of their territory. So far as is known, this display is not directed at any species other than the Australian Magpie.

Observed encounters between groups of Apostlebirds have usually involved calls and threats, which were enough to repel an encroaching neighbouring group. Sometimes these encounters end in fighting, with pecking and claw-grappling by one or more birds of each group. In the threat display, the Apostlebird arches its neck, lowers and spreads its wings and spreads its tail, while holding the back feathers erect and other body feathers fluffed. The threatening individual often runs at its opponent, making harsh "kreech" calls. Threats can be directed at intruders or at other members of the group, as by a dominant individual towards a subordinate one. In less intensive threats, the feathers are fluffed and the tail is slightly fanned. Potential predators, such as birds of prey and the large lizards known as goannas (*Varanus*), are mobbed by the whole group, with threats and aggressive "kreech" and "chee-ow" calls. If the predator is in a tree, the Apostlebirds surround it while calling and swooping, pecking and clawing at the threat.

Various types of behaviour exhibited by White-winged Choughs and Apostlebirds have been interpreted as being play, generally between first-year birds and adults. They include play-fighting, tug-of-war, chasing, and the manipulating of small branches, flowers and stones.

Voice

Neither of the struthideids has what would be considered a song in the usual ornithological sense of the word. Nevertheless, both species are vocal, this being particularly true of the Apostlebird.

The most characteristic vocalization of the White-winged Chough is a clear piping whistle, usually descending in pitch and ventriloquial in character. The calling individual sounds as if it is either close to or far from the human observer, depending on the position of the bird's head and bill. There are shorter and softer variations of this call, and a variety of harsher churring calls is given in threat, while foraging or during the change-over of incubating adults. When captured, White-winged Choughs emit an ear-piercing shriek when they are handled by humans.

Apostlebirds are highly vocal, having a great variety of calls based on "kreech", "chee-ow" or "churr" sounds, all raucous and harsh. This species is rarely silent, chattering noisily in most circumstances.

Food and Feeding

Both White-winged Choughs and Apostlebirds forage predominantly on the ground. A survey of the diets of Australian bird species, undertaken by R. D. Barker and W. J. M. Vestjens, revealed that the two struthideid species consume a wide range of insects and seeds.

The White-winged Chough uses its bill to rake through leaf litter and turn over branches, followed by probing for insects. It also digs in soil and under tussocks and cowpats. The individuals in a group forage 1–2 m apart from one another, and in this way the group efficiently covers a large area. This species may also take advantage of other food, and it has been recorded as probing in the mud of a creekbed for freshwater mussels (of the family Hyriidae), which it prised open with the bill or smashed against a rock. Apostlebirds likewise forage as a group, the birds digging in the ground, turning over litter, and picking up seeds. They also extract seeds from the cones of the native cypress-pine, and they forage in trees, taking insects from under bark and removing eggs from the nests of other birds. During a plague of house mice (*Mus musculus*), J. N. Hobbs watched both White-winged Choughs and Apostlebirds as they chased mice from under grass tussocks in open paddocks, grabbed them by the neck, and beat the small mammals against the ground until they could be consumed.

The detailed studies of White-winged Choughs and Apostlebirds suggest that the mode of feeding employed by these two species involves a high degree of skill and is time-consum-

Struthideids consume a wide range of insects and seeds, the former predominating in summer and the latter in winter. The ***White-winged Chough*** *uses its bill to rake through leaf litter and turn over small branches, before probing for insects. It also digs in soil, and under tussocks and cowpats. Struthideids will also take small mammals. During a plague of house mice* (Mus musculus), *both species were seen to chase mice from under grass tussocks, grab them by the neck, and beat them against the ground before swallowing them. The White-winged Chough has also been recorded probing in the mud of a creekbed for freshwater mussels, which it prised open with the bill, or smashed against a rock.*

ing. Juveniles are slow to learn the required techniques, and also to make the seasonal changes from a predominantly insect diet in the summer to a diet mostly of seeds in the winter.

Breeding

Groups occupy breeding territories in more or less the same places each year. Two conspicuous features of the breeding behaviour of the White-winged Chough and the Apostlebird are that both species construct sturdy conspicuous mud nests and both breed co-operatively. Co-operative breeding is characterized by the presence of both breeding adults and non-breeding, mature individuals in a social group. The non-breeders are usually termed "helpers", and in the case of the Struthideidae they contribute by assisting in the tasks of nest-building, the feeding of nestlings and caring for fledglings, as well as attacking or distracting predators and in general territory defence. Within such groups, the patterns of mating are often unknown, but both the White-winged Chough and the Apostlebird have been the subject of detailed studies in respect of their social and mating systems. In the case of White-winged Choughs, the studies by Heinsohn and others have shown that, in groups that had been stable for many years, breeding was by a single monogamous pair, all eggs being laid by the female of this pair and fertilized by the male. These groups did not receive immigrants, and their members were generally closely related to one another, many or all being offspring of the breeding pair. After high mortality during a period of severe drought had disrupted many groups, new groups formed through the amalgamation of individuals and coalitions of relatives. In these White-winged Chough groups of less closely related individuals, it was found that more than one male or more than one female bred in various forms of polygamy. Mating patterns among Apostlebirds are probably similar to those of White-winged Choughs.

With both species, there are occasional records of clutches consisting of 7–8 eggs, rather than the usual 3–5 eggs, suggesting that more than one female lays eggs in the group's single nest. In Rowley's study of White-winged Choughs, it was estimated that about 15% of clutches were the result of contributions by two females.

Information on the breeding seasons of the Struthideidae is derived largely from observations made in temperate regions. The details from such areas indicate that egg-laying occurs in the austral spring and early summer, mainly from September to December, the struthideids having a capacity to nest also after unseasonal rains at other times, especially in drier areas. Among more northerly populations, laying may begin as early as July. If the first nest fails for any reason, White-winged Choughs will lay a replacement clutch, and some larger groups may nest again later in the season, in December, after having successfully reared one brood. In the study of Apostlebirds by I. A. Woxvold in central New South Wales, it was found that most groups attempted two broods.

White-winged Choughs usually build their nests on horizontal, often forked branches of tall trees, mainly eucalypts, at heights ranging from 2·4 m to 20 m, with a mean of about 10 m. Apostlebirds, too, prefer horizontal branches, generally in eucalypts, casuarinas (*Casuarina*) or acacia trees, but they nest lower down than White-winged Choughs, 3–12 m above the ground, the average nest height being about 8 m. Most of the nests of both species that have been found have been sited not far from a source of mud.

The constructing of the mud nest is not a quick process, and the two species use similar, characteristic methods. All group-members join in the work, although yearlings are conspicuously inept. The nest has to be built in several stages: first, a saddle is fastened to the chosen branch and allowed to dry; a platform is then built on this; and subsequently, from that platform, the walls of the bowl are raised in several sessions of work. During this final stage, both White-winged Choughs and Apostlebirds gather a piece of fibre or grass stem of suitable length, 4–6 cm, and take this to a source of mud, where they "dabble" it until it is liberally impregnated. The builder then flies, carrying this load, to the nest, places the material on the rim, and uses the bill to "trowel" it into position. Once the load is firmly settled, the bird places its bill sideways to the rim and opens and closes the mandibles rapidly, apparently achieving an effect similar to that of the vibrator of a

The brief display that leads to copulation in the ***White-winged Chough*** *may be initiated by either sex. The bird fluffs its feathers, fans its wings and tail, and shivers its body. It may crouch, or lower its head. Its partner may repeat this display one or more times after which the male, still displaying, mounts and copulates, an act which lasts about two seconds. In the courtship display of the Apostlebird* (Struthidea cinerea), *one or both birds pick up food or a twig, and the two walk side by side, with feathers raised, quivering their bodies. Before copulation, the male spreads his wings and tail so that they touch the ground, and produces a hoarse whispering with the bill open. The female responds with a similar display, and the two stand and beat their wings rapidly for about a minute.*

[*Corcorax melanoramphos melanoramphos*, Lara, Victoria, Australia. Photo: Peter Fuller]

concrete worker. A building session may last for an hour, but in this time the birds seldom raise the rim by more than 2 cm; this is because wet mud is unstable until it dries and hardens, which requires at least 24 hours depending on the weather conditions at the time. Completion of a new nest therefore takes several days, and can even take longer than the life of conveniently sited puddles. Even individual birds less than one year old, which can never before have seen a nest being built, attempt to assist; although they may try to carry mud to the nest, more often they accompany others and watch the proceedings. Once, a yearling White-winged Chough, in its excitement, caused the collapse of the new wall of a nest by inadvertently treading on it before the mud had set hard. Individuals in their second year build as keenly and as competently as adults.

Nest-building tends to be an opportunistic event following suitable rainfall, and the several stages may be interspersed with intervals of several weeks of inactivity. Building is not confined to the breeding season, although more is done then. Nests are frequently reused, but, since branches having a smooth bark are usually selected, old nests can become unstable as a result of the periodic bark-shedding action of the tree.

Breeding displays of the Struthideidae are rarely seen and little known, but they appear not to be elaborate. Either the male or the female White-winged Chough may initiate a brief display which leads to copulation. The bird fluffs its feathers, fans its wings and tail, or swings the tail from side to side, and shivers its body, and it may crouch or lower its head. The partner may repeat this display one or more times before the male, still displaying, copulates briefly, the last-mentioned action lasting for about two seconds.

During the nest-building period, Apostlebirds which are on the ground and collecting mud sometimes perform an excited display similar to the Wing-wave Tail-wag display of White-winged Choughs (see General Habits). A "Quivering" display by this species appears to function as a courtship and pre-copulatory display, usually initiated by the male. One or both sexes pick up food or a twig, and the two birds walk side by side, with feathers raised, while quivering the body. This display may be only brief, but after a longer parallel walk the two participants may fly to a tree and then fly out from it in a circular movements. Copulation by Apostlebirds is preceded by an intensive stationary Quivering display, during which the wings and tail are spread and touch the ground, while the bill is held open and a hoarse whispering sound is heard. A receptive female responds with a similar display, and the two then stand and beat their wings rapidly for about one minute, before the male mounts and copulates quickly.

The standard clutch of both species consists of three to five oval eggs. These are laid on successive days, and are incubated for 19–20 days by all members of the group. As already noted, there are occasional instances of more than one female laying in the one nest, resulting in an extra large clutch of up to ten eggs, with eggs laid at intervals of less than one day. White-winged Chough eggs are 40 × 30 mm in size, and have a creamy-white ground colour with a few dark brown and blackish blotches on top of grey or lavender ones. Apostlebird eggs are smaller, 30 × 22 mm, and are bluish-white with a few blotches of brown, grey and lavender. Although all the eggs in extra-large clutches sometimes hatch, only rarely do more than four chicks survive to leave the nest. Nestlings tend to hatch asynchronously, and they are brooded and fed by all group-members.

Young White-winged Choughs leave the nest 24–30 days after hatching and young Apostlebirds 18–20 days after the hatch, in both cases before they are capable of flying. They flutter down to the ground, where they are able to run and seek cover; they are completely dependent on the other group-members to feed them for at least four weeks after they have left the nest. Fledgling White-winged Choughs then slowly attain independence over the next 6–7 months, as they gradually learn to forage for themselves. They do not, however, reach sexual maturity and adult body weight until 4–5 years of age. The studies by Heinsohn and others suggest that this is partly because of the long time that they take in learning to forage efficiently. In the first four years of life, young birds that work hard at incubation and brood-feeding at the nest lose weight over this period, whereas adults do not. Juvenile White-winged Choughs do not disperse from the natal group but, instead, remain there until they reach sexual maturity and beyond, assisting with breeding attempts but not themselves breeding. They stay in the group as helpers until a breeding position becomes available, or until some catastrophic event leads to group disintegration and re-formation. Apostlebird fledglings are fed by other group-members for at least ten weeks. As with White-winged Choughs, they do not disperse from their natal group but remain as helpers, even after they reach sexual maturity, which probably occurs at two years of age.

For White-winged Choughs, the main cause of nest failure is chick starvation, particularly among small groups. Many chicks

*Nests of the **White-winged Chough** are built on horizontal branches of tall trees, at heights of 2·4–20 m. All group members join in the work. First, a saddle is fastened to the branch and allowed to dry. A platform is built on the saddle, and finally, the walls of the bowl-shaped nest are raised on the platform. During this final stage, a bird carries a piece of fibre or grass stem to a muddy patch, where it "dabbles" it until it is liberally impregnated. The builder then flies back to the nest, places the material on the rim, and uses the bill to "trowel" it into position. Construction is done in sessions over several days, or longer if the sources of mud dry up.*

Co-operative breeding in ***Apostlebirds*** *involves one breeding pair, and up to 17 helpers. Yearling helpers can be conspicuously inept at nest-building, but by their second year, immature birds build as keenly and competently as their parents. Clutches are usually of 3–5 eggs, laid on successive days. Occasional larger clutches are the product of more than one female. Although all the eggs in large clutches may hatch, only rarely do more than four chicks survive to leave the nest. All group-members incubate the eggs, although most work is done by the primary female. Eggs hatch asynchronously after 19–20 days.*

[*Struthidea cinerea cinerea*, Cunnamulla, Queensland, Australia. Photo: David Stowe]

die at nests from which one or more nestlings fledge, and there are data to indicate that heavier nestlings receive the most food, suggesting that, when food is scarce, adults feed the most viable young. Some nests or eggs are destroyed by neighbouring White-winged Chough groups, and nests are occasionally dislodged by strong winds. A major nest predator is the Pied Currawong (*Strepera graculina*), and other recorded predators are the Australian Raven (*Corvus coronoides*), the Australian Magpie, and a large monitor lizard known as the lace goanna (*Varanus varius*). Brood parasitism of White-winged Choughs by the Channel-billed Cuckoo (*Scythrops novaehollandiae*) has been recorded, but it was not found during two long-term studies carried out near Canberra, in Australian Capital Territory.

Starvation is a significant cause of mortality also of nestling Apostlebirds, about 23% of broods losing at least one nestling, usually the smallest of the brood. Nest predators and brood parasitism of Apostlebirds are not well known; raven and crow species (*Corvus*), the Grey Butcherbird (*Cracticus torquatus*) and

The nestling period of the ***White-winged Chough*** *is 24–30 days. The chicks are brooded and fed by all members of the group. However, most care of the young is offered by the older group-members, as individuals in their first four years are less efficient foragers, and usually struggle to feed themselves. Breeding success is linked to group size: large groups are the most productive; most nest failures involve smaller groups, and are due to the starvation of nestlings. There are indications that when food is scarce, adults feed the heaviest, most viable young.*

[*Corcorax melanoramphos melanoramphos*, Bugaldie, near Coonabarabran, New South Wales, Australia. Photo: W. R. Taylor/Ardea]

the Australasian Goshawk (*Accipiter fasciatus*) are recorded as predators of this species.

In Rowley's studies of White-winged Choughs near Canberra, 65% of nests produced at least one fledgling, but over 67% of nestlings died in the nest, giving an average of 1·1 fledglings per nest. Similarly, in the studies by Heinsohn and others in Canberra, 77% of nests fledged at least one young, but nearly 50% of chicks did not fledge. Nesting success increases with group size; in none of the studies of White-winged Choughs has a successful nest attended by only two birds been recorded, and groups of three individuals are seldom successful. Among groups of 4–8 individuals, however, about 75% of nests produce fledged young, and almost all nests of larger groups succeed. Most groups of more than four individuals that fail at their first nesting attempt of the season succeed at the second attempt, so that most groups containing more than three individuals produce at least one fledgling per year. As already mentioned, a group of White-winged Choughs will occasionally renest after having successfully raised a first brood; these tend to be large groups, and some of the members take over the care of the young while the others start on the second clutch.

In Woxvold's study of Apostlebirds, about 80% of nests succeeded in producing at least one young, with an average of 2·6 fledglings per nest. More broods were initiated than was the case with White-winged Choughs, and over the course of the breeding season groups produced an average of 4·2 fledglings, of which about 62% survived to the next breeding season. Only one group consisting of just two individuals attempted to breed, but it was unsuccessful, and groups of three did not produce more than one fledgling. As with the White-winged Chough, productivity of Apostlebirds increases with group size, the greatest improvement occurring over the range of 3–5 individuals.

For both White-winged Choughs and Apostlebirds, the importance of a large group for improved nest success lies in its capacity to provide adequate food for nestlings and more effective defence of nests. In large groups, the amount of help increases with the age of the helper, and all adults contribute more or less equally. In smaller groups, young helpers work harder. Nestlings within larger groups are fed at a higher rate, and large groups are also much more successful at defending the nest against intruders, whether these are other White-winged Chough groups or predators. Moreover, young birds in larger groups survive better in their first month after fledging, and in addition have a better rate of survival to one year and beyond. The main mortality occurs in the first year of life, and the first winter is a particularly difficult time, only about 50% of fledgling White-winged Choughs and 62% of Apostlebirds surviving to reach one year of age. The survival of adults is high. Many of the adult White-winged Choughs in Rowley's study were present throughout the seven years of the study, those that were adult at the start reaching at least 12 years of age. In Woxvold's study of Apostlebirds, the annual survival rate of adults was approximately 85%.

The two members of Struthideidae appear to be among the few bird species that are obligate co-operative breeders, as pairs on their own appear unable to rear any young. Members of White-winged Chough and Apostlebird groups other than the breeding pair are very much involved at most stages of the reproductive cycle, including the brooding and feeding of nestlings and the tending of fledglings. Heinsohn has suggested that, ultimately, it is the birds' foraging style which has shaped their social behaviour. Foraging is a slowly learnt skill, and food is collected slowly over a large area (see Food and Feeding), so that the breeding pair, in order to succeed in rearing young, needs the assistance that the helpers provide. Even the task of nurturing fledglings to sexual maturity requires the help and protection provided by the group. Because there is so little dispersal, helpers are usually assisting in the rearing of close relatives of themselves; even though the helpers are not rearing their own offspring, they are at least deriving an indirect benefit from helping to rear close kin. The destruction of nests belonging to nearby White-winged Chough groups that are not large enough to repel intruders is regarded as a way of reducing competition for food close to the intruders' own nest, and the kidnapping of fledglings from one group by another (see General Habits) increases the kidnappers' group size to levels at which reproductive success is almost assured.

Movements

White-winged Choughs and Apostlebirds are sedentary, and the Atlas of Australian Birds project shows no evidence of broad-

If they avoid starvation, nest predators, and attacks by other groups of conspecifics, young ***White-winged Choughs*** *and Apostlebirds* (Struthidea cinerea) *leave the nest before they are capable of flying. They flutter down to the ground, where they are able to run and seek cover. They remain completely dependent on group-members to feed them for at least a month; indeed, fledgling Apostlebirds are fed by group-members for at least ten weeks. Young White-winged Choughs gradually attain independence over the following six to seven months. Young birds in larger groups survive better in their first month after leaving the nest, and have a better rate of survival to one year and beyond.*

[*Corcorax melanoramphos melanoramphos*, Stanthorpe, Queensland, Australia.
Photo: Graeme Chapman]

Only about 62% of ***Apostlebirds*** *survive to reach one year of age, and the first winter is a particularly difficult time. Young birds take a long time to learn their foraging skills, which goes some way to explaining their co-operative breeding habits. The young stay in the group as helpers until a breeding position becomes available, or until the group disintegrates. The survival rate for adults is high, at 85% for Apostlebirds, while many White-winged Choughs* (Corcorax melanoramphos) *reach at least twelve years of age.*

[*Struthidea cinerea cinerea*, Murray-Sunset National Park, Victoria, Australia. Photo: Peter Fuller]

scale movement by either species. The co-operative breeding groups occupy stable territories during the breeding season, and do not move outside them until their fledglings are able to travel with the group. The group then moves over a much larger home range, of up to 1000 ha in the case of White-winged Choughs and at least 100 ha for Apostlebirds.

Movements in the non-breeding season may involve a shift in habitat for the White-winged Chough, from open forest into pasture and cereal stubble. Non-breeding birds may form large aggregations at an abundant source of food, but the group structure is retained. At the start of the next breeding season, the groups usually return to the same breeding territories that they had occupied in the previous year. Apostlebird groups sometimes form large assemblies close to permanent water or good feeding habitat, such as cereal stubble. At the edge of their range in arid and semi-arid areas, and when seasonal conditions are favourable, these movements of Apostlebirds outside the breeding season can lead to a gradual extension of the species' range.

Relationship with Man

Despite widespread clearing of their preferred habitats, both White-winged Choughs and Apostlebirds have adapted to the changes and now co-exist successfully with human habitation. White-winged Choughs were once considered a pest in wheat crops, where they were said to pull up shooting grain, but the large scale of current wheat farms has eliminated this problem. In rural areas, both species are attracted to food and water sources around farm and station homesteads, such as stockyards and fowlyards, and to picnic areas in national parks or at the roadside. Here, both species can become very tame, and groups will approach a picnic party of people in expectation of food scraps.

In the more densely inhabited agricultural areas closer to the east coast, White-winged Choughs have adapted to life in the parks and gardens of country towns. A population resident in the Botanic Gardens in Canberra, Australia's capital city, has been the subject of a long-running study by Heinsohn and others.

Status and Conservation

Neither of the species of Struthideidae is globally threatened. Nor are they included among the species listed as "Threatened" by the Australian Environmental Protection and Biodiversity Conservation Act of 1999. Both species occur over a wide area and, although a significant part of their ranges has been cleared for agriculture, enough suitable habitat remains, both within and outside reserves, for the two species to be considered secure overall. Nevertheless, some local populations have suffered significant decline.

The South Australian subspecies *whiteae* of the White-winged Chough has a restricted range on the Eyre Peninsula, and is considered "Rare" by the South Australian Department of Environment and Heritage, largely on account of habitat loss. The other subspecies, the nominate race, has a much larger range, within which it often found in plantations of exotic pines, in timbered farmland, and in parks and large gardens with trees in suburban areas.

The Apostlebird is listed as "Threatened" in Victoria. A population which lived in south-west Victoria and adjacent south-east South Australia has become extinct, but Apostlebirds still occur in a very limited area in the north and north-west of Victoria, where much of their preferred eucalypt woodland habitat near the Murray River has been cleared for agriculture. A survey of historical records by I. A. W. McAllan and R. O'Brien, however, suggests that these latter birds are more recent arrivals, the result of range expansion of the New South Wales population. The range of the Apostlebird, while contracting in some areas owing to habitat loss, is expanding farther westwards in New South Wales and into South Australia, and the species is spreading to the east and west of the northern parts of its range in Queensland.

Genus *CORCORAX* Lesson, 1831

1. White-winged Chough

Corcorax melanoramphos

French: Corbicrave leucoptère **German**: Drosselkrähe **Spanish**: Corvino Negro
Other common names: Apostle-bird(!), Black Jay/Magpie

Taxonomy. *Coracia melanoramphos* Vieillot, 1817, New South Wales, Australia.
Family treatment much disputed over the years, and present species has variously been placed in Corvidae, Grallinidae or a monospecific Corcoracidae; close relationship with *Struthidea* generally agreed. Geographical variation minimal, and species formerly treated as monotypic. Races intergrade in SE South Australia (in and just E of Mt Lofty Ranges). Proposed race *subniger* (from Ringwood, in Victoria) synonymized with nominate. Species name often misspelt "*melanorhamphos*". Two subspecies currently recognized.
Subspecies and Distribution.
C. m. melanoramphos (Vieillot, 1817) – E Australia from E half of Queensland (S from region of Clarke Range) S to New South Wales (except NW), Victoria (mainly N of Great Dividing Range) and SE South Australia (Mt Lofty Ranges).
C. m. whiteae Mathews, 1912 – S & SE South Australia (Eyre Peninsula and Mt Lofty Ranges).

Descriptive notes. 44–50 cm; 280–425 g. Nominate race has plumage entirely black, except for white wingpanel (c. 8 cm; visible only in flight) across most of primaries; some greenish gloss on new head feathers; old plumage with brownish tinge; iris red to orange, sclerotic ring sometimes engorded, turning bright red, in moments of excitement or aggression; bill and legs dark grey to blackish. Distinguished from superficially similar ravens and crows (*Corvus*) by long, slender downcurved bill, long tail, relatively small head, white in wing, red (not white or black) eye colour. Sexes similar. Juvenile differs from adult only in having brown eyes; eye colour changes with age, acquiring more orange over four years, and as in adult in fifth year. Race *whiteae* is very similar in appearance to nominate but smaller, with slightly shorter and thinner bill, perhaps also with faint pinkish wash in wingpanel. Voice. Clear piping whistle, usually descending in pitch and ventriloquial; also a variety of harsher calls.
Habitat. Open habitats, mainly eucalypt (*Eucalyptus*) woodlands and open forests in which canopy is not closed; found also in plantations of exotic pines (*Pinus*), in well-wooded farmland and in suburban areas with well-established parks and large gardens. Prefers sparse understorey with grass and few shrubs, and a thick layer of leaf litter, fallen bark and twigs. Also forages out over stubble of harvested crops.
Food and Feeding. Wide range of seeds and insects; insects predominate in summer, and seeds in winter. Also occasionally small mammals and bivalve molluscs. Forages mainly on ground, where it digs with the bill, turning over and raking through litter. Once, during a plague of house mice (*Mus musculus*), both this species and *Struthidea cinerea* seen to chase mice from under grass tussocks, grab them by the neck, and beat the victims against ground before consuming them. Has been recorded also as probing in mud of a creekbed for freshwater mussels (of family Hyriidae), which it prised open with the bill or smashed against a rock. Forages in groups, members of which 1–2 m apart in a line; very few prey items in their path are overlooked. Young do not become skilled in all methods of food-finding for at least two years.
Breeding. Laying in Sept–Dec (in austral spring and early summer), but can breed after rain at other times in drier areas; sometimes two broods. Co-operative breeder in group consisting of generally one breeding pair and up to 18 helpers, latter largely offspring of main pair. Nest, built by all group-members, a large bowl constructed of mud, placed 2·4–20 m (mostly 8–10 m) above ground on horizontal branch or fork of tree, most commonly a eucalypt; built slowly, as each layer of mud has to dry before next layer added. Clutch usually 3–5 eggs, larger clutches the product of more than one female; incubation by all group-members, period 19–20 days; chicks brooded and fed by all members of group, nestling period 24–30 days; fledglings cared for by non-breeding helpers, allowing female to renest, most care of young by older group-members as individuals in first four years are less efficient foragers and struggle to feed themselves; young do not become independent until 6–7 months, and remain with group in subsequent years as helpers. Large groups most productive; most nest failures involve smaller groups, and due to starvation of nestlings; pairs without helpers always unsuccessful.
Movements. Sedentary, wandering over large home range of c. 1000 ha in non-breeding season, with stable territory in breeding season. Does not disperse from natal group unless a vacancy for a breeding male or female occurs in a nearby group.
Status and Conservation. Not globally threatened. Widespread, but never common; South Australian race *whiteae* rare. Rather sparsely distributed, as groups require large home range and, further, species has suffered from habitat clearance for agriculture. Main threats, in addition to habitat loss, are fire and also disruption of breeding by drought and increasing aridity, which prevent the building of mud nests. In addition to wildfires, man-made "fuel-reduction burns" remove understorey vegetation and the ground litter on which this species depends. Can co-exist with man in well-wooded farmland, in pine plantations and on fringes of country towns or suburban areas with extensive parks. Occurs in many national parks and other protected areas.

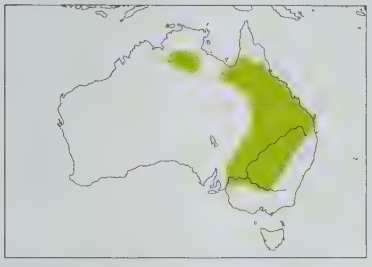
Genus *STRUTHIDEA* Gould, 1837



2. Apostlebird

Struthidea cinerea

French: Apôtre gris **German**: Gimpelhäher **Spanish**: Corvino Apóstol

Taxonomy. *Struthidea cinerea* Gould, 1837, interior of New South Wales, Australia.
Family treatment much disputed over the years, and present species has frequently been placed in Grallinidae or a monospecific Struthideidae; close relationship with *Corcorax* generally agreed. Races intergrade in NC Queensland. Isolated population in Northern Territory formerly thought to represent a distinct race from that in N Queensland, but now considered identical. Although name *swainsoni* predates *dalyi*, former regarded as invalid, as description and measurements of type specimen ambiguous and possibly based on intermediate specimen, and type locality (N Queensland) imprecise and could lie within zone of intergradation with nominate. Two subspecies recognized.

Subspecies and Distribution.
S. c. dalyi Mathews, 1923 – N Northern Territory (mainly S of Roper R) and N & NC Queensland, in N Australia.
S. c. cinerea Gould, 1837 – C & S Queensland, inland New South Wales, N Victoria (along Murray R) and E South Australia (mainly N of Murray R).

Descriptive notes. 29–33 cm; 110–155 g. Distinctive, with rather pointed feathers on head and neck giving shaggy appearance, and long dark tail; short, deep bill similar to that of a finch (Fringillidae). Nominate race has head and body grey, feathers with dark shaft streaks and paler edges, lores and ear-coverts blackish, breast paler grey; wing brown, tail black with greenish gloss; iris greyish with thin pearly outer ring, iris becomes reddish-brown in excitement; bill and legs blackish. Sexes similar. Juvenile is similar to adult, but feathers of head and body softer, with looser texture, and streaking less marked, iris brown. Race *dalyi* is slightly larger than nominate, has larger bill, is darker and more streaked above and paler grey ventrally. Voice. Very vocal. Range of generally harsh, scolding or squeaky calls, including "kreech" as a threat or warning, also "chee-ow" given to intruders or in territorial disputes and also in play-chases by juveniles.
Habitat. Open habitats, especially arid and semi-arid woodlands, or shrublands with scattered trees. Bold and tame around modified habitat: farms, camping and picnic grounds and country cemeteries.
Food and Feeding. Diet chiefly seeds and insects; also takes eggs from nests of other birds, and small mammals taken occasionally. Forages on the ground, and occasionally in low vegetation. Feeds on insects flushed from ground or from vegetation; also rakes through litter, and scratches with the bill around grasses or shrubs; extracts seeds from cones of native cypress-pine (*Callitris*), and takes insects from beneath bark. Uses bill to hammer at hard insects or seeds. Once, during a plague of house mice (*Mus musculus*), both this species and *Corcorax melanoramphos* seen to chase mice from under grass tussocks, grab them by the neck, and beat the victims against ground before consuming them. Forages as a group; in non-breeding season, aggregations of up to 100 individuals may form at water or where food is abundant.
Breeding. Laying in Aug–Feb (in austral spring–summer), but may breed in response to rain at other times in drier areas; often two broods. Co-operative breeder in group consisting of generally one breeding pair and up to 17 helpers, latter largely offspring of main pair. Nest, built by all group-members, a bowl of dried mud, reinforced with grass and twigs, placed 3–12 m (mostly 6–8 m) above ground on horizontal branch or fork of tree, especially casuarina (*Casuarina*) or eucalypt (*Eucalyptus*), and often acacia (*Acacia*); grass or twigs taken to source of mud, dipped in mud until coated, and then carried to nest, also mud alone added; nest built in stages, allowed to dry before new layer of material added. Clutch usually 3–5 eggs, occasional larger clutches the product of more than one female; incubation by all group-members, most of work done by primary female, incubation period 19–20 days; chicks fed by all members of group, nestling period 18–20 days; fledglings fed by group-members for c. 10 weeks; juveniles remain with group as helpers in later years. High proportion of nests successful, but many (especially those of smaller groups) suffer partial brood loss through starvation.
Movements. Sedentary; group territorial in breeding season, at other times wanders over larger home range (to up to 1 km from breeding territory). Does not disperse from natal group unless to fill vacancy for breeder (male or female) in nearby group.
Status and Conservation. Not globally threatened. Widespread, and locally fairly common. Range had expanded to N; decline in E & SE, where clearance for agriculture has destroyed woodland habitat. Main threats, in addition to habitat loss, are fire and the disruption of breeding by drought and increasing aridity, which prevent the building of mud nests. As well as wildfires, man-made "fuel-reduction burns" remove understorey vegetation and the ground litter on which the species depends. Able to co-exist with humans in well-wooded farmland and on fringes of country towns. Occurs in many national parks and other protected areas.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family ARTAMIDAE (WOODSWALLOWS)

- Small, fast-flying insectivorous passerines with long pointed wings, short tail and blue-grey bill; plumage mainly grey, brown, black and white.
- 12–21 cm.

- South and east Oriental Region, Australasia and south-west Pacific.
- Open forest and woodland, savanna and grassland.
- 1 genus, 11 species, 25 taxa.
- No species threatened; none extinct since 1600.

Systematics

Woodswallows form a very uniform family, with only one genus, *Artamus*, generally accepted. The first recorded specimen was brought from Manila, in the Philippines, to Paris, France, by M. Poivre, and was described by Linnaeus in 1771, in his *Mantissa Plantarum*, as a shrike, "*Lanius leucoryn*[*chus*]"; this specimen has since been lost. In 1801, J. Latham described a *Turdus sordidus* and a *Loxia cyanoptera* from Sydney, Australia, but these were, in fact, one and the same species, now known as the Dusky Woodswallow (*Artamus cyanopterus*). In 1816, L. J. P. Vieillot first used *Artamus* as a generic name for woodswallows; the word derives from the Greek *artamos*, meaning a butcher or a murderer, and, as the birds were still thought to be shrikes, the alternative English name was "swallow-shrike". The German common name, *Schwalbenstar*, which means literally "swallow-starling", refers to the pointed shape of the wing in flight, which resembles that of the Common Starling (*Sturnus vulgaris*).

The Artamidae were recognized as a monogeneric family in all classifications until the mid-1980s, when C. G. Sibley and J. E. Ahlquist undertook studies of DNA–DNA hybridization. These authors inferred, from analyses of their results, that the woodswallows fell within their greatly expanded family Corvidae, and their closest relatives seemed to be the Australian currawongs (*Strepera*), butcherbirds (*Cracticus*), previously grouped in the family Cracticidae or the family Streperidae. The Sibley and Ahlquist classification included the woodswallows, the currawongs, the Australian Magpie (*Cracticus tibicen*) and the butcherbirds in the tribe Artamini within the Corvidae. Subsequent taxonomic usage within Australia has been to recognize a family Artamidae that includes the members of the Artamini. R. Schodde and I. J. Mason showed that, apart from genetic similarity, the woodswallows share many distinctive features of skull morphology with *Strepera* and *Cracticus*.

Much of the nineteenth century was a time of taxonomic confusion, created to a large extent by collectors who referred their new material to museums or private collections in different parts of Europe. Communication was difficult and slow, as a consequence of which it was rare for similar species to be directly compared. Several different genera of woodswallows were created: *Artamus*, by Vieillot in April 1816, *Angroyan*, by J. K. W. Illiger in December 1816, *Leptopteryx*, by J. G. Wagler in 1827, *Ocypterus*, by R. Lesson in 1830, and *Cataphania*, by J. Gistel in 1848. These genera were used until R. B. Sharpe regularized the nomenclature in 1890, creating the family Artamidae with a single genus, *Artamus*.

In 1912, G. M. Mathews, at the height of his "splitting" frenzy, introduced a further four genera. These were *Campbellornis*, for the Masked Woodswallow (*Artamus personatus*) and the White-browed Woodswallow (*Artamus superciliosus*), *Austrartamus*, for the Black-faced Woodswallow (*Artamus cinereus*), *Pseudartamus*, for the Dusky Woodswallow, and *Micrartamus*, for the Little Woodswallow (*Artamus minor*). Two years later, Mathews resurrected Illiger's genus, replacing *Pseudartamus* with

Woodswallows form a very uniform family, with only one genus, Artamus, *generally accepted. All eleven species have a squat silhouette, a short tail and long pointed wings, short legs, a broad-based, conical bill, and a brush-like tongue. In nine species, the sexes are similar. The plumage is generally bicoloured, in combinations of white, brown, grey and black. In some species, like the* ***Ashy Woodswallow****, the contrast between darker head and wings and lighter underparts is relatively muted; in others, the contrast is much bolder. Throughout its range, which extends from the Indian Subcontinent eastwards to south-east China and South-east Asia, the Ashy Woodswallow is the only representative of the family.*

Angroyan, and subsequently describing a taxon as *Angroyan cyanopterus perthi*, but all of these innovations failed to find general acceptance. E. Stresemann, in 1913, reviewed the subspecies of the White-breasted Woodswallow (*Artamus leucorynchus*) and drew up a useful key for their separation. Four-and-a-half decades later, A. Keast reviewed the variation and movements of the six Australian woodswallows, commenting that the most mobile species exhibited little regional variation and that the sedentary Black-faced Woodswallow was the most variable. E. Mayr, who contributed the section on Artamidae in J. L. Peters's *Checklist of Birds of the World*, in 1962, listed ten species, of which five, namely the Ashy Woodswallow (*Artamus fuscus*), the Great Woodswallow (*Artamus maximus*), the White-backed Woodswallow (*Artamus insignis*), and the Masked and White-browed Woodswallows, currently remain as monotypic species; the Ivory-backed Woodswallow (*Artamus monachus*) was treated as a monotypic species by C. M. N. White and M. D. Bruce, in 1986, and the Little Woodswallow was considered by Schodde and Mason to consist of two subspecies. S. Eck disagreed with Mayr's listing of the Ivory-backed Woodswallow and the White-backed Woodswallow as separate species. He regarded the latter as being an allopatric subspecies of the Ivory-backed Woodswallow, despite the fact that the two have geographically discrete ranges between which the Great Woodswallow occurs. Eck also regarded the Fiji Woodswallow (*Artamus mentalis*) as a separate species, a treatment followed by H. E. Wolters, by Sibley and B. L. Monroe, and by D. Watling. The Fiji Woodswallow has often been treated as a subspecies of the White-breasted Woodswallow, but it differs from that in possessing a duskier back and crown, a characteristic throat pattern, a more extensively white rump, and white tips on the wing and tail.

In a thorough review of the family, published in 1977, R. D. Étchécopar and F. Hüe agreed with Mayr's listing, except that they regarded the subspecies *celebensis* of the White-breasted Woodswallow as synonymous with the race *albiventer*, as did White and Bruce in 1986. Most of the nine forms of the White-breasted Woodswallow are allopatric island populations that show a reluctance to fly across expanses of open water; until comprehensive DNA analyses are performed, decisions on the systematic status of these populations cannot be made with any degree of confidence. Although Linnaeus, in his original description, wrote the name of the species as "*leucoryn*", this truncated spelling has virtually never been used throughout the ornithological history of this taxon. The spelling "*leucorynchus*" has been widely used and now becomes the valid version on the basis of prevailing usage, as laid down by the International Code of Zoological Nomenclature.

Less widespread, the four subspecies of the Black-faced Woodswallow listed by Mayr in 1962 have undergone considerable taxonomic readjustment. A few years after Mayr's list was published, very thorough research by G. F. Mees indicated that, contrary to Vieillot's statement in 1817, the type specimen of the Black-faced Woodswallow did not come from Timor. When describing and naming *Artamus cinereus*, Vieillot had drawn his details from the 1807 catalogue of the dealer C. J. Temminck, giving Timor as the type locality. When the type specimen was finally located, in the Rijksmuseum van Natuurlijke Historie, in the Netherlands, it was clearly of the Australian race, having the two central rectrices black-tipped, whereas birds of this species from Timor, now known as the subspecies *perspicillatus*, have all rectrices tipped white. The type specimen had been mounted, and the label mentioned Australia and "N.S.Wales". The story did not end there, however, and in 1978 J. Ford pointed out that the Black-faced Woodswallow is an inland species in eastern Australia, that exploration west of the Great Dividing Range did not take place until 1813, and that the specimen could not therefore have been collected in what is now New South Wales in 1807 as Mees had claimed. In 1982, after further searching, Mees reported that Stresemann had shown, three decades earlier, that Temminck's specimen bore the collector's number 166 in the Temminck catalogue, which indicated that it had been collected by J. Labillardière not later than 1799. This further excludes New South Wales as the type location, as Labillardière visited only Tasmania and south-western Australia. The only place from where he could have collected the specimen is the mainland opposite the Archipelago of the Recherche, in extreme south Western Australia, in December 1792. This has been confirmed by material collected more recently, as Mees pointed out.

In 1999, Schodde and Mason regularized the nomenclature for the Black-faced Woodswallow. They separated those with a

*The **Ivory-backed Woodswallow** shows a strong contrast between its mostly white body and its brownish-grey head and throat, and blackish-grey wings and tail. The absence of sexual dimorphism, in both plumage and measurements, has severely limited behavioural observations of woodswallows. It has been suggested that the White-backed Woodswallow* (Artamus insignis)*, which has similarly contrasting plumage, white with sooty black head, throat, wings and tail, is a subspecies of the Ivory-backed Woodswallow. However, the two species are widely separated geographically, with the Great Woodswallow* (A. maximus) *occurring in between.*

[*Artamus monachus*, Lore Lindu National Park, Sulawesi. Photo: Pete Morris]

*The **White-browed Woodswallow** is one of only two woodswallow species in which the sexes have different plumage. The other is Masked Woodswallow* (Artamus personatus), *with which the White-browed often associates in its nomadic movements, both species being found in the more open habitats of mainland Australia. The male White-browed stands out among the generally dull-plumaged members of the genus, with its bright rufous or chestnut underparts. The female has the same basic plumage pattern as the male, but is noticeably paler and duller, and with a much less conspicuous eyebrow. Immature White-browed Woodswallows are similar in plumage to the females, but with some streaking and pale mottling. The juvenile plumage of the monomorphic species is not unlike that of the adults, though browner above, and having pale tips or fringes to the feathers. The blue grey bill with a black tip, clearly visible in this picture, is common to all eleven species. As a result of their main foraging technique, woodswallows require a perch from which they can view their surrounds and launch themselves in pursuit of prey. This means that they frequently perch conspicuously on dead trees, and on telephone and power lines. White-browed Woodswallows are found in inland shrubland, as well as open woodland and adjacent farmland; also in parks, and occasionally in built-up areas.*

[*Artamus superciliosus*, Hattah-Kulkyne National Park, Victoria, Australia. Photo: Dean Ingwersen]

Woodswallows fly fast in pursuit of prey, but they also soar and glide extensively. Their flight is characterized by short glides interspersed with rapid wingbeats, and is superficially similar to that of the Common Starling (Sturnus vulgaris). *Nine subspecies of* ***White-breasted Woodswallow*** *are currently recognized. Most are island populations, which appear reluctant to fly across expanses of open water. They vary in the coloration of the head and upperparts, and also in overall size, bill size and wing length. The race* leucopygialis, *shown here, occurs in northern and eastern Australia, as well as the Moluccas, New Guinea and the Aru Islands.*

[*Artamus leucorynchus leucopygialis*, Broome, Western Australia, Australia. Photo: Rohan Clarke]

white vent, the subspecies *normani* and *dealbatus*, from those with a black vent, the nominate race and *melanops*, leaving *perspicillatus*, with its completely white-tipped set of rectrices, as the representative of this species in Timor.

In 1982, Wolters suggested that the genus *Artamus* could be split into three subgenera. These, although not employed taxonomically in the present treatment, do nevertheless provide a convenient subdivision of the family. The first of the three subgenera is *Artamus*, incorporating six species: the Ashy, White-breasted, Ivory-backed, Great, White-backed and Fiji Woodswallows. These six are sexually monomorphic in plumage, which is bicoloured in white and slate, brown or black, with a white rump; the tail is stubby and usually plain-tipped. The second is *Campbellornis*, containing the Masked and White-browed Woodswallows: these two are sexually dimorphic in plumage, and have a plain rump and a slender and white-tipped tail. The third and last subgenus, *Angroyan*, with the Black-faced, Dusky and Little Woodswallows, is again characterized by the possession of sexually monomorphic plumage, which is plain, light to dusky grey-brown, with a plain rump and a contrastingly white-tipped tail.

Morphological Aspects

The eleven species of woodswallow share several characteristic features. They all have a squat silhouette, a short tail, long pointed wings with a vestigial tenth primary, a conical broad-based blue-grey bill with a black tip, short legs and a brush-like tongue, and all have a soft-textured plumage with constantly growing powder-downs. Schodde and Mason demonstrated that they share certain features of skull morphology, especially that of the palate, with butcherbirds, the Australian Magpie and currawongs, all of which are currently placed in the family Cracticidae (see Systematics).

Woodswallows are rather dull-plumaged birds, especially when compared with many other passerines occurring in the same regions. Their main colours are black, brown, grey and white. One species, the White-browed Woodswallow, adds a touch of rufous in the plumage, having the underside of the body, from the lower breast to the vent, chestnut to light rufous in colour. Tracts of continuously growing powder-down feathers are unusual among passerines, and are found only in the woodswallows and the cotingas (Cotingidae). The purpose of these is obscure, but they are presumed to serve in feather maintenance. Originally commented on by C. L. Nitzsch in 1867, these unusual feather tracts were not noticed by other workers for more than a century, until M. H. Clench redescribed them in 1985.

Nine of the eleven woodswallow species are monomorphic, both in plumage and in measurements. This has severely limited most behavioural observations, since mating, when the roles of the sexes are obvious, is a brief affair and the partners are usually indistinguishable from each other once they have separated. Even with studies of colour-ringed individuals it is rare for the human observer to be able to identify the sex of the woodswallows involved, and the male and the female appear to participate equally in most parental duties. Copulation and the act of egg-laying, however, are rarely witnessed. The Masked and White-browed Woodswallows are the only members of the family which are sexually dimorphic in plumage. With each of these two, the female has the same basic plumage pattern as that of the male of the species, but she is noticeably paler and duller.

Juvenile plumage is gene5rally not at all unlike that of the adult, differing primarily in being browner above, and having pale fringes or tips of the feathers. As an example, the juvenile Ashy Woodswallow, compared with its respective adult, has a browner head and upperparts, with buff feather fringes on the mantle, upperwing-coverts and remiges; in addition, it has a paler, more buffish-grey throat and underparts with brownish vermiculations. The immatures of the Masked and White-browed Woodswallows, the two sexually dimorphic species, are similar in plumage to their respective females, but with some streaking and/or pale mottling.

Little is known about the moult of woodswallow species outside Australia. In the latter country, adults have a complete post-breeding moult, from November to May. From the limited information available, the primaries are moulted outwards and the secondaries inwards, and this probably applies to all members of the family. The nestlings are covered with down at hatching or soon thereafter, and they leave the nest in juvenile plumage. After a few months, they undergo a partial body moult and acquire an adult-like plumage; when they are about one year old, they have a complete moult into the adult plumage. In subsequent years, there is a complete post-breeding moult each year,

Woodswallows appear to be extremely sociable when at rest or roosting. They typically forage alone, but in the intervals between feeding, the birds tend to gather on a convenient branch, as these ***White-browed Woodswallows*** *are doing. This species often gathers in large numbers at dusk, and sometimes forms large clusters during the day, when they may mingle with congeners, especially Masked* (Artamus personatus) *and Black-faced Woodswallows* (A. cinereus). *Both White-browed and Masked Woodswallows appear to camp in dense foliage, and are so sensitive to intruders that there seem to be no detailed observations of their nocturnal roosting behaviour. The variable movements of these species may prevent them from gathering regularly at particular sites. White-browed Woodswallows live predominantly in the eastern half of Australia, and their annual movement is described as an "inland circle": the birds move north in the winter, and return southwards by a more inland route, which may take them into Western Australia. They travel in flocks of up to 200 individuals, often mixed with Masked Woodswallows. The proportion of the White-browed species in the mixed flocks increases towards the east; the White-browed is also found further to the south than the Masked. In the western half of Australia, the Masked Woodswallow tends to form single-species flocks of up to 1000 birds. In the breeding season, the sudden arrival of a flock of White-browed Woodswallows may be followed by the rapid establishment of a breeding colony, but these irruptions do not occur regularly at the same places.*

[*Artamus superciliosus*, Thylungra Station, Queensland, Australia. Photo: Graeme Chapman]

*Tightly packed along a branch or telephone line, roosting **White-breasted Woodswallows** have been described as "looking like black and white pegs on a clothes line". The birds will struggle with one another in order not to be left at the ends of the rows. Woodswallows move along a perch by shuffling sideways, moving one foot after the other. The long, strong claws, clearly visible in this picture, can anchor them securely to the trunk of a tree throughout the night, when sheltering from a storm. The strong grip of the claws also enables them to retreat stealthily to the underside or far side of a branch to avoid being seen by a predator. But they are usually aggressive towards predators, and will chase away much larger birds from the vicinity of their nests.*

[*Artamus leucorynchus leucopygialis*, Northern Territory, Australia. Photo: Günter Ziesler]

with no change in appearance. Geographical variation in the timing of the moult is little known. In arid regions where breeding is irregular, moult can take place over an extended period, and K. Immelmann observed simultaneous moult and breeding by Black-faced Woodswallows.

Habitat

The preferred habitat of woodswallows includes savanna woodland, although these species are found also in more open forest throughout the south-west of Australia and the forest of the wet tropics of the north-east, as well as in other parts of the family's geographical range.

Being aerial insectivores, woodswallows require a perch from which they can view their surrounds and launch themselves in pursuit of prey. This means that they frequently perch conspicuously in such places as dead trees and on telephone and power lines, and they are rarely found in extensive open cultivation, although they may soar and trawl for insects over treeless habitats.

Typically, woodswallows are inhabitants of open wooded country, shrublands, open woodland and adjacent farmlands. They occur in areas of cultivation so long as suitable perches are available for them at sufficient densities and not too widely scattered. The White-breasted Woodswallow, for example, is common in open country, cultivation and light woodland, and this species can also be found in mangroves; it is often observed near habitation, and it frequently attends herds of cattle or water buffalo (*Bubalus*). The Little Woodswallow is widespread in Australia, where it is found in scrublands, on rocky hills and cliffs, and around the low scarp tops and coloured outcrops known as "breakaways".

In New Guinea, the Great Woodswallow is more a species of forest, in which it is found mainly in clearings and in garden areas with dead trees, occasionally appearing in tall emergent trees above the canopy of primary forest. This species is found above 800 m, but most members of the family seem to prefer the lowlands. Nevertheless, the White-breasted Woodswallow is occasionally observed in forest clearings at elevations of up to 1500 m.

General Habits

Woodswallows are aerial hunters and fly fast in pursuit of prey, but they also soar and glide extensively and appear to enjoy extreme sociability at rest or when roosting, frequently preening both themselves and each other.

Mayr, in 1945, rated *Artamus* species as the best fliers among the oscine passerines. The flight of woodswallows is characterized by short glides interspersed with rapid wingbeats, and is superficially similar to the flight of the Common Starling. They fly fast and with great agility when hunting close to the ground or when high up, but if the wind is very strong they make only brief sorties from convenient low perches, such as from fencelines or from isolated weeds left standing in stubbles. On the ground, woodswallows hop with both feet together and appear clumsy, since the short tarsi are placed to the rear of the body. They usually perch on exposed branches, from which they can easily launch themselves and make aerial sorties. If they need to move along a branch, they shuffle sideways by moving one foot after the other. Long strong claws enable them to cling to the trunk of a tree all night when roosting, to shelter from a rainstorm, or to retreat stealthily to the underside or the rear surface of a branch to avoid being seen by an approaching raptor or other predator. Although brave in defence of its nest, a solitary woodswallow perched on an exposed branch, if it does become aware of the approach of a raptor, may slip sideways, keeping the branch between itself and the predator, and quickly changing sides after the latter has passed. This behaviour is possible because of the woodswallow's short tarsi and strong claws. It may well be unique among passerines, as it is employed as a means of avoiding being seen in what would otherwise be a very exposed position and where flight may be even more dangerous.

Small birds rivalling the true swallows (Hirundinidae) in their aerial skills, woodswallows are one of the few groups whose members sometimes soar on thermals and frequently glide for

Little Woodswallows *are associated mainly with cliffs and rocky outcrops, where they will pack themselves into holes or clefts when resting and roosting. The two other plain, mostly brown species, the Black-faced* (Artamus cinereus) *and Dusky Woodswallows* (A. cyanopterus), *also tend to roost in scrum-like clusters. The birds gather about 20 minutes before sunset, and fly around the site before settling. The roost-site may also be a hollow stump, a scar left by a fallen branch, or the stick nest of a larger bird. Roosts tend to be used for several nights in succession, with alternative sites used if the birds are disturbed or the wind changes. These species are very sensitive to disturbance, and will "explode" from the roost when approached.*

[*Artamus minor minor*, Mileura Station, Western Australia, Australia. Photo: Graeme Chapman]

several minutes. Their aerial competence was well described in 1967 by E. T. Gilliard, who watched the Great Woodswallows high in the Adelbert Mountains of northern New Guinea:

> "Woodswallows may fly up and away from the perch, but they usually dive from it. They simply step off and fall nearly straight down for 10 feet [3 m], then open the wings and level out in a long graceful swoop, nor do they then flap the wings but usually continue to soar in fast graceful arcs. They flutter the wings in short bursts, often when it seems unnecessary as in the following case: a bird dove from a perch and then soared out over the valley. Out of curiosity, I counted slowly (averaging a second to a number) and watched for the first sign of wing motion. I counted to 135 before the first flapping took place and then the bird, which had mounted ever higher in the sky, fluttered steeply upwards for some unknown reason, certainly not to just gain altitude. Probably an insect was sighted. But the woodswallows generally soar and flutter going down and through the dead trunks and out into the valley in long static soars, gliding like a child's paper airplane, then breaking into flurries of wing motion, only to glide again. In landing they usually come in low and dive up to the perch, but some come directly at it and then back paddle with the wings."

Woodswallows display two very different tendencies in their interactions with other birds. On the one hand, they are very aggressive towards predators, particularly when these are anywhere near their nests, and, on the other, they are compulsively social in their resting and roosting habits. A good example of artamid aggression was recorded by S. Garnett and G. Crowley during their study of the globally threatened Golden-shouldered Parrot (*Psephotus chrysopterygius*). These authors found that the young parrots, as well as several other bird species, regularly foraged in the vicinity of active Black-faced Woodswallow nests, with the advantage that any approaching would-be predator, such as a butcherbird or a kookaburra (*Dacelo*), was "chivvied and chased until it changed its mind".

During intervals between foraging, which is a solitary exercise for most woodswallows, the birds tend to gather on a convenient branch, where they preen themselves and each other. When it comes to roosting, this sociality reaches an extreme. White-breasted Woodswallows, for instance, form a compact line along a branch or a telephone wire, even in the middle of some cities, at which time they battle with one another in an effort to avoid being left at the end of the line, with "the usual unavailing struggling to squeeze back into the pack"; in these situations they often sleep snugly in rows right under the light, "looking like black and white pegs on a clothes line".

The social behaviour of woodswallows includes preening in the intervals between foraging excursions, as shown by these ***White-breasted Woodswallows****. Individuals, as well as themselves, will also preen each other. All woodswallows have constantly growing powder-down feathers, a feature that is unusual among passerines, and otherwise found only in the cotingas (Cotingidae). The function of powder-downs is not altogether clear, but the fine powder they yield probably plays a part in feather maintenance.*

[*Artamus leucorynchus melaleucus*, New Caledonia. Photo: Roland Seitre]

Wing-stretching may occur as part of the suite of activities associated with feather maintenance, or simply the easing of tired muscles. While stretching its wing, this ***Dusky Woodswallow*** *is displaying one of the plumage differences between the nominate race, found on the south-eastern side of Australia, and race* perthi, *found in the south-west. The nominate race has white streaks on the outer 2–4 long primaries, while* perthi *has less white, restricted to the outer 2–3 long primaries. These races are weakly differentiated, and intergrade in South Australia.*

[*Artamus cyanopterus cyanopterus*, Glen Davis, New South Wales, Australia. Photo: Drew Fulton]

Neither Masked Woodswallows nor White-browed Woodswallows have been found to roost at night side by side or clumped together. Perhaps the rather nomadic, footloose movements made by these species preclude the luxury of regular, well-known sites, and their nesting colonies are usually unpredictable surprises. They appear to camp in dense foliage, and they are so sensitive to intruders that there seem to be no detailed observations of their nocturnal roosting behaviour. White-browed Woodswallows often gather in large numbers at dusk, and sometimes form large clusters during the day, when they may mingle with congeners, especially Masked and Black-faced Woodswallows.

The three plain brown, more sedentary species, the Black-faced, Dusky and Little Woodswallows, tend each to roost in a dense cluster, reminiscent in appearance of a rugby scrum. These aggregations follow a set routine, the birds gathering about 20 minutes before sunset and indulging in brief flights around the site before settling. Suddenly, a sharp call is given and the group flies off to the roost-site, which may be a scar on a tree trunk where a limb has fallen, a hollow tree stump, or perhaps the interior of a stick nest of an Australasian babbler (*Pomatostomus*) or raven (*Corvus*). These sites tend to be used for several nights in succession, but a group usually has several potential places to go to if disturbed or if the wind conditions change. These species are very sensitive to inspection when roosting, "exploding" from the site when approached by a human observer.

The strength of the urge to roost together was exemplified in a study of colour-ringed Dusky Woodswallows. In this instance, the four attendants at a nest deserted their 12-day old, well-feathered nestlings, leaving them unguarded all night while they joined a roosting cluster of the species more than 100 m away. The brood survived, and five days later all of the young fledged, and joined the adults in their cluster-roost.

Daytime roosting in a cluster, which tends to occur in response to cold, windy weather, is a much easier phenomenon to observe. The woodswallows tend each to grasp the substrate with their feet, usually with the head pointed upwards. As many as 200 Dusky Woodswallows have been seen to remain clustered for several hours on the leeward side of a forest tree. It has been frequently suggested that these birds cluster in this manner in order to preserve body heat, but this hardly explains why the behaviour persists through hot summers. The only way which would seem likely to provide an answer would be to measure the temperature in these scrums, but nobody has yet managed to do this.

Head flung back as though in full song, this ***Great Woodswallow*** *is actually sunbathing! The sun's rays can be used to help condition feathers that may be slightly out of shape. In fact, woodswallow song is seldom heard. Delivered from a high perch, it consists of a prolonged soft jumble of notes, including imitations of other birds, and is similar to the songs of New World mockingbirds (Mimidae). More often heard is the chattering "kakakaka..." given by groups of perched Great Woodswallows.*

[*Artamus maximus*, Tari Valley, New Guinea. Photo: Brian J. Coates]

Voice

For the White-breasted Woodswallow, B. E. Smythies, in *The Birds of Borneo*, quoted from J. Whitehead's published field notes,

Woodswallows will often consume small items while still in flight, but they normally carry larger items, either in the bill or in the feet, back to a favourite perch. ***White-breasted Woodswallows*** *typically harvest their prey in flight above the treetops. They will also take advantage of insects disturbed by tractors or large animals, and they frequently attend herds of cattle or water buffaloes. Although woodswallows occasionally forage singly or in twos or threes, they are generally found in small to large groups when hunting. They often associate with other species, such as swallows (Hirundinidae) and swifts (Apodidae). This species is a vagrant to Japan.*

made in the last decades of the nineteenth century. "Their note is a ceaseless disagreeable sharp chatter… . They are most disagreeable little birds; they sit in families of four or five, huddled close together on the bare branches of some dead tree, and attack every other species that [comes] near the spot."

Very often, the first inkling that woodswallows are nearby is the characteristic brief contact calling as the birds soar high overhead. They may be a travelling flock or foraging local residents. Most descriptions of woodswallows refer to this vocalization as a loud, brisk chirping "peet-peet", "tseet-tseet" or "chek-chek". Woodswallows call also as they approach to feed a brood of nestlings or to communicate with an incubating individual. When perched together in a row or spread through the branches of a dead tree, they keep up a ceaseless chirping chatter. A softer call is sometimes given by an individual sitting alone, apparently "talking to itself", but perhaps keeping contact with other group-members not far away. This is probably the "soft twittering song" referred to in many accounts and field guides, and which may incorporate contact and other calls, as well as an element of mimicry. On the basis of his extensive studies of New Guinea birds, J. M. Diamond stated that the song of the Great Woodswallow was delivered from a perch in the crown of a tall tree, and was rarely heard. He described it as being a prolonged soft jumble of notes, including imitations of other birds, and thought it very similar to the songs of New World mockingbirds (Mimidae); song elements include squawks, chirps and short trills, each repeated up to five times.

Immelmann commented on the differences in the frequency with which vocalizations were delivered. Black-faced Woodswallows accompany almost every movement with calls, whereas White-breasted Woodswallows give voice much less frequently, and a group of Little Woodswallows may often utter no sounds at all for periods of several minutes.

During a total of 55 hours spent in a hide established 3 m from a nest of Black-faced Woodswallows, the observers identified several different types of vocalization. These were the following: contact calls exchanged between conspecifics; greeting calls uttered by group-members at an active nest; calls emitted by hungry nestlings; and loud calls given by an individual on guard duty at a nest, these varying from mild alert to intense alarm. When the intruder posed a real threat, as was the case with, for example, a raven, a raptor or an approaching human, fox (*Vulpes*) or reptile, the members of the group uttered harsh calls as they swooped, mobbing the intruder, and occasionally making physical contact.

Greeting calls were given by the incubating or brooding woodswallow as soon as it sighted an individual that was approaching in order to relieve it. These loud repeated "qua" notes became more and more excited, especially if the arriving bird had food to

Woodswallows will seize large beetles (Coleoptera) or larvae from foliage, or pounce on them on the ground. During prolonged windy spells, when winged insects are not flying, they may feed on the ground for more extended periods, consuming large ants (Formicidae). When locusts (Acrididae) are present in plague numbers, the ***Black-faced Woodswallow*** *becomes a specialist predator, coincidentally performing a valuable service for farmers. The birds snap the locusts up as they jump, and may even hover in anticipation. Woodswallows eat a number of other potential "pest" species, including cockroaches (Blattodea), termites (Isoptera), and moths and their caterpillars (Lepidoptera).*

[*Artamus cinereus melanops*,
Windorah, Queensland,
Australia.
Photo: Graeme Chapman]

The large insects which ***Great Woodswallows*** *capture on the wing are brought back to the perch to be dismembered. Woodswallows use their feet to clamp the prey against the branch, while tearing it to pieces with the beak. Food for nestlings is often prepared in this way. Although sociable at other times, the Great Woodswallow tends to be a solitary hunter. Living in New Guinea, it is more a species of forest than of extensive open habitats, the normal habitat of the family. Found mainly in clearings and in garden areas with dead trees, it occasionally appears in tall emergent trees above the canopy of primary forest.*

[*Artamus maximus*, Ambua Lodge, EC New Guinea. Photo: Jon Hornbuckle]

offer, in which case the sitter began vigorous wing-fluttering. Frequently, such series incorporated a distinctive rattle consisting of a rapid series of progressively louder short syllables. The rattle was generally followed by a series of loud "qua" sounds.

Nestling woodswallows, as they grow, become more and more vocal in expectation of food, but they quieten abruptly when an alarm is given. A series of graded, loud, short alarm calls is given by adults when potential danger is identified near an active nest; these range from mild alert to the louder calls that accompany the active mobbing of an intruder. A brief call similar to the low-level alarm chatter is given just before the group moves to its final roosting spot for the night.

Food and Feeding

With their strong bill and their aerial agility, woodswallows are able to take in a wide variety of prey, ranging from flies (Diptera) to moths (Lepidoptera), beetles (Coleoptera) and grasshoppers (Orthoptera). They will often consume small items while still in flight, but they normally carry larger items, either in the bill or in the feet, back to a favourite perch, where they swallow the food. If the item is too large or too tough to be swallowed whole, the woodswallow will use its feet to clamp the food against the branch and tear it to pieces. Food destined to be fed to nestlings is often prepared in this way.

Much of the foraging carried out by resident members of this family involves hunting from a lookout post. The woodswallow sits quietly on a perch providing a clear view, and from there launches itself into the air to pursue prey, returning to the perch to eat it. Woodswallows catch much of their food in the air, but also catch items on the ground or other substrate. They will seize large beetles or larvae from foliage or pounce on them on the ground. When the opportunity presents itself, they will "follow the plough" in agricultural areas, seizing larvae and insects as these are uncovered by the digging blades. During plagues of grasshoppers they hunt the insects in a most "professional" manner, snapping them up as they jump, and sometimes even hovering in anticipation. Strong winds preclude a lot of insect activity and renders aerial feeding by woodswallows unprofitable, if not impossible. During prolonged windy spells, the birds sometimes feed on the ground and consume large ants (Formicidae).

The brush-like tongue of the Artamidae enables the members of this family to take advantage of the "honey-flow", the nectar, produced by flowering trees such as eucalypts (*Eucalyptus*) or the silky oak (*Grevillea robusta*). This food source is particularly important for two migrants which spend the winter in tropical northern Australia, the Masked and the White-browed Woodswallows, species that are labile enough in their movements to exploit blossom bonanzas. Although attracted to the nectar, woodswallows certainly relish the additional fare provided by

Woodswallows have a brush-like tongue, similar to those of nectar specialists like honeyeaters (Meliphagidae) and lorikeets (Loriinae). This enables them to vary their diet to take advantage of the seasonal food produced by flowering trees such as Eucalyptus. *As well as feeding on nectar, this* ***Black-faced Woodswallow*** *may also be taking insects that are attracted to the blossom. Nectar is a particularly important food for Masked Woodswallows* (Artamus personatus) *and White-browed Woodswallows* (A. superciliosus), *which spend the winter in tropical Northern Australia, when insect availability drops in the south.*

[*Artamus cinereus melanops*, Winton, Queensland, Australia. Photo: Graeme Chapman]

*This mixed flock of **White-browed** and **Masked Woodswallows** has stopped to drink during the circular inland journey of these species. Their movements in the northern regions are irregular, probably being dependent on the amount of rainfall during the preceding summer. Rainfall, and the consequent abundance of insects and blossom, has a direct influence on the timing of breeding in most species of woodswallow. Black-faced Woodswallows* (Artamus cinereus) *have been observed to begin courtship within minutes of rain starting.*

[*Artamus superciliosus* and *A. personatus*, Cobar, New South Wales, Australia.
Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

the insects and other arthropods that swarm at the blossoms and the pollen of the flowers and elsewhere. Centipedes (Chilopoda), dragonflies (Odonata), cockroaches (Blattodea), termites (Isoptera), grasshoppers and crickets (Orthoptera), cicadas (Cicadoidea), beetles, moths, caterpillars, wasps and bees (Hymenoptera), ants, scorpions (Scorpiones) and spiders (Araneae) have all been recorded in their diet. Woodswallows have been recorded also as consuming a variety of plant seeds, including those of the genera *Xanthorrhoea*, *Enchylaena*, *Rhagodia*, *Melaleuca* and *Grevillea*.

Although woodswallows occasionally forage singly or in twos or threes, they are generally found in small to large groups when hunting (see also General Habits). They tend to make aerial forays individually. Most artamids associate with other species, at least on occasion, especially when at abundant food sources. In several parts of the family's range they will forage in the air with hirundinids or swifts (Apodidae), and they will at times join other birds such as honeyeaters (Meliphagidae) and bee-eaters (Meropidae).

Breeding

Although the nest-sites and eggs of all Australian species of woodswallow have been described, little more is known about the breeding biology of most artamids, especially those that do not breed in Australia. All of those species for which the relevant details are available build a flat cup-nest of thin twigs, placed in a twiggy fork or crotch of a tree, and lay a comparatively small clutch of 2–4 eggs. Two species, the Dusky and Black-faced Woodswallows, have been the subject of more detailed study, and what is known of other members of the family suggests that the breeding habits of these are similar in many respects to those of the two studied species.

Those species that are relatively well known usually breed as resident pairs or small groups, maintaining territories against conspecifics. The resident species maintain their pair-bonds throughout the winter months. At least six of the eleven species of *Artamus* have been recorded as sometimes breeding co-operatively, whereby members of a group other than the parents help to defend a nest and feed the brood, but few long-term studies have been carried out to determine whether or not they are group-living throughout the year. The six are the White-breasted, Great, Fiji, Black-faced, Dusky and Little Woodswallows. In the case of the resident Black-faced Woodswallow, young ringed as nestlings were known to stay with the group for up to three years, and were helping to feed siblings, since the breeding pair remained the same. With the Dusky Woodswallow, co-operative breeding occurs even among populations which are not resident throughout the year. In no studies of other co-operatively breeding woodswallows has the origin of group-members been determined, nor has it been shown whether or not the individuals remain together as a group all year. Many of the reports of woodswallows in field guides refer to "small parties" or "groups of 3–10 individuals" and similar, but there is no evidence from studies of marked individuals that these are family parties.

In this family, co-operative breeding is characterized by the presence of breeding and non-breeding mature individuals in a social group. The non-breeders, usually termed "helpers", assist in the defence of the nest and in attacking predators or cuckoos (Cuculidae). In particular, they contribute to the reproductive efforts of the senior breeding pair by feeding the nestlings and caring for the young after these have left the nest. Although many groups of woodswallows contain more than a simple pair of adults, there has been no documented case of extra-pair or extra-group copulation and no indication that such phenomena may occur.

The timing of breeding by woodswallows varies considerably, being influenced mainly by latitude and the seasonal distribution of rainfall for particular populations. Australian woodswallows generally breed during the austral spring and early summer, although in arid regions they may breed at other times in response to rainfall. The widely distributed White-breasted Woodswallow breeds from August to February in Australia and New Guinea, and tends to nest from April to June in Indonesia; in the Philippines, its breeding season begins in March and April. The widespread Black-faced Woodswallow breeds in Western Australia from August to January in the tropical north with high summer rainfall; farther south, in the arid regions north

Little is known about the breeding biology of most woodswallows, especially those that do not breed in Australia. Two species that have been studied in more detail are the ***Black-faced Woodswallow*** *and the Dusky Woodswallow* (Artamus cyanopterus). *Copulation is preceded by an elaborate courtship display, which may be initiated by either partner. One bird partly opens its wings, and begins to wave them in time with the rotation of its spread tail, about ten times in 15 seconds. The second bird joins in, and the birds display to one another for a minute or more, until they appear to have achieved synchrony. The male then flies to the female, and the act of copulation takes place rapidly, lasting no more than five seconds.*

[*Artamus cinereus melanops*, Lake Bindegolly National Park, Queensland, Australia. Photo: Chris Tzaros]

and south of the Tropic of Capricorn, it breeds from July to October, and occasionally from December to April if heavy cyclonic rains pass through the region in summer. In the southern winter-rainfall region, breeding by this species occurs from September to early January in the wetter south-west and from July to September in the drier southern interior. In central Australia, Immelmann observed the response of Black-faced Woodswallows to heavy rain in early May, after a dry period of several months, in Alice Springs. He saw courtship several minutes after the beginning of the rain, and the first copulations occurred about two hours later. The woodswallows began to pick up nesting material while rain was still falling, and the first nest was completed six days and the first eggs laid twelve days after the rain had started. The better-known Australian species may make a second nesting attempt if the first nest fails, and sometimes if it is successful. In the only studies of known individuals hitherto undertaken, however, there were no successful second broods in a season.

Breeding by Ashy Woodswallows in the Indian Subcontinent varies locally, from March to June in some regions and from January to July in others, depending on the rainy season. This species breeds in March–June in South-east Asia. The timing of breeding of the White-backed, Great and Ivory-backed Woodswallows is little known, but information on the reproduction habits of other birds in the New Guinea region suggests that most breeding occurs before or after the peak of the wet season.

Copulation is a brief affair, lasting not longer than five seconds, and is preceded by an elaborate and beautiful display, which I. C. R. Rowley described for the Dusky Woodswallow. Either the male or the female may initiate the display when the two birds are 5–10 m apart, often in different trees. One individual partly opens its wings and begins to wave them in time with the rotation of the spread tail, about ten times in 15 seconds. The partner very soon joins in with an identical display, which may last for more than a minute until the pair appears to have achieved synchrony. The male then flies to the female and briefly mounts her. Similar displays have been observed to be performed by the Black-faced, White-browed, White-breasted and Little Woodswallows. Immelmann noted that woodswallows do not utter any vocalizations during copulation.

All of the woodswallow species build an open cup-shaped nest. The work is shared by both members of a pair, each in turn bringing a single twig or piece of grass. The outer framework of the cup is of thin twigs in a relatively loose construction, which is then usually lined with fine grass and rootlets. Most nests are placed conspicuously in a twiggy fork or crotch of a tree or shrub, but woodswallows may also use man-made structures, such as the tops of fence posts, telephone poles, electricity pylons and

Although pairs may nest solitarily, ***Masked Woodswallows*** *also form loose breeding colonies of ten or more pairs, with nests 10 m apart. In the east of their range, they are often found in mixed colonies with White-browed Woodswallow* (Artamus superciliosus). *Once a flock settles at a site, nests are built rapidly, within a week. The work is shared, each partner bringing a twig or piece of grass in turn. But not all woodswallows tolerate the proximity of their conspecifics when breeding. Despite their sociability in most other activities, Dusky Woodswallows* (A. cyanopterus) *defend an area with a radius of 50 m around the nest.*

[*Artamus personatus*, Hattah-Kulkyne National Park, Victoria, Australia. Photo: Dean Ingwersen]

All woodswallow species for which nesting information is available build a loose, cup-shaped nest of thin twigs, lined with finer materials such as grass and rootlets. The ***White-browed Woodswallow*** *nests relatively low down, in a forked branch, in a hollow stump, or behind creepers or bark. Other species favour higher positions; the nest of the Great Woodswallow* (Artamus maximus)*, for example, is usually more than 15 m up in a dead tree. In Australia,* Artamus *nests are generally placed 1–10 m above the ground. Occasionally woodswallows will pick man-made structures such as utility poles and fence posts. Clutch size, where known, ranges from two to five eggs, most frequently three or four. All species lay similar eggs, with a creamy-white ground colour, spotted with grey or red-brown. Larger species lay larger eggs. Incubation takes around 14 days in the Black-faced* (A. cinereus) *and Dusky Woodswallows* (A. cyanopterus)*; the range for the White-browed Woodswallow is 12–16 days, with a mean of 13 days. Incubation is undertaken by both parents, and in at least some species, also by helpers. At least six of the eleven species of woodswallow have been recorded as sometimes breeding co-operatively, with non-breeding adults, perhaps the young of previous years, helping with the care and feeding of the young birds, and with defence against predators. In one group of resident Black-faced Woodswallows, birds ringed as nestlings stayed with the group for up to three years, and were helping to feed their own siblings, since the breeding pair remained the same. But in no studies of other co-operatively breeding woodswallows has the origin of group members been determined, nor has it been shown whether the individuals remain together as a group all year.*

[*Artamus superciliosus*, Bollon, Queensland, Australia.
Photo: Raoul Slater]

*In the **Dusky Woodswallow**, co-operative breeding occurs even among populations that are not resident throughout the year. In southern New South Wales, where the species is migratory, an immature ringed as a nestling helped at a nest of its father one year later. At first, the nestlings are brooded almost continuously, mostly by the breeding pair, but with short periods of brooding by the helpers. The breeding female takes the major share in incubation and brooding, but more than half of the feeding visits can be made by the helpers, and the frequency increases as the growing nestlings become more demanding.*

[*Artamus cyanopterus cyanopterus*, Chiltern–Mt Pilot National Park, Victoria, Australia. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

buildings. Many species will also occasionally make use of tree spouts or the lips of hollow stumps. Little Woodswallows, which frequently live near rocky cliffs or steep hillsides, often nest on a small shallow ledge or cleft in a cliff, or in a hole in the face of a boulder. In Australia, *Artamus* nests are generally placed 1–10 m above the ground, and typically below 5 m, although higher nests have been reported for White-breasted Woodswallows. The comparatively low nest height for such aerial species reflects the low-growing vegetation of the arid and semi-arid areas which constitute a large part of their range in Australia. The nesting habits of the Great, Ivory-backed and White-backed Woodswallows are very inadequately known, but there is a report by Gilliard and M. LeCroy that nests of Great Woodswallows in the New Guinea mountains are sited at a relatively high level, above 13 m.

Because so few marked individuals have been studied, the spacing of nests is not well known. Rowley noted that Dusky Woodswallows, despite their sociability when flocking or roosting, defended a territory within a radius of about 50 m of the nest, from which they chased away any intruding conspecifics. The area around the nest defended by Black-faced Woodswallows is usually smaller, although Rowley noted that nests were no closer than 100 m in continuous vegetation. Colonial nesting has been described for the very mobile, nomadic Masked and White-browed Woodswallows, which sometimes nest in loose colonies of ten or more pairs; such colonies consist of either one of the two species or of both mixed together.

The eggs of all woodswallows for which information is available are very similar to one another. They have a creamy-white ground colour which is spotted with grey or red-brown in a zone at the blunter end. Eggs increase in size with the body size of the female; they range from 19·1 × 14 mm, as laid by the Little Woodswallow, to 23 × 17 mm, the size of those of the White-breasted and Dusky Woodswallows. The eggs of the largest members of the family, the Great and White-backed Woodswallows, have not been described. Clutches are small, and exhibit little variation with season or latitude. For most species, clutch size has been found to range from two eggs to four eggs, with three eggs the most frequent. For the Dusky Woodswallow near Canberra, in south-east Australia, Rowley found the mean clutch size to be 3·3 eggs, and for Black-faced Woodswallows in southern inland Western Australia the mean was 3·2 eggs. Eggs are laid in the morning, at one-day intervals. Incubation of the eggs is undertaken by both partners, and also by any helpers which the pair may have. In the case of the Black-faced Woodswallows studied by Rowley, incubation began with the laying of the second egg in a three-egg clutch and with the third egg in a four-egg clutch. Rowley found an incubation period of 14 days for the Black-faced Woodswallow and 14–15 days for the Dusky Woodswallow. At hatching, the nestlings are pink, with sparse down. They rapidly darken as the feather shafts begin to emerge. The chicks of these two species left the nest 18–19 days after hatching.

At a nest of Black-faced Woodswallows attended by a marked group of five individuals, including three helpers, the breeding pair and the helpers carried food to the nest and removed faecal sacs. At first, the nestlings were brooded almost continuously, mostly by the breeding pair but with short periods of brooding by the helpers, the latter accounting for about one third of the brooding time. Once the chicks were well feathered, brooding was not necessary, but when the nest was exposed to sun, during very hot weather, the attendants that fed the nestlings, after having delivered food, usually remained at the open nest and shaded it with their wings. The presumed breeding female was most active in incubation and brooding, but more than half of the feeding visits were made by the helpers; feeding rates increased as the nestlings aged. All of the group took part in nest defence. A similar role was taken by helpers in feeding the young of Dusky Woodswallows, and it seems probable that the behaviour is much the same among the other artamid species which are described as breeding co-operatively, namely the Little, Great and White-breasted Woodswallows. The young left the nest together, and stayed nearby for a day or two. Fledglings can fly only weakly

*In the **Masked Woodswallow**, the chicks are brooded and fed by both parents, with no helpers involved. The nestling period is 12–13 days, occasionally longer, and the fledglings are attended by the parents for at least 12 days. In the White-browed Woodswallow* (Artamus superciliosus), *with which the Masked frequently flocks and nests colonially, the nestling period is 13–16 days, and fledglings continue to be fed by the parents for at least a further three weeks after leaving the nest. Both species breed opportunistically and irregularly, and lack an attachment to specific places. They are prone to abandoning breeding colonies suddenly, probably because of food shortages.*

[*Artamus personatus*, Lake Cronin Nature Reserve, Western Australia, Australia. Photo: Jiri Lochman/ Lochman Transparencies]

when they leave the nest, and their flight-feathers continue to grow for a further week or so.

For most members of the family, the fate of the young after they leave the nest is not known, since there appear to be no relevant studies of marked individuals. As woodswallows are generally so sociable, roosting and flocking together (see General Habits), it is tempting to suppose that family-members stay together. Dusky Woodswallows in Australia were migratory at the localitity where Rowley studied them, in southern New South Wales, but they returned to the same nesting area each year; an immature, ringed as a nestling, helped at a nest of its father one year later. In a resident population of Black-faced Woodswallows, progeny stayed with their natal group for up to three years. One young male left his natal group and made a breeding attempt nearby, but, when that nest failed, he returned to help with brood-feeding at his parents' nest.

In the Dusky and Black-faced Woodswallows, only half of the nests succeeded in terms of producing fledged young, and groups of Black-faced Woodswallows produced a mean of 1·5 fledglings per year. No information is available on breeding success of other species in the family. In the case of the two better-studied woodswallows, the exposed fragile nests were susceptible to wind and storms, which unseated several and tipped out the eggs or nestlings. No nest predators were identified for either species, although woodswallows aggressively mobbed many potential nest predators, such as the Brown Falcon (*Falco berigora*), the Australian Kestrel (*Falco cenchroides*), the Laughing Kookaburra (*Dacelo novaeguineae*) and the Australian Raven (*Corvus coronoides*). M. G. Brooker and L. C. Brooker identified the Australian species of *Artamus* as biological hosts of the Pallid Cuckoo (*Cuculus pallidus*), and R. E. Johnstone and G. M. Storr recorded this cuckoo as an occasional parasite of Masked, Dusky, White-breasted and Black-faced Woodswallows. Rowley did not record brood parasitism as a cause of failure, although Black-faced Woodswallows were seen to chase Pallid Cuckoos aggressively.

Not surprisingly, in view of the fact that these are such little-known, mobile birds, there appears to be no available information on the survival or longevity of any of the eleven species.

Movements

So far as is known, the woodswallows living outside Australia are resident, with some seasonal local movement. All of the Australian species, however, are nomadic or migratory to some extent.

The Black-faced Woodswallow is most likely to be resident, although some of its populations appear to be locally nomadic. There seems to be some movement by this species towards the north coast in the dry season, when populations in such areas as the Kimberley region, in Western Australia, and near Darwin, in Northern Territory, are augmented by visitors from inland areas farther south. The Dusky Woodswallow lives predominantly in southern Australia. In the northern part of its range on the east coast it is sedentary, but southern populations, those in Tasmania and southern Victoria, move north in the austral winter, leaving southern New South Wales in late April, and do not return until September. Little Woodswallows are found mostly in the northern half of Australia, and, while the northern populations are probably resident, those living farther south move northwards in winter, into the region of the tropical dry season.

White-browed Woodswallows live predominantly in the eastern half of Australia, and their movement is described as an "inland circle". These birds move north in the winter, and return southwards by a more inland route which may take them into Western Australia. They migrate usually in large flocks, and often in company with Masked Woodswallows. In the breeding season, the sudden arrival of a flock may be followed by the rapid establishment of a breeding colony, but irruptions do not occur regularly at the same place. Masked and White-breasted Woodswallows in eastern Australia fly north-west in the winter. In Western Australia, the Masked Woodswallow shifts north from

All members of a co-operative breeding group, parents and helpers, take part in defending the nest. When the nest is exposed to the sun, parents and helpers may also stay behind after delivering food, and shade the young with their wings. But despite the contributions of helpers, fewer than half of the studied nests of ***Dusky Woodswallows*** *and Black-faced Woodswallows* (Artamus cinereus) *succeeded in producing fledged young, and groups of Black-faced produced a mean of just 1·5 fledglings per year. The problems begin with woodswallows' exposed, flimsy nests. Those of the Black-faced, for example, are often unlined, and so sparsely woven that the eggs are visible from below. Several of the nests in the study were unseated by winds and storms, tipping out the eggs or nestlings. No nest predators were identified, although the two studied species mobbed potential predators like falcons* (Falco), *kookaburras* (Dacelo) *and ravens* (Corvus) *aggressively. The Pallid Cuckoo* (Cuculus pallidus) *has been recorded as an occasional parasite of Masked* (A. personatus), *White-breasted* (A. leucorynchus), *Dusky and Black-faced Woodswallows. No information is available on the breeding success of other woodswallow species.*

[*Artamus cyanopterus cyanopterus*, near Penrith, Sydney, New South Wales, Australia. Photo: David Stowe]

*The chicks of **Black-faced Woodswallows** leave the nest 18–19 days after hatching. At first the fledglings can fly only weakly if at all, and their flight-feathers continue to grow for a further week or more. The fledglings continue to be attended and fed by the parents and helpers, for a period of at least twelve days in the Masked Woodswallow* (Artamus personatus)*, and 50 days or more in the White-breasted Woodswallow* (A. leucorynchus).

[*Artamus cinereus perspicillatus*, West Timor, Lesser Sundas. Photo: Morten Strange]

southern regions, but its movement in the northern regions is highly irregular, probably being dependent on the amount of rainfall during the preceding summer.

Underlying all these movements is the fact that aerial insectivores do not find cold southern winters very profitable, whereas the tropical savanna woodlands provide abundant insects and nectar after summer rain. The distribution of these summer rains is highly irregular, and is governed by the paths taken by tropical cyclones when they move inland. As a consequence, while woodswallow movements may be in a very general overall direction, these species are perhaps best considered as being more nomadic, with a northerly or southerly bias in their movements.

Relationship with Man

Woodswallows are not widely known birds in urban Australia, nor do they appear to have any special significance for people living in other parts of the family's range. Their main habitats in Australia are found inland and in northern regions, and they are

*Young **Little Woodswallows** leave the nest at around 16–20 days. They continue to be fed by both parents, and perhaps helpers too, although this is another species whose breeding biology is not well known. What happens to the young of most woodswallow species after fledging is similarly unknown, since there appear to be few relevant studies of marked individuals. Given the highly sociable nature of these species, families may stay together, and in a resident population of Black-faced Woodswallows* (Artamus cinereus)*, the progeny stayed with their natal group for up to three years.*

[*Artamus minor derbyi*, Cunnamulla, Queensland, Australia. Photo: David Stowe]

little known in the large southern coastal cities. In northern cities, they are more visible, making use of power lines, street lighting and other structures for foraging and for their pre-roost gatherings. Even there, however, their feeding habits do not bring them into city gardens.

Because they consume large quantities of insects, woodswallows could well be beneficial to humans. It is likely that, at least on occasion, they eat good numbers of insects which are considered by man to be pests. As an example, Black-faced Woodswallows in Australia are known to become specialist predators on locusts (Acrididae) at times when these orthopterans occur in plague proportions.

Status and Conservation

*None of the eleven species of woodswallow is listed as globally threatened, although some subspecies may be less secure, and some local populations have disappeared. The restricted-range **Fiji Woodswallow**, for example, is no longer found on many of the Fijian islands on which it was reported in 1920. But following the early loss of moist lowland forest and savanna which were possibly its original habitat, this species seems to have adapted well to human-altered habitats.*

[*Artamus mentalis*, Fiji. Photo: Jon Hornbuckle]

As they are aerial insectivores, woodswallows are not subject to the same pressures as those that affect understorey birds, for example loss of ground-level vegetation through overgrazing and burning. In consequence, none of the eleven species and 25 taxa in the family Artamidae is listed by BirdLife International under any category of threat.

In Australia, no species or subspecies of woodswallow has become extinct since the time of European settlement, in 1788. This conclusion is based on a review initiated by the Australian Government Department of the Environment (or Natural Heritage Fund), carried out by Garnett and Crowley and published in 2000. The only Australian artamid population that may be endangered is the Cape York Peninsula subspecies, *normani*, of the Black-faced Woodswallow, a race which occurs also in south New Guinea. This population has lost a lot of habitat owing to the increased burning of grasslands by pastoralists and the consequent shortage of suitable nest-sites in open savanna woodland. Careful fire management and the existence of national parks should help to ensure that its current status as a common species throughout Australia can be maintained.

The main risks facing species outside Australia are loss of habitat. This is a particular problem for those woodswallows that live in forest in Indonesia and on the Pacific islands, where this habitat is subject to clearance in many areas. Throughout its range, which extends from the Indian Subcontinent eastwards to south-east China and South-east Asia, the Ashy Woodswallow is the only representative of its family. Everywhere within its area of distribution it is fairly common to common but rather local, but it seems not to be at any immediate risk.

*The **White-breasted Woodswallow** is locally common throughout most of its range. The race* amydrus *has even colonized Peninsular Malaysia. However, the Palau endemic subspecies* pelewensis, *once probably found throughout the island group, is now confined to the upper savannas of the island of Babeldaob, and may number fewer than 100 birds; it therefore qualifies as threatened. Those species that depend on forest in Pacific and Indonesian islands may be at risk. The White-backed Woodswallow* (A. insignis) *lost 12% of its habitat on New Britain in the 1990s, and is now scarce or absent from much of its former range.*

[*Artamus leucorynchus pelewensis*, Ngardmau, Babeldaob, Palau Islands. Photo: Mandy Etpison]

Clearing of wooded habitat for agriculture in southern inland Australia has been largely beneficial for woodswallows. So long as sufficient trees are left for roosting, nesting and perching, this human activity has created new areas of suitable habitat for these birds. The replacement of old telegraph wires, strung between poles, by underground cables has made woodswallows less visible along many country roads, although fences, in places where they are present, may serve as perches if nothing else is available. In some of the savanna woodlands of Cape York Peninsula, in north Queensland, which are subject to grazing by cattle, the routine burning of grasslands has resulted in a large increase in the amount of closed scrubland in place of the open woodland favoured by Black-faced Woodswallows for nesting. In contrast, removal of timber from closed forests in south-east and south-west Australia has created open spaces, something that has suited Dusky Woodswallows for the purposes of nesting.

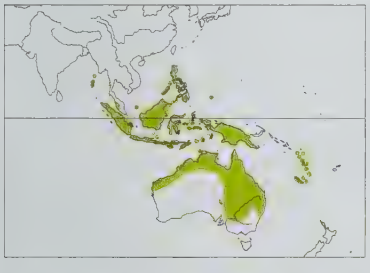
Genus *ARTAMUS* Vieillot, 1816

1. **Ashy Woodswallow**

Artamus fuscus

French: Langrayen brun **German**: Grauschwalbenstar **Spanish**: Artamo Ceniciento
Other common names: Ashy Swallow-shrike/Wood Swallow, Ashy Woodswallow Shrike

Taxonomy. *Artamus fuscus* Vieillot, 1817, Bengal, India.
Monotypic.
Distribution. Most of Indian Subcontinent (S to Sri Lanka) E to Myanmar, S & SE China (including Hainan), Thailand (except S) and Indochina.
Descriptive notes. 19 cm; 37–42 g. Has slate-grey head with darker mask (lores and area around eye), greyish-maroon mantle and pinkish-grey underparts; white-tipped tail with narrow greyish-white horseshoe-shaped band across uppertail-coverts; iris dark brown; bill pale blue-grey, tip black; legs grey to dark grey. Sexes similar. Juvenile resembles adult, but has browner upperparts, with buff feather fringes on mantle, wing-coverts and remiges, and pale buffish-grey throat and underparts with distinct brownish barring.
Voice. A frequently uttered wheezy "chee-chee-chee" or harsh nasal "chek"; also a long pleasant twittering song starting and ending with harsh "chack" notes.
Habitat. Open wooded country, often with palm trees, also cultivations, to c. 2100 m.
Food and Feeding. Insectivorous. Obtains most of its prey in flight. Glides and circles in air in search of food items; also sallies from treetop or other perch, pursuing insects in flight. Sometimes captures items on ground or other solid substrate. Forages singly, in pairs and in small flocks.
Breeding. Season Mar–Jul; laying Feb–Jun in Sri Lanka. Nest a shallow loose cup of rootlets and other fibrous material, placed up to c. 12 m above ground, often at junction of palm frond with trunk; occasionally in tree hole. Clutch 2–3 eggs. No other information.
Movements. Generally resident, with some local wandering dependent on weather conditions and



abundance of food. Some post-breeding movement from higher-lying areas (above 1000 m) to lower levels.
Status and Conservation. Not globally threatened. Widespread, and fairly common to common over most of its range. Somewhat patchily distributed in W of range. Occurs in many protected areas in most countries within its range.
Bibliography. Chen Fuguan *et al.* (1998), Cheng Tsohsin (1987), Étchécopar & Hüe (1983), Grimmett *et al.* (1998), Henry, G. M. 2. White-breasted Woodswallow

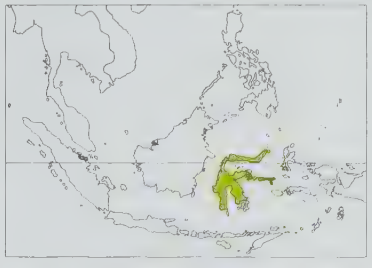
Artamus leucorynchus

French: Langrayen à ventre blanc **Spanish**: Artamo Ventriblanco
German: Weißbauch-Schwalbenstar
Other common names: White-breasted Swallow-shrike, White-rumped/Lesser/Ashy(!) Woodswallow

Taxonomy. *Lanius leucoryn* Linnaeus, 1771, Manila, Luzon, Philippines.
May belong to the superspecies that contains *A. monachus*, *A. maximus* and *A. insignis*, but sympatric with first of those in Sulawesi; replaced by *A. maximus* at higher elevations in New Guinea. Sometimes treated as conspecific with *A. mentalis*, but differs in plumage and voice. Proposed races *celebensis* (from Sulawesi) and *longipennis* (Peleng, off E Sulawesi) considered synonymous with *albiventer*. Geographical variation uncertain and validity of some races questionable; reassessment of races required. Original spelling of species name has almost never been used; current spelling is valid under the Code, due to prevailing usage; sometimes spelt *leucorhynchus*, which becomes an unjustified emendation. Nine subspecies currently recognized.
Subspecies and Distribution.
A. l. humei Stresemann, 1913 – Coco Is (N of Andamans) and Andaman Is.
A. l. leucorynchus (Linnaeus, 1771) – Philippines, Sulu Is, Natuna Is, and Borneo (including islands off N coast and Maratua, off E coast).
A. l. pelewensis Finsch, 1876 – Palau Is, W of Micronesia.
A. l. amydrus Oberholser, 1917 – Sumatra, W Peninsular Malaysia, Bangka I, Java, Masalembu Besar (in E Java Sea), Kangean Is, and Bali.
A. l. albiventer (Lesson, 1831) – Sulawesi and Lesser Sundas (Lombok to Timor and Wetar).
A. l. musschenbroeki A. B. Meyer, 1884 – Babar and Tanimbar Is, in E Lesser Sundas.
A. l. leucopygialis Gould, 1842 – Moluccas, New Guinea, Aru Is and N & E Australia.
A. l. tenuis Mayr, 1943 – Banks Is and Vanuatu.
A. l. melaleucus (Wagler, 1827) – New Caledonia and Loyalty Is.



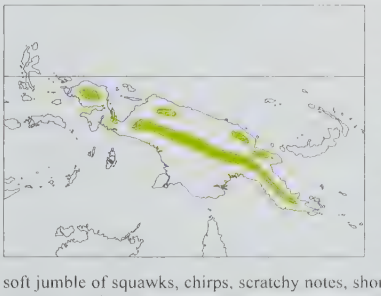
Descriptive notes. 18·5 cm; 36–49·6 g. Nominate race has head, chin, throat and upperparts dark slate-grey to blackish-grey or dark brownish-grey, except for white rump and uppertail-coverts; primaries and tail blackish, remiges and tail with thin white tip when plumage fresh; underparts white to creamy white; iris dark brown; bill pale blue-grey, tip black; legs dark blue-grey. Sexes similar. Juvenile is similar in pattern to adult, but more dark brownish with pale feather tips above, underparts sometimes washed light buff, upperwing-coverts and breast feathers tipped rusty or buff, tail more broadly tipped whitish, bill and legs brownish-horn. Races vary in overall size, bill size and wing length, also in colour of head and upperparts: *humei* has head to chin and throat bright slate-grey, paler than nominate, bill shorter; *albiventer* resembles previous, but with buff wash below, lores (sometimes to malar region) blackish, distinct colour change from greyish head to more brownish mantle, bill longer and finer; *amydrus* is very like nominate, but paler on hindneck, back and chin (though darker than previous race), usually lacks thin white margins on wing and tail feathers; *musschenbroeki* is like nominate but back less brown, and bill is stronger and deeper-based; *leucopygialis* has crown, throat and chin intermediate in colour tone between darker nominate and paler *humei*; *pelewensis* has head, chin, throat and back black, with no trace of grey or brown, tail entirely black; *melaleucus* has crown, chin and throat black, as previous but black of throat not extending so far onto chest, and back light brown; *tenuis* is like last but smaller, particularly in wing and tail lengths. Voice. Loud, brisk scolding "pirt pirt" or "aerk aerk", often given in flight; also nasal contact chatter, and pleasant chattering song including mimicry of other bird species.
Habitat. Open country with scattered trees, cultivation, light woodland, and mangroves; occasionally in forest clearings, commonly so in Andaman Is. Sea-level to 500 m, locally to 1500 m. Often near habitation; frequently attends herds of cattle or water buffalo (*Bubalus*).
Food and Feeding. Insectivorous. Prey usually harvested in flight above canopy; perches conspicuously before making aerial sorties. Forages singly or in small groups.
Breeding. Breeds Mar–May in NW of range, from Mar in Philippines, and Apr–Jun in Java; from Aug to Feb (mainly Sept–Jan), when and where propitious, in Australia, where sometimes two broods recorded. Sometimes breeds co-operatively, with up to five individuals attending a single nest. Nest built by both sexes, an unlined cup made of sticks and grass, placed in spout or hollow branch or in fork of tree, including mangrove, or in man-made structure (e.g. utility pole or fence post), or often in old nest of other bird species. Clutch 2–5 eggs, usually 3–4; incubation of eggs and feeding of nestlings by both sexes, helped by other group-members if present; no reliable information on duration of incubation and nestling periods; fledglings attended by both parents, and by any helpers present, for up to 50 days or more after leaving nest.
Movements. Resident in much of range. Nomadic locally; some N–S migratory movements in Australia.
Status and Conservation. Not globally threatened. Common locally throughout most of range; uncommon to fairly common in Coco Is, common in Andamans; rare in upper savannas of main island of Palau. Colonized W coast of Peninsular Malaysia in c. 1977, presumably having crossed sea from E Sumatra. Occurs in numerous protected areas over its broad range, e.g. Way Kambas National Park, in Sumatra, Bali Barat National Park, in Bali, and Rivière Bleue Reserve, in New Caledonia.
Bibliography. Barker & Vestjens (1990), Brüggemann (1876), Coates (1990), Dickinson *et al.* (1991), Doughty *et al.* (1999), Eck (1974), Étchécopar & Hüe (1977), Finsch (1876b), Grimmett *et al.* (1998), Hartert (1930), Higgins *et al.* (2006a), Holm *et al.* (2008), Johnstone & Storr (2004), Keast (1958), Mayr (1943a, 1944, 1962b), Meyer (1884), Neumann (1941), Oberholser (1917a), Ogilvie-Grant (1915), Rasmussen & Anderton (2005b), Schodde & Mason (1999), Serventy & Whittell (1976), Sheldon *et al.* (2001), Smythies & Davison (1999), Stresemann (1913, 1952), Watling (1983), Wells (2007), White & Bruce (1986).

3. Ivory-backed Woodswallow

Artamus monachus

French: Langrayen à tête noire **Spanish**: Artamo Cabecinegro
German: Weißrücken-Schwalbenstar
Other common names: White-backed(!)/Hooded/Celebes Woodswallow

Taxonomy. *Artamus monachus* Bonaparte, 1850, Sulawesi.
Forms a superspecies with *A. maximus* and *A. insignis*, this group perhaps including also *A. leucorynchus* and *A. mentalis*. Birds from Sula Is described as a geographical race, *sulaensis*, but regarded as insufficiently differentiated from those in rest of species' range. Treated as monotypic.
Distribution. Sulawesi, Lembeh, Banggai Is and Sula Archipelago.



Descriptive notes. 19–20 cm. Most of plumage is white, with brownish-grey head and throat, black lores and chin, blackish-grey wing and tail; iris dark brown; bill pale blue-grey, tip black; legs blue-grey. Sexes similar. Juvenile undescribed. Voice. A series of monosyllabic notes, more metallic and penetrating than those of *A. leucorynchus*; also "tschirr-woouit", given twice.
Habitat. Forest, forest edges and openings, at 200–2000 m. Favours more heavily wooded areas than those occupied on Sulawesi by sympatric *A. leucorynchus*.
Food and Feeding. Insects. Soars and hawks above canopy of unbroken forest; perches at edge of small forest clearings, making short sallies. In pairs, in small groups and in flocks of up to 20 individuals.
Breeding. One active nest in late Jul; situated c. 15 m up tree, at base of large epiphyte. No other information.
Movements. No information.
Status and Conservation. Not globally threatened. Widely but patchily distributed in Sulawesi; generally uncommon but locally common at lower elevations. Less numerous than sympatric *A. leucorynchus*. Occurs in several protected areas, including Dumoga-Bone National Park.
Bibliography. Coates & Bishop (1997), Holmes & Phillipps (1996), Indrawan *et al.* (2006), Stresemann (1934a), Stresemann & Heinrich (1940b), Wardill *et al.* (1999), Watling (1983), White & Bruce (1986).

4. Great Woodswallow

Artamus maximus

French: Grand Langrayen **German**: Riesenschwalbenstar **Spanish**: Artamo Grande
Other common names: Giant/Greater/Papuan/New Guinea/Black-breasted Woodswallow

Taxonomy. *Artamus maximus* A. B. Meyer, 1874, Hatam, Arfak Mountains, New Guinea.
Forms a superspecies with *A. monachus* and *A. insignis*, this group perhaps including also *A. leucorynchus* and *A. mentalis*. Monotypic.
Distribution. Mountain ranges of New Guinea, from 800 m to 2800 m.

Descriptive notes. 20–21 cm; 52–69 g. Has head and throat to upper breast and upperparts (except rump) and tail dark slate-grey; rump uppertail-coverts and underparts white; white patch on inner leading edge of wing diagnostic in flight; iris dark brown; bill pale blue-grey, tip black; legs dark blue-grey. Distinguished from *A. leucorynchus* by larger size, darker plumage coloration, white wing patch. Sexes similar. Immature has light buffy mottling on back and white tips on wing and tail. Voice. Chattering "kakakaka..." given by perched groups; also an upslurred "chirp" or "cheep", often in flight. Seldom heard song a prolonged soft jumble of squawks, chirps, scratchy notes, short trills, and mimicry of other bird species.
Habitat. Mainly clearings and garden areas with dead trees, above 800 m; occasionally in tall emergents above canopy of primary forest. Sympatric with *A. leucorynchus* at lower elevations.
Food and Feeding. Insects, often quite large ones. Prey usually taken in flight and brought back to a perch, where held in the feet for dismembering. Launches sorties from tall perches, and soars sometimes for long spells (e.g. 135 seconds) without a wingbeat. Usually solitary when on the wing; sociable at other times.
Breeding. Breeding recorded in Aug–Dec (from middle of dry season to early wet season). Nest an open cup, usually more than 15 m up in dead tree. Most reports are of three nestlings fed by both parents and by other group-members. No other information.
Movements. Resident, so far as is known.
Status and Conservation. Not globally threatened. Widely distributed throughout all mountain ranges of New Guinea, where fairly common to scarce. In some places seems to be commensal with humans in towns.
Bibliography. Beehler (1978b), Beehler *et al.* (1986), Coates (1990), Diamond (1972), Gilliard & LeCroy (1967a), Loke Wan Tho (1957), Ogilvie-Grant (1915), Rand & Gilliard (1967).

On following pages: 5. White-backed Woodswallow (*Artamus insignis*); 6. Fiji Woodswallow (*Artamus mentalis*); 7. Masked Woodswallow (*Artamus personatus*); 8. White-browed Woodswallow (*Artamus superciliosus*); 9. Black-faced Woodswallow (*Artamus cinereus*); 10. Dusky Woodswallow (*Artamus cyanopterus*); 11. Little Woodswallow (*Artamus minor*).

5. White-backed Woodswallow

Artamus insignis

French: Langrayen des Bismarck **Spanish**: Artamo Dorsiblanco
German: Bismarckschwalbenstar
Other common names: Black-headed/Bismarck/Sclater's/New Britain Woodswallow

Taxonomy. *Artamus insignis* P. L. Sclater, 1877, New Ireland.
Forms a superspecies with *A. monachus* and *A. maximus*, this group perhaps including also *A. leucorynchus* and *A. mentalis*. Monotypic.
Distribution. New Britain and New Ireland, in Bismarck Archipelago.

Descriptive notes. 18–19 cm; 49–54 g. Head, throat, wing and tail are sooty black, remainder of plumage white; iris brown, pale greyish-blue eyering; bill pale blue-grey, tip black; legs pale blue-grey. Differs from *A. maximus* in slightly smaller size, white (not dark) back. Sexes similar. Immature has head tinged with brown, hindneck grey-brown (not white), and remiges and outer rectrices tipped white. Voice. A piercing upslurred, high "zwink zwink" the only call reported. Presumed song is a quiet fantail-like scratchy warble.
Habitat. Tropical moist lowland forest, including clearings and adjoining gardens; mainly in hills to 900 m, locally also in adjoining lowlands.
Food and Feeding. Insects. Prey taken on the wing. Makes aerial sorties from perches in dead trees; soars more in manner of *A. maximus* than does *A. leucorynchus*. Usually seen in groups of up to ten individuals.
Breeding. No information.
Movements. Resident; reluctant to cross water, though has been recorded as vagrant to Watom (off NE New Britain).
Status and Conservation. Not globally threatened. Locally common, but mostly either scarce or absent. Restricted to New Britain and New Ireland; absent from outlying islands in Bismarck Archipelago. Estimated to have lost 12% of its habitat on New Britain during 1990–2000.
Bibliography. Buchanan *et al.* (2008), Coates (1990), Dahl (1899), Dutson (2008a), Gilliard & LeCroy (1967b), Hartert (1925), Mayr (1955), Mayr & Diamond (2001).

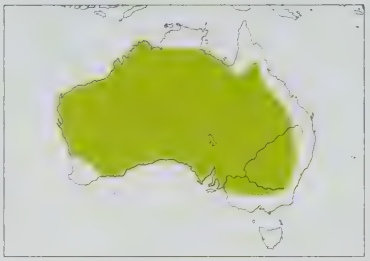
6. Fiji Woodswallow

Artamus mentalis

French: Langrayen des Fidji **German**: Fidschischwalbenstar **Spanish**: Artamo de las Fiyi

Taxonomy. *Artamus mentalis* Jardine, 1845, Fiji Islands.
Sometimes treated as conspecific with *A. leucorynchus*, but differs in plumage and voice; the two may belong to the superspecies that contains *A. monachus*, *A. maximus* and *A. insignis*. Monotypic.
Distribution. W & N Fiji Is: Viti Levu, Vanua Levu, Taveuni and Gau.

Descriptive notes. 17 cm; 33–48 g. Head to chin, upperparts and wing are black, except for white rump and uppertail-coverts; tail black with white tip; underparts white, extending up over lower throat onto central ear-coverts; iris dark brown; bill pale blue-grey, tip black; legs grey. Differs from *A. leucorynchus* in having white (not black) lower throat and central ear-coverts, separated irregularly (not evenly) from black colour of head. Sexes alike. Juvenile is similar to adult, but with paler feather edgings above. Voice. Commonest call a rapid chatter; alarm "wit-wit-wit", with metallic quality. Song, heard infrequently, a mix of mellow whistles and chortling sounds.
Habitat. Open habitats, including cultivation and savanna, especially on drier sides of the larger islands; occurs also in urban habitat on Viti Levu (in Nadi and Suva). Lowlands; ascends into highlands on Viti Levu.
Food and Feeding. Insectivorous. Impressive aerial forager, with fast pursuit-flight. Seizes prey in aerial sally launched from conspicuous perch; occasionally pounces on items near ground; will also make sweeps over flowering plants, and snap at insects. Smaller items swallowed whole; large prey taken back to perch and dismembered before being consumed.
Breeding. Season Aug–Nov, sometimes earlier. Often breeds co-operatively, in group of up to six individuals. Nest, built by all group-members, cup-shaped, constructed from small twigs and grass stems, often placed in forked branch in tree canopy, sometimes in hollow in cliff. Clutch 2 or 3 eggs; incubation of eggs and feeding of chicks by all group-members; no information on duration of incubation and nestling periods.
Movements. Resident, with some local wandering. Family group will remain for several years in and around a tree in which they roost and nest.
Status and Conservation. Not globally threatened. Locally common. Apparently decreased in 20th century; in 1920, reported on various islands throughout Fiji except in S Lau Archipelago, but thereafter disappeared from many islands (e.g. Koro, Makogai, Kadavu, Yasayasamoala, and islands in N Lau Group). Following early loss of moist lowland forest and savanna (possibly its original habitat), this species seems to have adapted well to human-altered habitats.
Bibliography. Clunie (1973, 1976b, 1984), Eck (1974), Langham (1989), Mayr (1945b, 1962b), Pratt *et al.* (1987), Watling (2001), Wolters (1982), Wood & Wetmore (1925).



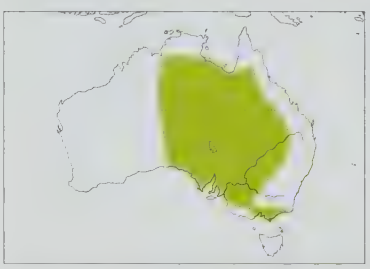
7. Masked Woodswallow

Artamus personatus

French: Langrayen masqué **German**: Maskenschwalbenstar **Spanish**: Artamo Enmascarado

Taxonomy. *Ocypterus personatus* Gould, 1841, southern and western Australia = York, Western Australia. Most closely related to *A. superciliosus*. Monotypic.

Distribution. Mainland Australia (except tropics N of 15° S, and E & SE coast, & SW forest).



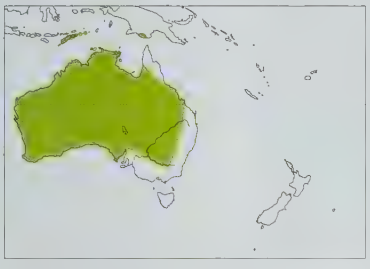
Descriptive notes. 18–20 cm; 25·5–42 g. A sexually dimorphic woodswallow. Male has face and throat black, bordered at rear by white crescent; crown and upperparts, including upperwing and tail, grey, tail tipped white; underparts white or whitish; iris dark brown; bill pale blue-grey, tipped black; legs grey to black. Female is similar to male but duller, with browner tinge, pale crescent behind facial mask indistinct, underparts washed brownish. Juvenile is like female but much duller still, mainly dark brown, greyer on wing and tail, streaked and spotted whitish above, diffusely streaked whitish below. Voice. Loud musical "chrrt" or "chapp-chapp", also softer "chrrup" sounds; some mimicry of other species. Song a soft twittering series.
Habitat. Inland shrublands, open woodland and adjacent farmland.
Food and Feeding. Largely insectivorous; feeds also on nectar, particularly in N of range (in austral winter). Insects taken mostly in air, during trawling flight high above vegetation; some pounced on from perch. Occurs in pairs and small groups; also in large flocks during migration.
Breeding. Season Jul–Mar (mainly Sept–Dec), mostly in S half of Australia. Nests solitarily, also in loose colony with nests 10 m apart; in E of range often in mixed colony with *A. superciliosus*. Once flock settles at a site, nest built rapidly, within one week, by both sexes, a shallow open cup made from twigs, grass, sometimes also rootlets and plant stems, lined with drier fine material, placed in fork of tree or shrub, or in end of hollow limb or stump, sometimes in old nest of other species. Clutch 2–3 eggs, rarely 1 or 4; incubation by both sexes, period c. 12 days; chicks brooded and fed by both parents, nestling period 12–13 days, occasionally longer; fledglings attended by parents for at least 12 days. Colonies often suddenly abandoned, probably in response to shortage of food.
Movements. Highly nomadic, most making post-breeding movement N into N parts of Australia, and returning S to breed in austral spring and early summer wherever food available. Travels in large flocks that may number more than 1000 individuals; in W half of Australia flocks tend to be largely monospecific, becoming mixed in E half, predominantly with *A. superciliosus* in Queensland, New South Wales and Victoria. Vagrant Tasmania, Lord Howe I, Norfolk I and New Zealand.
Status and Conservation. Not globally threatened. Widespread and common, but locally irregular, throughout its range. Has bred King I, in Bass Strait.
Bibliography. Barker & Vestjens (1990), Barrett *et al.* (2003), Blakers *et al.* (1984), Franklin (1999), Higgins *et al.* (2006a), Johnstone & Storr (2004), Joseph *et al.* (2006), McCarthy (2006), Schodde & Mason (1999), Serventy & Whittell (1976).

8. White-browed Woodswallow

Artamus superciliosus

French: Langrayen bridé **German**: Weißbrauen-Schwalbenstar **Spanish**: Artamo Cejiblanco

Taxonomy. *Ocypterus superciliosus* Gould, 1837, Hunter River, New South Wales, Australia.
Closest to *A. personatus*. Monotypic.
Distribution. Mainly C & inland E Australia; irregular in other parts of continent.



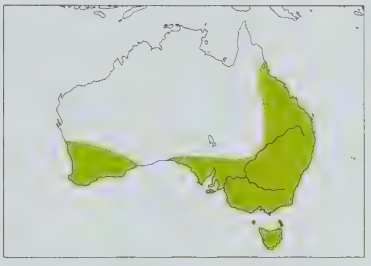
Descriptive notes. 18–19 cm; 30–41·1 g. Sexually dimorphic. Male is dark grey above and from chin to upper breast, with clear white eyebrow; tail tipped white; underparts below upper breast dark rufous; iris dark brown; bill pale blue-grey, tip black; legs lead-grey. Female is generally duller and paler than male, with brownish wash above, eyebrow less conspicuous, underparts below breast much paler. Juvenile is duller and browner than adult, heavily spotted and streaked whitish above and below, with prominent black lores, and grey wing and tail feathers with white tips; immature like adult, variable, wing and usually tail like those of juvenile. Voice. Contact call a high-pitched musical "tchep-tchep"; harsh scoldings; quiet song includes mimicry of other bird species.
Habitat. Inland shrublands, open woodland and adjacent farmland, also parks, less often forest edge; occasionally in built-up areas.
Food and Feeding. Largely insectivorous; feeds also on nectar, particularly in N of range (in austral winter). Nestlings fed with grasshoppers (Acrididae), cicadas (Cicadoidea) and large flying insects. Trawls high above the vegetation; makes sorties from perch, but sometimes pounces on visible prey. Occurs in pairs and small groups; also in large flocks, especially during migration.
Breeding. Breeds opportunistically Jul–Jan (mainly Sept–Dec) in S, irregularly in N. Nests solitarily, but more often in loose colony of up to c. 15–50 pairs, nests c. 10 m apart, sometimes in mixed colony with other woodswallows, mainly *A. personatus*. Nest built by both parents within a week of arrival at site, a loosely made shallow cup of twigs and grass, plant stems and rootlets, usually lined with finer material, generally at rather low height in tree fork, in hollow limb or stump, or behind bark, sometimes in creepers or in dense foliage, or in old nest of other species, occasionally in artificial site e.g. fence post or utility pole. Clutch 2–3 eggs, occasionally 1 or 4; incubation by both sexes, period 12–16 days, mean c. 13 days; chicks brooded and fed by both parents, nestling period 13–16 days, generally c. 14 days; fledglings continue to be fed by parents for at least a further 3 weeks after leaving nest. Colonies frequently abandoned suddenly, presumably because of food shortage.
Movements. Highly nomadic, most moving N in austral winter and returning S to breed in spring and early summer. Travels in large flocks of up to 200 individuals, often mixed with *A. personatus*; in C Australia numbers of present species in mixed flocks increase towards E, and in E of range (E of 140° E) present species predominates in such flocks and reaches farther S than its congener. Wanders irregularly over large parts of Western Australia, occurring sporadically in small numbers; shows similar pattern along coastal fringe of E Australia; vagrant to Tasmania and New Zealand.
Status and Conservation. Not globally threatened. Common locally, but irregularly, throughout its range. Has bred in Western Australia; has bred Tasmania. Possibly bred in New Zealand (South I) in 1970s.
Bibliography. Barker & Vestjens (1990), Barrett *et al.* (2003), Blakers *et al.* (1984), D'Ombrain (1934), Higgins *et al.* (2006a), Ingram (1973), Johnstone & Storr (2004), Joseph *et al.* (2006), Keast (1958), McCarthy (2006), Recher & Schulz (1983), Schodde & Mason (1999), Serventy & Whittell (1976), Sharland (1972).

9. Black-faced Woodswallow

Artamus cinereus

French: Langrayen gris **German**: Schwarzgesicht-Schwalbenstar **Spanish**: Artamo Carinegro
Other common names: Grey/Grey-breasted/White-bellied Woodswallow; White-vented Woodswallow (*normani*, *dealbatus*)

Taxonomy. *Artamus cinereus* Vieillot, 1817, Timor; error = south coast of Western Australia opposite Archipelago of the Recherche.
Race name *dealbatus* is a replacement for *hypoleucus* (itself a new name for *albiventris*, which preoccupied), since type specimen of *hypoleucus* is from an intergrade population. Geographical variation rather complex and not fully understood; races intergrade extensively where they meet, e.g. nominate race intergrading with *melanops* over very wide area across SW of species' range; further study desirable. Five subspecies currently recognized.
Subspecies and Distribution.
A. c. perspicillatus Bonaparte, 1850 – Timor, Leti and Sermata Is, in E Lesser Sundas.
A. c. melanops Gould, 1865 – N, C & inland SE Australia.
A. c. cinereus Vieillot, 1817 – SW Australia.
A. c. normani (Mathews, 1923) – SC New Guinea and NE Australia (C & S Cape York Peninsula, and inland NE Queensland).
A. c. dealbatus Schodde & Mason, 1999 – EC Queensland.



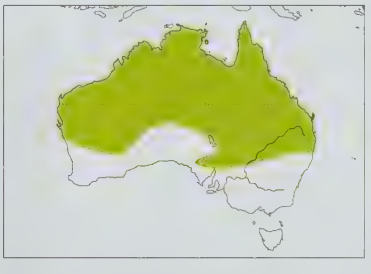
Descriptive notes. 18 cm; 30·9–40 g. Nominate race has head and upperparts brownish-grey, black from lores to upper throat, black rump and uppertail-coverts; tail black, all rectrices except central pair broadly tipped white; throat and underparts as above but somewhat lighter brown-grey, thighs blackish, vent black (occasionally a few small whitish tips); iris brown; bill pale blue-grey, tipped black; legs light slate-grey. Sexes similar. Juvenile differs from adult in having crown to hindneck browner and streaked whitish, black of face mask duller, upperparts brown with heavy whitish streaking, upperwing-coverts narrowly tipped white, remiges narrowly fringed white at tips, and throat and underparts finely streaked whitish. Races vary mainly in plumage tone, vent colour, and size: *melanops* is smaller than nominate, slightly less dark above and below, variable (somewhat darker below and with less black on throat in NW of range); *normani* is similar in size to previous, but has face mask smaller (not reaching throat), less extensive black on rump, vent and undertail-coverts white (not black) and sharply demarcated from belly, broader white tips on rectrices; *dealbatus* is very like last, but slightly paler below, with whitish belly centre, contrasting black band on rear flanks and across lowermost belly, also normally has slightly more extensive black on face (extending to throat); *perspicillatus* is similar to nominate but larger (largest race), and with white tips on all rectrices (i.e. including central pair). Voice. Very vocal, almost every movement accompanied by calls. Has noisy chattering call, like that of Common Blackbird (*Turdus merula*), when attacking an enemy; higher, drawn-out clamour, "tchiff-tchiff-tchiff", as contact; soft twittering song incorporating mimicry of other bird species, as well as all the other sounds of its own.
Habitat. Open woodland, shrubland and cultivation; absent from closed forest, where replaced by *A. cyanopterus* in SW Western Australia.
Food and Feeding. Insectivorous, taking wide variety of invertebrates. When locusts (Acrididae) present in plague numbers, becomes a specialist predator. Forages mostly aerially, by soaring and trawling, also by pursuing prey from a perch. In very windy weather, snatches prey from low perches or from ground. Forages in ones and twos, also in small flocks; often in mixed-species flocks.
Breeding. Season mainly spring to early summer, but eggs recorded in all months except Jun. Often breeds co-operatively, in groups of up to six individuals. Nest an open shallow cup, loosely made from rootlets, twigs and grass, sometimes lined with finer material, often unlined and so sparsely woven that eggs visible from below; placed 3–15 m above ground in tree or shrub, or in artificial site e.g. telephone pole, pylon or fence post. Clutch 1–5 eggs, usually 3–4; incubation by both sexes and by any helpers present, period 13–14 days, occasionally up to 17 days; chicks brooded and fed by all group-members, nestling period c. 18 days.
Movements. Generally resident; some movement reported, especially in N of range, but nature of this uncertain.
Status and Conservation. Not globally threatened. Widespread and locally common throughout range.
Bibliography. Barker & Vestjens (1990), Barrett *et al.* (2003), Beehler *et al.* (1986), Blakers *et al.* (1984), Crowley *et al.* (2004), Ford (1978), Higgins *et al.* (2006a), Horn & Vriens (1987), Immelmann (1960, 1963, 1966), Johnstone & Storr (2004), Joseph & Wilke (2006), Keast (1958), Macdonald (1967), McCarthy (2006), Mees (1968, 1982), Recher & Davis (2005), Rowley (1999, 2002b, 2006), Schodde & Mason (1999), Serventy & Whittell (1976).

10. Dusky Woodswallow

Artamus cyanopterus

French: Langrayen sordide **German**: Rußschwalbenstar **Spanish**: Artamo Sombrío

Taxonomy. *L(oxia) cyanoptera* Latham, 1801, New Holland = Sydney, New South Wales, Australia.
Races weakly differentiated, and they intergrade in S South Australia (Eyre Peninsula region). Two subspecies recognized.
Subspecies and Distribution.
A. c. cyanopterus (Latham, 1801) – E, CS & SE Australia, including Kangaroo I (South Australia), islands in Bass Strait (King I, Flinders I) and Tasmania.
A. c. perthi (Mathews, 1915) – SW Australia E to S South Australia (Eyre Peninsula).



Descriptive notes. 18 cm; 21–47 g. Nominate race is mostly smoky grey-brown above and below; upperwing gunmetal-grey, white streak on outer web of outer 2–4 long primaries; tail black, all except central pair of rectrices tipped white; iris dark brown; bill pale blue-grey, tipped black; legs grey-black. Sexes similar. Juvenile differs from adult mainly in having dense whitish streaking above, tertials and upperwing-coverts with pale tips, narrow pale fringes on tips of remiges, diffuse pale streaking on underparts. Race *perthi* is very like nominate, but has less white on primaries (restricted to outer 2–3 long primaries) and less white in outer tail feather. Voice. Contact call a brisk "peet-peet", in flight or when perched; also brassy chirps or chirrups and a softer "vut-vut". Song quiet but animated, sometimes includes mimicry.
Habitat. Open forest, woodlands and agricultural areas receiving more than 400 mm annual rainfall.
Food and Feeding. Mostly insects; nectar and fruit, also some seeds, occasionally taken. Captures animal prey usually on the wing while trawling above canopy, or snatches items in pursuit from a perch. In windy weather may forage on the ground, and take ants (Formicidae). Forages singly or in small parties, sometimes in larger flocks; occasionally in mixed-species flocks.
Breeding. Season Aug–Feb (mainly Oct–Dec), in austral spring. Nests usually as simple pair; sometimes breeds co-operatively, with one or two helpers. Nest, built by both members of pair, an untidy, shallow open cup made from twigs, rootlets and grass, lined with finer materials (sometimes including horsehair), occasionally unlined, placed in crotch or fork of tree or shrub, in hollow limb or stump, behind bark or on weathered top of fence post. Clutch 2–3 eggs, sometimes 4, rarely 1; incubation by both sexes, period 14–15 days, sometimes up to 17 days; chicks brooded and fed by both parents, also by any helpers present, nestling period 16–19 days, generally 18 days.
Movements. General movement N during autumn–winter. Leaves Tasmania in Apr, migrants reaching N as far as Rockhampton (E Queensland); generally returns in spring to same breeding locality, arriving in Oct.
Status and Conservation. Not globally threatened. Common locally throughout its range. May have benefited from increase in available habitat following clearance for agriculture; such clearing, however, also permits competition with *A. cinereus* in Western Australia.
Bibliography. Baird (1991a), Barker & Vestjens (1990), Barrett *et al.* (2003), Blakers *et al.* (1984), Fulton (2005), Higgins *et al.* (2006a), Hindwood (1956), Johnstone & Storr (2004), Maddocks & Geiser (2007), Marchant (1986b), Rowley (1951, 2000), Schodde & Mason (1999), Serventy & Whittell (1976).

11. Little Woodswallow

Artamus minor

French: Petit Langrayen **German**: Zwergschwalbenstar **Spanish**: Artamo Chico

Taxonomy. *Artamus minor* Vieillot, 1817, Shark Bay, Western Australia.
Two subspecies recognized.
Subspecies and Distribution.
A. m. derbyi Mathews, 1912 – N & E Australia (S, in E, to N New South Wales and E South Australia).
A. m. minor Vieillot, 1817 – Western Australia (Pilbara and Murchison regions) E to ranges of S Northern Territory and NW South Australia.

Descriptive notes. 12 cm; 13·1–20·9 g. Nominate race is dark chocolate-brown above and below, becoming dark grey on rump and grey-black on uppertail-coverts, with deep gunmetal-grey wings and tail; somewhat darker, more blackish-brown, on face; tail tipped white on outer rectrices; iris dark brown; bill pale blue-grey, tip black; legs gunmetal-grey. Differs from similar *A. cyanopterus* mainly in smaller size and lack of white on primaries. Sexes similar. Juvenile is similar to adult but somewhat paler, has diffuse buff streaking above and below, buff tips on upperwing-coverts, and narrow buff fringes at tips of flight-feathers. Race *derbyi* is smaller than nominate, and perhaps more often has dusky cast to plumage. Voice. Vocalizes less frequently than other members of family. Brisk "peet-peet" (1–4 notes) in flight, also softer "peep"; song a pleasant soft twittering, including mimicry of other bird species.
Habitat. Open scrublands, rocky hills, cliffs and breakaways; also open woodland. Associated mainly with cliffs, escarpments and rocky outcrops.
Food and Feeding. Mainly insects; nectar taken occasionally. Captures prey generally in flight; occasionally among foliage or flowers, or on ground. Forages singly and in pairs, also in small flocks; occasionally in mixed-species flocks, usually with congeners.
Breeding. Not well known. Eggs recorded Sept–Jan. Occasional co-operative breeding, with one or two helpers. Nest, built by both sexes, a shallow open cup of sticks, grass, plant stems and similar material, flimsily constructed, placed on ledge in cave or in crevice among rocks, sometimes in hollow in tree. Clutch 1–4 eggs, usually 2–3; incubation period (for two eggs) 16 days or shorter; chicks fed by both parents, nestling period (for one chick) c. 16–20 days; one juvenile seen fed by both parents.
Movements. Not well known. Probably resident in some areas, e.g. parts of Western Australia; also partly migratory and locally nomadic.
Status and Conservation. Not globally threatened. Common locally throughout range. May have benefited in some areas from increase in available habitat following clearance for agriculture.
Bibliography. Barker & Vestjens (1990), Barrett *et al.* (2003), Blakers *et al.* (1984), Chapman (2000), Higgins *et al.* (2006a), Johnstone & Storr (2004), Schodde & Mason (1999), Serventy & Whittell (1976).

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family CRACTICIDAE (BUTCHERBIRDS)

- Medium-sized to large passerines, most with longish wings, long tail, long and generally stout bill with hooked tip, ground-foraging species short-tailed; plumage black and white, sometimes with grey, two species with red.
- 18–57 cm.

- Australia and New Guinea.
- Rainforest, eucalypt forest and savanna woodland.
- 3 genera, 12 species, 43 taxa.
- No species threatened; none extinct since 1600.

Systematics

As was the case for much of the Australian fauna, early travellers and ornithologists tried to fit newly discovered birds into known families from Europe or Africa, and the cracticids were, therefore, thought to belong in the shrike family (Laniidae) or the crow family (Corvidae). J. Latham, in 1801, described the Grey Butcherbird (*Cracticus torquatus*), with its large hooked bill, in the shrike genus *Lanius*, and the Australian Magpie (*Cracticus tibicen*) in the genus *Coracias*, a roller (Coraciidae); the Australian Magpie was later placed by G. R. Gray in a new genus, as *Gymnorhina tibicen*. In 1837, J. Gould assigned Latham's "*Lanius torquatus*" to the genus *Vanga*, in which he likewise placed the Pied Butcherbird (*Cracticus nigrogularis*). He described the Pied Currawong (*Strepera graculina*), a large black bird the size of a crow, in the genus *Corvus*, although he later recognized the relationship of the three genera *Cracticus*, *Gymnorhina* and *Strepera*, believing them to be close to the Laniidae.

Some influential ornithologists were clearly uncertain about the relationships of these three genera. Thus, R. B. Sharpe, of the British Museum, initially placed *Strepera* in Corvidae while keeping *Gymnorhina* and *Cracticus* in Laniidae, in which he retained them when he later used the family Streperidae for *Strepera* alone. G. M. Mathews followed this arrangement in his 1912 publication *A Reference-List to the Birds of Australia*. J. A. Leach's anatomical study in 1914 established that *Strepera*, *Gymnorhina* and *Cracticus* were closely related, as Gould had asserted, and assigned them to the family Streperidae. Mathews, in Volume 10 of his *Birds of Australia*, published in 1923, placed the three together in the family Cracticidae (see page 46), and he maintained this in later publications, although the 1926 Royal Australasian Ornithologists Union *Checklist* used the family name Streperidae.

In the years between the 1926 checklist and C. G. Sibley and J. E. Ahlquist's publication on the Australian passerines, in 1985, the family included only the three genera *Cracticus*, *Strepera* and *Gymnorhina*. D. Amadon reviewed the family in 1951, and this formed the basis of the section on the Cracticidae in the 1962 volume of J. L. Peters's *Check-list of Birds of the World*, edited by E. Mayr and J. C. Greenway. None of these arrangements included the woodswallows (*Artamus*), until the studies based on DNA–DNA hybridization, by Sibley and Ahlquist, supported by the protein-allozyme studies of L. Christidis and R. Schodde, found that the old Cracticidae and the woodswallows were close relatives, with the New Guinea genus *Peltops* an early offshoot of the lineage giving rise to the butcherbirds, the Australian Magpie and the currawongs. *Peltops* had previously been classified as a monarch-flycatcher (Monarchidae), while the close relationship with the woodswallows had been hinted at by earlier anatomical studies such as those by W. P. Pycraft, Leach, W. J. Beecher and A. McEvey, which showed that the two genera shared some morphological characters, especially of the skull, in addition to the bluish-white bill. Sibley and Ahlquist treated the new group as the tribe Artaminae of their subfamily Corvinae within a greatly expanded family Corvidae. Current usage in Australia treats

Within Cracticidae, the butcherbirds (Cracticus) *possess the longest bills in relation to body size. That of the* ***Hooded Butcherbird*** *is also particularly wide and deep at the base, and very massive and powerful. The members of* Cracticus *have distinctive bluish-white bills, a feature they share with the woodswallows (Artamidae), a group which DNA analysis has shown to be the Cracticidae's closest relatives.*

[*Cracticus cassicus cassicus*, Tabubil, New Guinea. Photo: Pete Morris]

With the exception of the genus Peltops, *the Cracticidae are black, white and grey in plumage coloration. Species of denser habitats are predominantly black. The nominate race of the rainforest-living* ***Black Butcherbird*** *has a glossy blue-black back, and duller black underparts. However, immatures of the race* rufescens *may be either rufous-brown or dull black, and sometimes both plumage types are found in the same brood. Butcherbirds gradually acquire adult plumage over several years.*

[*Cracticus quoyi rufescens*, Kuranda, Queensland, Australia. Photo: Phil Gregory]

Artamidae as one of a number of families within the superfamily Corvoidea, following the 1994 *Taxonomy and Species of Australian Birds* by Christidis and W. E. Boles, Schodde and I. J. Mason's 1999 *Directory of Australian Birds*, and Christidis and Boles's 2008 *Systematics and Taxonomy of Australian Birds*.

Recent molecular studies by F. K. Barker and colleagues and by J. Fuchs have supported the relationship with *Artamus*, but have also corroborated the judgement made by Gould, who had named the Pied Butcherbird as a vanga and placed the Australian cracticids with the true shrikes in the family Laniidae. The work of Barker and colleagues suggests that the *Artamus–Cracticus* group is close to the Asian ioras (Aegithinidae) and the African bush-shrikes (Malaconotidae), helmet-shrikes (Prionopidae) and batises (*Batis*). More recent investigations, by Fuchs and by R. G. Moyle, suggest that, at some point 24–20 million years ago, one branch of an old corvoid lineage split to give rise to one lineage that dispersed out of Australia, and to another that diversified within Australia and New Guinea and from which arose the woodswallows, the butcherbirds, the Australian Magpie, the currawongs and the peltops species. The closest relatives of the Cracticidae and the Artamidae would thus appear to be helmet-shrikes, batises, bush-shrikes and ioras, and also the Bristlehead (*Pityriasis gymnocephala*) of Borneo. Earlier work by Sibley and Ahlquist had suggested that *Pityriasis* should be included with the cracticids, but studies by Moyle place it clearly with the malaconotid bush-shrikes.

The ancestral habitats of Australian passerines were probably the rainforests that covered much of the region more than 30 million years ago. As Australia became progressively drier, the rainforest diminished in extent until it was finally reduced to patches in the north and along the east coast. Some birds remained in the rainforests, whereas other adapted to the drier conditions and became widespread. At various times in the last 30 million years, most recently less than two million years ago, Australia and New Guinea were contiguous across what is now the Torres Strait. Some species that occur only or predominantly in New Guinea, and are widespread in rainforest habitats, such as the Black (*Cracticus quoyi*) and Hooded Butcherbirds (*Cracticus cassicus*) and the Highland (*Peltops montanus*) and Lowland Peltops (*Peltops blainvillii*), may have been isolated in New Guinea during an early period when the two landmasses were connected. Other species, such as the Australian Magpie and the Black-backed Butcherbird (*Cracticus mentalis*), may have evolved in drier habitat in Australia, and spread across the landbridge to the drier southern part of New Guinea during the most recent connection. At the same time, the Black Butcherbird may have spread to suitable rainforest or mangrove habitat in northern Australia.

Within the family Cracticidae, one area of discussion over many years has been the generic position of the Australian Magpie, which has often been placed in the monotypic genus *Gymnorhina*. Mathews briefly included this species within *Cracticus* in 1912, but he did not maintain that arrangement later. G. M. Storr, in 1952 and subsequent publications, treated the Australian Magpie as a member of *Cracticus*. Other authors have maintained *Gymnorhina*, while agreeing that further investigation is warranted. An unpublished study of the Australian species by R. T. Chesser and J. ten Have, based on mitochondrial and some nuclear DNA, has indicated that the Black Butcherbird and the Australian Magpie are each other's closest relatives, within the group of *Cracticus* species which is the sister-group to the *Strepera* species. Within the genus *Cracticus*, the Grey Butcherbird and the Black-backed Butcherbird are closely related, and there is some indication that, in *Strepera*, the Pied Currawong is closest to the Grey Currawong (*Strepera versicolor*), contrary to the usual view that it is most closely related to the Black Currawong (*Strepera fuliginosa*). Schodde and Mason, in 1999, maintained *Gymnorhina* as distinct from *Cracticus*, emphasizing its adaptations for terrestrial foraging, including long legs and a long, strong bill. Almost a decade later, Christidis and Boles followed Storr in placing the Australian Magpie in *Cracticus*, as they did not consider foraging adaptations sufficient reason for retaining *Gymnorhina* as a separate genus. This treatment is considered the preferable one in the present arrangement.

The Grey and Black-backed Butcherbirds have sometimes been placed in a separate genus, *Bulestes*, and the Black Butcherbird was at times accorded its own monotypic genus, *Melloria*, but there seems no good reason to retain these genera. As with the Australian Magpie, all three are currently treated within *Cracticus*.

Relationships among cracticids at the species level are not in dispute, with the exception of the position of the Australian Magpie. At the level of subspecies, however, a comprehensive review relating morphology to modern molecular-genetic analyses remains to be undertaken. Some recent studies, by L. Joseph and colleagues on *Artamus* and by J. M. Hughes and others on the Australian Magpie, have raised the possibility that the described morphological variation is of recent origin in response to ecological factors, and is not matched by genetic variation that would justify separation of populations at the subspecies level.

Butcherbirds have a style of flight which is fast, level and direct. They sometimes intersperse rapid, powerful flapping with shallower wingbeats, or gliding with wings held close to the body. In contrast, currawongs (Strepera) *have an undulating flight, their deep, jerky wingbeats interspersed with deeper swoops. The* ***Grey Butcherbird*** *has a white patch in the secondary coverts, which is visible in flight and is particularly well marked in the race* leucopterus. *There is a white tip to the tail, but this is normally abraded.*

[*Cracticus torquatus leucopterus*, Geelong, Victoria, Australia. Photo: Peter Fuller]

One poorly known member of this family is restricted to the island of Tagula in the Louisiade Archipelago, off south-east New Guinea. This is the Tagula Butcherbird (*Cracticus louisiadensis*), the relationships of which are uncertain. It appears to be close to the Hooded Butcherbird, which is widespread throughout New Guinea. Indeed, some authors have suggested that it might be conspecific with the latter. Until more is known about the Tagula taxon, however, it is probably better to treat it as a separate species.

The widespread species of the Australian mainland display considerable variation in size and plumage, as a consequence of which large numbers of subspecies have been described, with many regions of two-way and three-way intergradation between them and many hybrid forms. The degree to which this is matched by underlying genetic variation has been investigated only for the Australian Magpie. The detailed genetic studies carried out by Hughes, P. B. Mather and colleagues on a large number of individual magpies, representing all eight of the Australian subspecies currently accepted by Schodde and Mason, found little congruence between genetic variation and morphological variation. The main genetic differences are those between eastern and western birds, whereas the main morphological differences are between black-backed forms in the north and north-west and white-backed forms in the south. It is suggested that, whereas the black-backed form is less conspicuous and would be favoured in open, northern habitats, a white-backed variant would have survived in the better-forested, closed southern habitats and would have been favoured by sexual selection, females preferring white-backed males. It is questionable whether the recognition of so many subspecies of the Australian Magpie, with so much complex intergradation among them, and races often differentiated only by size, is appropriate. Further study of genetic differences between populations is required in order to shed some light on the situation.

The pattern of subspeciation in the widely distributed Australian species, the Grey and Pied Butcherbirds, is characterized by variation from east to west, as with the Australian Magpie, but neither Amadon nor Schodde and Mason recognized the many subspecies of these two species that were described in the past. For the Pied Currawong, with its north–south distribution in eastern Australia, and the Grey Currawong, extending from east to west in southern Australia, many subspecies are recognized, and it will be interesting to see how a future study of genetic variation in *Cracticus* and *Strepera* will compare with that found in the Australian Magpie. Joseph and Hughes and their respective colleagues have suggested that the morphological variation is of recent origin, in response to environmental factors, in populations that expanded rapidly after a period of aridity associated with Pleistocene glaciation, and that it is not matched by genetic variation.

Among Victorian populations of the Pied Currawong, Schodde and Mason distinguished two forms that differed from the medium-sized black-and-white nominate race of the east coast north of Sydney. One, from eastern Victoria, was a large sooty form with less white in the wings and tail than the nominate race, and the other, from western Victoria, was a small sooty-slate form with only traces of white. The large form was described as a new subspecies, *nebulosa*, while the small form was *ashbyi*, a name used by Mathews in 1913. Intermediates between these two races exist, and Schodde and Mason suggested that *ashbyi* is a regional form once separated from *nebulosa* but now being invaded, and genetically swamped, by it. S. T. Garnett and G. M. Crowley proposed that habitat changes in response to the end of Aboriginal burning regimes might have allowed the spread of *nebulosa*.

In the case of the Grey Butcherbird, the two north-western subspecies, *argenteus* and *colletti*, are separated from the other races of the species by significant desert barriers. These two are sometimes considered to represent a separate species, the "Silver-backed Butcherbird", a treatment recently preferred by Schodde and Mason, who considered that *argenteus* is at least as close to the Black-backed Butcherbird as it is to the Grey Butcherbird. The ranges of the three "species" do not overlap, and where that of the nominate race of the Grey Butcherbird abuts the range of the Black-backed Butcherbird there is no evidence that the two intergrade. The "Silver-backed Butcherbird" shares some plumage characters with the Grey Butcherbird and others with the Black-backed Butcherbird. Schodde and Mason believed that the relationships were better expressed by maintaining *argenteus* (with *colletti*) as a distinct species, forming a superspecies with the Grey and Black-backed Butcherbirds, until their relationships are better resolved by molecular analysis. The subspecies *colletti* is often subsumed into *argenteus*, but it seems to be reasonably distinctive.

Morphological Aspects

The Cracticidae are fairly typical passerines divided into three genera that have distinct modes of foraging, for which they exhibit morphological adaptations. The family covers a large range of sizes, from the small *Peltops*, 18–20 cm in length and with a body mass of about 30 g, to the Grey Currawong, 57 cm and

weighing up to 500 g, the last being crow-sized but not so robust as a *Corvus* crow. Between these extremes are the butcherbirds, ranging from the Grey Butcherbird, at 28 cm and 94 g, to the Black Butcherbird, 38 cm and 180 g, and the Australian Magpie, which is 40 cm long and weighs about 300 g.

Only the flycatcher-like genus *Peltops* of New Guinea, with its striking red rump and lower underparts, is an exception in its plumage, all other members of the family being characteristically black, white and grey in coloration. These plumage patterns render the butcherbirds, the currawongs and the Australian Magpie almost invisible when they are perched in the broken, patchy light in the open canopy of a eucalypt (*Eucalyptus*). The sit-and-pounce predators of open habitats, the Pied, Grey and Black-backed Butcherbirds, are the best example of this. Birds living in denser habitats are predominantly black. Many cracticids have extensive white patches on the wing, back or abdomen that are particularly obvious when the bird is flying. Only the Black Currawong of Tasmanian forests and the Black Butcherbird of the rainforests of New Guinea and north Queensland appear entirely black, although the Black Currawong does have a greatly reduced white wing patch.

With most of the species, sexual dimorphism in plumage is not marked, often being just a slight difference in pattern or a duller appearance that may enable the sex of individuals to be recognized. The males of most species are larger than the females. In the widespread Australian Magpie, some of the nine subspecies exhibit only slight plumage differences, whereas others are distinctively different. Males of the races *dorsalis*, *hypoleucus* and *tyrannicus* have a brilliant white back, their respective females having the back black with white scalloping.

The butcherbirds and the Australian Magpies, but not the peltops species or the currawongs, show a distinctive bluish-white bill with a black tip. This is a feature they share with the woodswallows, a group with which cracticids have been linked in many modern classifications (see Systematics). The bill of juveniles is typically leaden in colour, gradually acquiring a bluish-white appearance in one to two years in the case of the butcherbirds and two to four years in the Australian Magpie.

All cracticids are predators of insects and small vertebrates, but they catch their prey in different ways, as reflected in the details of their morphology. Some species also eat fruits and seeds. The butcherbirds have the longest bill in relation to body size within the family; the bill is strongly hooked. With their relatively long wings and tail, these species are effective, manoeuvrable strikers and pouncers. The bill of some butcherbirds, particularly the Black and Hooded Butcherbirds, is not only long, but also wide and deep at the base, very massive and powerful; this may be linked with the component of fruit in the diet or to the size of animal prey taken. Compared with the rest of the family, the ground-foraging Australian Magpie has long legs and a short tail for its size. Its bill has only a slightly hooked tip, is relatively shorter and stouter, and is used for probing and digging in the ground. The currawongs, although larger, are more slender than the magpie, and have a long bill, which is not hooked at the tip, and a long tail. Much of their foraging consists of arboreal scavenging and gleaning. Cracticids are strong fliers, the currawongs with a characteristic undulating flight in which the white patches in the wings of the Pied and Grey Currawongs are strikingly obvious. Australian Magpies have a strong direct flight, and are sometimes heard before the bird itself is seen, because of the whooshing noise produced by the wing movement as the bird passes. A white patch at the leading edge of the inner wing is very obvious as the magpie flies towards an observer.

Although the Cracticidae share many skeletal features with other corvoids, such as the single pneumatic fossa in the humerus, they have several distinct features of the skull, in the region of the palate and orbit, which they share with the woodswallows. One of the most easily observed of these is the presence of two zygomatic processes, instead of one; these are discussed in detail by Schodde and Mason. Many of these features were first described in the work by Leach, in 1914, demonstrating that the butcherbirds, the Australian Magpie and the currawongs are closely related (see Systematics).

Adults undergo a complete post-breeding moult during a period of three to four months, from early summer to mid-autumn. As the timing of the breeding season varies with seasonal conditions and latitude, so the timing of the post-breeding moult is variable. About three months after fledging, the juveniles undergo a partial moult of the body feathers in which the soft and loosely textured feathers are exchanged for those with the texture of adult feathers, but retaining the brownish streaky mottled pattern of immature plumage. In the case of the butcherbirds, the yearlings

*The **Grey Currawong** is the largest of the cracticids, at 52 cm and up to 500 g. Although raven-sized, it is not as robust as a corvid. The races are very variable in plumage tones and pattern, and for a long time four separate species were recognized, but they intergrade wherever they come into contact. The nominate race is mostly mid-grey, with a blackish face, crown and throat, white vent, and white tips of flight-feathers; the male is larger and darker than the female. The race* melanoptera *is the same size as the nominate, but is much darker, and lacks the white tips to the flight-feathers.*

Previously classified as monarch-flycatchers (Monarchidae), the New Guinean genus Peltops *has been shown by DNA and protein-allozyme studies to be an early offshoot of the lineage that gave rise to the rest of the Cracticidae. At around 18 cm and 30 g, the peltops are the smallest members of the family. Their red rump and lower underparts are in colourful contrast to the black, white and grey plumages of the rest of the family. Both species live in tropical forest, but at different altitudes. The* ***Highland Peltops*** *is found in montane rainforest above 600 m, while the* ***Lowland Peltops*** *frequents lowland rainforest. The two do not overlap, and have strikingly different songs, but make use of similar parts of their respective habitats. They are observed most often in tall forest trees at the edge of open spaces, such as near landslips, treefalls or forest edge, and along roads or rivers. Large-headed and stout, with a powerful hook-tipped bill and forked tail, the Highland Peltops differs from the very similar lowland species in the usually more extensive white patch on the side of its head, and the larger and more conspicuous white patch on its upper back. Although the Highland Peltops is the larger of the two, its bill is the same size as that of its congener, and so appears proportionately smaller.*

have a post-breeding moult which may result in a more adult-like appearance but with some immature characteristics, such as streaks where the adult has white, and a generally browner appearance; some individuals may acquire full adult plumage at this stage. The Australian Magpie can take four or five years to gain the full appearance of an adult. In the second year, both sexes of this species have a female-like plumage, and by the third year most males display features of the adult male plumage, such as white on the back in the white-backed forms. For both males and females, however, a longer period is required before the glossy black feathers of the abdomen and the full extent of whitish on the bill are acquired. The moult of currawongs is not well known, but they appear to undergo a change from juvenile to immature plumage when about three months old, and then acquire adult appearance at about one year of age, with subsequent yearly post-breeding moults. No information is available on the moults of the two peltops species of New Guinea.

Habitat

Hardly any part of Australia or New Guinea is without at least one member of the family Cracticidae. The only areas in which none is found are the Great Sandy Desert of north-western Australia and the very high, treeless mountain regions of New Guinea. In Australia, the widespread Pied and Grey Butcherbirds and Australian Magpie live in open habitats, the open sclerophyll forests and woodlands that once covered large areas of Australia, including the belt of savanna woodland across the north. Here, the dominant tree species are usually eucalypts, but can also be species of acacia (*Acacia*), cypress (*Callitris*), paperbark (*Melaleuca*) or casuarina (*Casuarina*). A necessary habitat feature for these pouncing and ground-foraging birds is an open understorey of low grasses or shrubs. They live also in the more arid mallee woodlands, consisting of low-growing multi-stemmed eucalypts, and acacia woodlands where the understorey may be chenopod shrubland or spinifex grassland, which generally has large open spaces between individual plants. Provided that there are some trees available for nesting, roosting and loafing, these areas provide suitable habitat for the open-country butcherbirds and the Australian Magpie. A further *Cracticus* species, the Black-backed Butcherbird, lives in open habitats, but it is found only in the tropical savanna woodlands of the northern Cape York Peninsula, in Australia, and across the Torres Strait in southern New Guinea, either in eucalypt open forest or paperbark woodland with a grassy understorey. The population of Australian Magpies in New Guinea shares this habitat.

The remaining butcherbirds live in less open habitats. The Hooded Butcherbird and its apparently close relative the Tagula Butcherbird are found in dense lowland rainforest and second growth, to about 650 m. The former, at least, prefers areas with some open space, either treefalls in forest or along roads and rivers. In Australia and southern New Guinea, the Black Butcherbird is a species mainly of coastal habitats, riparian forests lining tropical rivers, rainforest patches and the extensive mangrove forests that fringe the coasts of southern New Guinea and northern Australia. In the rest of New Guinea, this species occupies forest, being found in most tropical forest types and plantations in the lowlands and up to about 1300 m. Finally, the two north-west Australian subspecies of the Grey Butcherbird, sometimes treated together as a separate species under the name of "Silver-backed Butcherbird" (see Systematics), live in coastal habitats, mangrove forest, riparian forest, small patches of rainforest and dense vine scrub.

Confined to New Guinea, the two peltops species both live in tropical forest, but at different altitudes. The Lowland Peltops frequents the canopy of lowland rainforest to an elevation of approximately 600 m, while the Highland Peltops is found in montane rainforest above this. The two do not overlap, and they have strikingly different songs. They are similar in the particular part of their habitat that they occupy: both species are observed most often in tall forest trees at the edge of open spaces, such as near landslips, treefalls or forest edges and along roads or rivers. J. M. Diamond observed that, in virgin forest, the two peltops species make use of tall trees emerging above the canopy, or on a ridge, from which they can sally out to catch insects.

The currawongs live in less open habitats than those preferred by Australian Magpies and Pied and Grey Butcherbirds. The primary habitat of the Pied Currawong is the open forests of east and south-east Australia, to the east of the Great Dividing Range and on its western slopes. This species extends into higher-rainfall open woodland, but not into the semi-arid and arid woodlands of

Aggressive towards intruders of their own species, cracticids also react very aggressively towards other species that may disturb them. Attacks are not confined to obvious predators posing serious threats, such as raptors and owls. ***Australian Magpies*** *will also mob small birds, such as Australasian Pipits* (Anthus novaeseelandiae), *reptiles such as snakes and goannas, and mammals such as possums, koalas and domestic cats. They are also notorious for attacking humans, particularly cyclists, during the breeding season, and every year people suffer serious eye injuries from such attacks.*

[*Cracticus tibicen tibicen*, Brisbane, Australia. Photo: Brian J. Coates]

Australian Magpies *have powerful feet with large, sharp claws, and during sustained attacks they may use these to cling to the victim. The target here is a Brown Falcon* (Falco berigora). *Mobbing, best known among Australian Magpies, is also performed by butcherbirds and currawongs. Alarm and rally calls are given to assemble the group, which flies at the intruder, often moving above and behind it, swooping down and pecking at its back and the back of its head. The intensity of the alarm call varies with the nature of the threat.*

inland Australia; in northern Australia, one subspecies of this currawong lives in rainforest. The Pied Currawong is now resident in some east-coast cities, Canberra, Sydney and Armidale, where mature parks and gardens with well-grown shrubs and trees provide food and shelter throughout the year. The Black Currawong, restricted to Tasmania and the islands in the Bass Strait, lives in moist mountain forest, both tall wet sclerophyll eucalypt forests, with canopy covering 70–90% of the ground below, and cool-temperate rainforests dominated by southern beech (*Nothofagus*.). It occurs also in tableland habitats, comprising moorlands, sedgelands and heathlands, so long as some trees are present. In the drier open forests of eastern lowland Tasmania, the Black Currawong is replaced by the Tasmanian subspecies *arguta* of the Grey Currawong, often known as the "Clinking Currawong". The Grey Currawong lives in a wide range of eucalypt forests and woodlands across southern Australia, from the tall wet sclerophyll forests and open forests of the south-east to those of the south-west, and through the eucalypt woodlands, including mallee woodlands, in between. In the drier areas of Victoria, South Australia and Western Australia, it may live in *Acacia* woodlands with a shrub or spinifex understorey, and even in arid shrublands where occasional trees are present. This species has not moved into cities as has the Pied Currawong, but it is often seen in exotic pine (*Pinus*) plantations and orchards. As land has been cleared for agriculture, more open habitat has been created for the Australian Magpie at the expense of the forests preferred by currawongs.

General Habits

Australian members of the family Cracticidae that live in or near towns or in closely settled areas are well known. These are the Australian Magpie, the Pied Currawong, and the Grey and Pied Butcherbirds. The other species, living only in more remote areas of Australia and New Guinea, are less well known, with a few brief reports of their social and other behaviour. The social life of the cracticids ranges from the large groups with complex mating and breeding patterns, as demonstrated by the Pied Butcherbird and some races of the Australian Magpie, to the pair-breeding Pied Currawongs that amalgamate into large migratory or nomadic flocks after the breeding season. In between are most of the other butcherbirds and the two peltops species of New Guinea, most observations of which are of pairs or small family groups in which one or more immatures remain with their parents at least until the next breeding season.

The Australian Magpie occurs throughout most of Australia and southern Papua New Guinea, and in all areas of its range pairs or groups are resident. Some or all defend all-purpose territories throughout the year. There is significant geographical variation in basic social organization and in the size of territorial groups; in some of this species' nine races, non-breeders form non-territorial flocks, which can contain as many as 100 individuals. Because of the Australian Magpie's commensal way of life, numerous brief accounts of its behaviour have appeared in Australian and New Zealand bird journals, summarized by P. J. Higgins and colleagues in 2006. Detailed studies have been carried out on the behaviour of several of the subspecies.

Australian Magpie groups are sedentary, remaining in the territory all year. The size of the territory varies with race and habitat, but no studies have yet investigated the relationships among habitat quality, group size and territory size. Not all subspecies are equally well known, and in Australia detailed studies have been done of the race *terrareginae* near Brisbane, in Queensland, and of *tyrannicus* in northern Victoria, by Hughes and co-workers, of the nominate race near Canberra, in the Australian Capital Territory, by R. Carrick, and of *dorsalis* in south-western Western Australia by I. C. R. Rowley and E. Rowley (Russell) and others. In the populations studied near Brisbane, most groups consisted of only two individuals during the breeding season; later, groups of up to five were observed, these including immatures until they dispersed before the next breeding season. Throughout Queensland and the Northern Territory, group sizes are small, of two to five individuals, and non-territorial flocks are not generally encountered. The fieldwork by Carrick near Canberra was one of the first detailed studies of demography and social organization of an Australian passerine based on marked individuals. The study areas included some with good breeding habitat for this species, as well as areas of poorer habitat. Carrick identified four types of territorial group, based on the quality of the territory held. The commonest type was a permanent group in a territory with good breeding and foraging habitat; such groups were the only ones to breed successfully. A second type consisted of marginal groups, with few breeding sites and poor foraging areas; these rarely bred successfully. Similarly, mobile groups, which defended a small breeding area and commuted to poor foraging areas, rarely succeeded in their breeding attempts. The fourth type, consisting of open groups, with no breeding sites, did not attempt to breed; they defended foraging areas against the non-territorial flock. As well as these various groups, there were non-territorial flocks, ranging in size from a few individuals to more than 100, which contained immatures and non-breeding adults, including failed breeders or birds that had lost a partner, and individuals that were not yet established in a group with a partner.

In southern populations of Australian Magpies, those in Victoria, Tasmania and South Australia, group sizes are significantly larger. Units of two individuals are rare, and groups generally

contain up to 15 adults, including more than one adult male and more than one adult female. In these groups, more than one female may nest, and in the study by Hughes and others up to five occasionally did so. Non-breeding flocks are also present, and in times of drought they can hold more than 100 individuals. Group sizes are largest in south-west Western Australia, where, in the early study by Angus Robinson, groups of 6–12 adults and subadults were recorded, with groups of up to 20 after the breeding season. A study carried out by P. Wood and H. F. Recher in Kings Park, a large area of parkland in central Perth, recorded groups of 2–9 individuals, with a mean of five, and the Rowley team's study of suburban magpie groups in an area of Perth bounded by riverine floodplain recorded groups of 2–13 at the start of the breeding season, with a mean of 6·1 over a nine-year period. No non-breeding flocks are seen in south-west Western Australia, where subadult males and females remain with the natal group at least until they are nearly two years old, when some males or females may disperse. The majority, however, stay with the natal group, and females eventually breed there, most groups having more than one breeding female. In the study in suburban Perth, the maximum number of white-backed males, those more than three years old, was seven, and the maximum of females was five. The largest recorded group, containing 13 individuals, included five adult males, five adult females, a single one-year-old female and two immatures from the previous breeding season. The studies by Hughes and others have shown that, in these large plural breeding groups of closely related individuals, the level of extra-group mating is very high (see Breeding).

*Groups of **Australian Magpies** may defend all-purpose territories throughout the year. However, among the different races there is significant variation in basic social organization, and in the size of territorial groups. Group organization and size is also influenced by habitat quality. All members of the group except the youngest juveniles take part in responses to intruders. According to the severity of the intrusion, responses range from parallel walking displays in boundary disputes with conspecific groups, to displays of increasingly aggressive swooping which may escalate into physical attacks. The victim of these Australian Magpies is a **Grey Currawong**. In this kind of attack, one or more birds fly above the victim, and force it to the ground. Group members are also aggressive to one another. This can involve puffing up the feathers to look larger and more intimidating, or a jab with a closed bill at an opponent. A more serious form of aggression within groups involves rushing at an opponent and jumping on its back, after which the birds may wrestle, lying on their sides on the ground and pecking at one another. Young birds may respond to aggression with submissive behaviour; juvenile Australian Magpies, for example, roll onto their backs with their feet in the air.*

[*Cracticus tibicen tibicen* and *Strepera versicolor versicolor*, Geelong, Victoria, Australia. Photos: Peter Fuller]

*After a cold night, cracticids may be found sunning themselves, as this **Black Currawong** shows. They may adopt a number of postures, from face down with the wings extended, to lying on their sides, or, as has been observed in Australian Magpies* (Cracticus tibicen)*, leaning against a surface such as a wall with the belly exposed. The feathers are ruffled to allow the warmth of the sun to penetrate. The birds may enter a trance-like state, in which it is possible for a human observer to approach them closely. A similar posture to this Black Currawong's has been observed in other families, when passively anting—allowing ants to run over them. This behaviour has not been observed in Cracticidae, where the few records of anting involve the birds placing the ants directly on their plumage.*

[*Strepera fuliginosa fuliginosa*, Tasmania. Photo: Don Hadden]

Groups, then, are formed by the retention of progeny within family parties. Such groups are remarkably stable over many years. For example, Wood and Recher's observations in Kings Park repeated a survey made six decades before by H. M. Wilson, and it was found that seven of the nine group territories recorded by Wilson were still occupied. The survival rate of established breeding adult Australian Magpies is high. For example, in ten of the 13 groups studied for ten years by the Rowley team, at least one individual that had been ringed in the first year of the study, in 1996, was still there at the start of the October 2005 breeding season. New birds joined established groups from outside only when the adult breeding male or female in the group disappeared. Established groups rarely broke up or disappeared; on the rare occasion when this was observed, it appeared to follow the disappearance of the dominant adult male in a group in which he was the only adult male. Carrick, in his Canberra study of what were smaller groups, reported a similar break-up or displacement of groups upon the loss of the dominant male. The larger groups studied at Seymour, in Victoria, by Hughes and others appear to be similar in most respects to those in south-west Western Australia.

Where all good breeding habitat is occupied all year by long-lived individuals, young birds are better off if they remain in their natal territory than if they disperse to poorer habitat. Large groups are better able to defend a good territory, and the act of allowing young birds to remain is, therefore, of benefit if the territory is good enough. There must, however, be a point at which the group is too large for the territory to support. It is tantalizing to speculate on the reasons for the observed differences in social organization of the Australian Magpie: pairs and no flock, a breeding group and non-breeding flocks, a large breeding group only and with no non-breeding flock. The type of social organization employed must reflect the balance between the production of juveniles, survival and the availability of good breeding habitat, but this information is not yet available for enough subspecies to allow the comparison to be made.

Such obviously group-living birds are automatically assumed to be co-operative breeders, any non-breeding individuals in the group helping to feed nestlings which are not their own offspring. In some early studies of Australian Magpies, probably of the south-east Australian race *tyrannicus*, introduced into New Zealand, C. J. Veltman failed to confirm the feeding of nestlings by group-members other than the mother and her male partner, and branded the Australian Magpie a species that was not a co-operative breeder. Work on other subspecies suggests that the magpie version of co-operative breeding is very much more complex than the simple helper-at-the-nest model would suggest; Australian

*Cracticids like this **Black-backed Butcherbird** use the bill for preening, except when dealing with the head and neck. These are raked with the claws, the leg being brought up over the wing. Quick bouts of preening may occur at any time, but during the hottest part of the day, cracticids of open habitats retire to the shade of trees to rest and preen more thoroughly. Intensive preening also follows bathing. Having bathed, flocks of Pied Currawongs* (Strepera graculina) *in Sydney preened in bouts lasting 5–10 minutes, first running the bill through the feathers of the throat and breast, and then through those of the wings and rump.*

Magpies are group-living and, in the case of some races, plural breeding, with a variable and sometimes very high level of extra-group mating (see Breeding). Groups may have non-breeding male and female members two or three years old, in addition to several adult males and females of breeding age. Studies by Hughes and others in Victoria have established that individuals other than the female parent and her male associate, if any, frequently feed the nestlings and, to an even greater extent, the fledglings. These helpers were birds in their first year or older, and studies of genetic relationships revealed that not all helpers were closely related to the nestlings that they fed, and that not all related potential helpers fed the nestlings. The Rowleys' observations at nests of the subspecies *dorsalis* in south-west Western Australia demonstrated that non-breeding group-members, generally young males or females, may help to feed the nestlings, but occasionally an old male brings food to a nest. Feeding at the nest by non-breeding helpers varies from group to group, but the feeding of fledglings by group-members other than the mother is more frequent. An important aspect of group behaviour in all studies, including that of Veltman, is the group defence of the territory, the nest and the fledglings. This is discussed in more detail later (see Breeding).

The defence of the territory is very much a group affair. All members except young juveniles take part. A constant element of territory defence is that of advertising by a kind of singing behaviour generally referred to as Carolling, a loud, melodious song given by all older group-members while standing with the head thrown back, the bill pointing up and the chest puffed out (see Voice). Early in the morning, bouts of Carolling are given, to which all neighbourhood groups respond. Border disputes and territorial intrusions are met with a variety of displays, from parallel walking displays in mild boundary disputes, with and without threat displays, to noisy aerial swooping displays involving all group-members and accompanied by loud alarm calls. Nesting Australian Magpies may direct these swooping displays at passing humans, sometimes causing serious injury to the latter (see Relationship with Man).

The basic threat display in aggression, both between and within groups, was termed the Puffed Posture by E. D. Brown and Veltman. The belly, flank and back feathers are erected, making the bird look much larger than it really is; the wings are held out from the body, depressed from the shoulder, showing the white wing patch, and the primaries are not fanned. In a slightly more intense threat, the bird stands tall, with the bill pointing down. This threat is most frequently directed by adults towards young individuals, especially those in their first year. There are many variants of this posture. In the most extreme one, the Elaborate Bill Down, the wings are drooped, with the primaries fanned, and the bird leans forwards while holding the body horizontal and the closed bill pointing down. A quick lunge with bill-snapping may also be given in any of these situations. Contact fighting within or between groups occurs at various levels. The lowest level involves a simple jab with the closed bill at an opponent. Rushing at the opponent and jumping on its back is a precursor to Wrestling, in which the two birds grip each other's feet tightly and peck each other, usually while lying on the ground on their sides. Somewhat more aggressive is a fight in which one or more individuals fly above another and force it to the ground, where they attack it. Finally, in the Dive-bomb, an aggressor knocks an opponent off a perch, flying at it and hitting it with force, this often accompanied by bill-snapping. The victim may fly away or it may stay and fight. This behaviour is frequently directed at human intruders near a nest.

Submissive or defensive responses to threats appear to occur most often within groups, and are given by young individuals, in their first or second year, in response to threats from adults. The threatened bird may crouch, with the feathers fluffed and the wings slightly drooped, or it may cringe, leaning away from the aggressor, with the folded wings held above its body. Young Australian Magpies, especially juveniles, most frequently respond to threat by lying on the back with their feet in the air; they may remain lying on the ground after the aggressor has departed. Angus Robinson, in his observations of the race *dorsalis*, recorded a Lyre-wing Submissive Display, given most often by immatures, and described also by Brown and Veltman. In this, the bird runs along with its wings extended and held above its back, slightly away from its body.

Australian Magpies, in addition to utilizing Carolling song, make use of a number of variations in flight for territorial advertisement and defence. Robinson described Tilt Flight, in which the bird tilts from one side to the other as it flies, with about five to seven wingbeats for each lateral tilt. This is sometimes performed also by intruding males as they escape through a rival group's territory, usually flying high above the treetops. In the Swoop Up display, described by Brown and Veltman, the displaying individual flies fast and directly 3–6 m above the ground, and then swoops upwards almost vertically for about 5 m. This occurs during inter-territorial clashes, or in a spontaneous boundary display. Another boundary display is that which Robinson termed the Semicircular Sally, usually performed by males, in

Pied Currawongs *bathe by wading into shallow water, squatting, and shaking the wings and dipping the head and back several times beneath the surface. They may repeat this up to four times, wading in and out of the water each time. They also bathe in rainwater dripping from leaves. A rather different form of maintenance also performed by this species involves scooping up mud or clay and rubbing it into the feathers while preening after bathing.*

[*Strepera graculina*, eastern Australia. Photo: Jean-Paul Ferrero/ Ardea]

*Cracticids vocalize throughout the year, and both sexes and all group members sing, but two categories of song are exclusive to dominant males. After the breeding season, and usually during the middle of the day, the main male in the group delivers a soft, extended song from a regular perch, known as Whisper, Warble or Autumn Song. The Whisper Song of the **Grey Butcherbird** contains elements of the Territorial and Breeding Songs, together with mimicry of other birds, and may continue for over an hour. The varied and complex Breeding Song is given early in the breeding season, starting before first light. It may advertise the male's location to females outside the group, as part of a system of extra-pair copulation.*

which the individual flies out to the nearest boundary from a central perch, then along the boundary for about 50 m, and then returns to its starting point. The flight is fast, direct and low. Many of these display-flights employ very noisy wingbeats; the human observer can hear the bird as it flies overhead and, without looking up, know that it is a magpie.

A group display involving the Carolling song is sometimes given when two groups of Australian Magpies are close together at a territory boundary, without fighting. In the Territory Carol, one individual begins a song with a short series of Warble Song elements (see Voice); it raises its bill above the horizontal and fluffs its breast and belly feathers. After the warble, a series of loud, long Carol elements is added by each bird in turn. Brown and Veltman suggested that there is a definite sequence in which the birds contribute their Carols.

Another group-living species of *Cracticus* is the Pied Butcherbird, which was studied in farmland on the outskirts of Brisbane, in southern Queensland, by Ann Robinson. Groups of 3–15 individuals, most commonly six, lived throughout the year in large territories of 13–22 ha. These groups contained at least one male and at least one female, but, since the birds could not easily be sexed on the basis of plumage, details of group composition are sparse. Groups contained an adult breeding female, young from the previous year, and other adults, some of which were offspring of the group from earlier years and some immigrants from other groups. Generally, only one female in the group bred, but occasionally a second female nested, albeit rarely successfully. Significant numbers of extra-group matings were recorded, as were many instances of intraspecific brood parasitism. Most individuals in the group helped to feed the nestlings and to look after the fledglings. Young stayed with the group at least until they were nearly two years old, when some dispersed; this timing coincided with the start of the second breeding season after the one in which they hatched. There was no indication that the young were evicted. Dispersing immatures eventually joined other groups, and there was no sign of a flock of non-breeding individuals. As with the Australian Magpie, much territorial defence was achieved by song, but relatively little information is available on other aspects of the Pied Butcherbird's territorial defence.

Other *Cracticus* butcherbirds are not well known. All are resident, and appear to maintain territories through the entire year. As with the Australian Magpie and the Pied Butcherbird, the most obvious method of territory defence is that of song, often given in antiphonal duets. There is little information on group size and composition for these species, apart from recorded observations that they may be seen in pairs or groups. In southern Australia, young Grey Butcherbirds have been recorded as remaining with their parents until the following breeding season, and helping to feed the young in the nest, but no studies of marked individuals have been undertaken. For the Hooded Butcherbird of New Guinea, W. S. Peckover and L. W. C. Filewood reported several pairs nesting quite amicably in close proximity to each other, while B. J. Coates quotes a report of four adults observed while feeding one nestling. In the light of the complex group structure of the Australian Magpie and the Pied Butcherbird, it is likely that some other species in the genus will have a similar social organization.

The two *Peltops* species from New Guinea are also resident throughout the year in a territory, but little more is known of their behaviour.

The best-known aspects of the behaviour of the currawongs relate to their movements and feeding habits, especially nest predation (see Movements, Food and Feeding). No detailed studies have been done on these species' social behaviour and social organization, which are consequently not well known. The seventh volume of the *Handbook of Australian, New Zealand and Antarctic Birds*, published in 2006, summarizes the many anecdotal reports and few detailed studies of the movements of the three *Strepera* species, the Pied, Black and Grey Currawongs. All are originally forest-dwellers, living in the forests of the Great Dividing Range of eastern and south-eastern Australia, of Tasmania and of south-western Australia. All three appear to be partial migrants, mostly altitudinal migrants, leaving the higher mountain forests for lower levels in winter; those pairs living in permanently favourable habitat are likely to be resident. Thus, unlike butcherbirds and the Australian Magpie, not all currawongs maintain territories throughout the year.

Pied Currawongs near Canberra studied by D. M. Prawiradilaga maintained breeding territories, including nesting and feeding areas, of 5–12 ha from August to December, while K. A. Wood's detailed study of several nests near Wollongong, in New

*Pairs or groups of **Australian Magpies** produce sequences of loud, melodious yodelling calls, known as Carolling. This is thought to have several functions, including territorial advertisement and defence, and group bonding. It is also used to signal that a good food source has been located. Other species join in duets, antiphonal singing or choruses, which may involve all group members, and which are thought to serve similar functions to Carolling. Carolling and territorial singing occur at all times of year, and at any time of the day. A senior male or female Australian Magpie normally begins a bout of Carolling, which is often performed from the ground.*

[*Cracticus tibicen tibicen*, Geelong, Victoria, Australia. Photo: Peter Fuller]

South Wales, reported a small breeding territory within a larger home range. In the latter case, both members of the breeding pair, but especially the male, defended a small area around the nest. The pair used a much larger home range when foraging, venturing up to 300 m from the nest, thereby covering an area of more than 20 ha. Within this area, other currawongs were observed to pass through, but they were not attacked unless they approached within 40 m of the nest. The family moved away from the area after the young had fledged. Whether the difference in territorial behaviour between Canberra and Wollongong is real or is just a matter of definition is not clear. Observations of other nests quoted by Wood suggest that territory size may vary with habitat.

In Tasmania, the Black Currawong is resident all year in some parts of the highlands, breeding in territories in spring–summer and remaining in flocks in winter, although some populations appear to descend to lowland areas after breeding (see Movements). The subspecies found on islands in Bass Strait, *colei* on King Island and *parvior* on Flinders Island, are both resident. Whether they maintain territories in their breeding areas is not recorded.

The third currawong species, the Grey Currawong, is generally thought to be sedentary, but it does seem to undertake some altitudinal movements (see Movements). Those living in Western Australia are said to maintain large permanent territories all year, but no detailed studies of Grey Currawongs have been carried out in any part of the species' range.

Among the cracticids, only the Australian Magpie and the currawongs form flocks at some time of the year. In the case of the former species, some of the races form flocks of non-breeding individuals while the breeders and their social group, if any, remain all year in the group territory. The non-breeding flock is made up of immatures, subadults, failed breeders and individuals that have lost a breeding partner. Currawong flocks may include breeding birds and their offspring that have left the breeding territory at the end of the season, and moved to different foraging areas in late summer and winter. Flocks of non-breeders probably exist throughout the year, and may remain separate from the flocks of breeders. The Pied Currawong in eastern Australia is most notable for its flocking behaviour, in part because of its loud, well-known calls and the size of its flocks, which can exceed 100 individuals, and partly because of range extensions to towns and cities. These built-up areas provide food all year around, so that birds which were once seasonal immigrants to, for example, Canberra, in the Australian Capital Territory, or Armidale, in New South Wales, are now permanent residents in those cities. Flocks of Black Currawongs are a familiar sight in Tasmania, but Grey Currawong flocks in southern Australia are much smaller, less noticeable and, in many areas, absent or no larger than a family group.

All members of the family are strong fliers, but there are clear differences between the currawongs and the butcherbirds. The flight of *Cracticus* species, which consist of the butcherbirds and the Australian Magpie, is fast, level and direct. These species sometimes intersperse rapid, powerful flapping with some shallower wingbeats or, in the case of the butcherbirds, short periods of gliding with the wings held close to the body. When flying through their own territories, Australian Magpies fly with shallow wingbeats, at or below the level of the treetops; intruders or strangers fly high above the treetops and use deeper wingbeats. The flight of currawongs is undulating, with deep, rather jerky wingbeats, interspersed with deeper swoops with the wings held close to the body.

When on the ground, butcherbirds may forage by hopping and, occasionally, running, although they usually pounce from a perch to the ground. Australian Magpies, with relatively long legs, are terrestrial foragers which walk or run, and will often, rather than flying, run a distance of 10–20 m in a rolling gait towards another individual or to a food source. Currawongs run or hop on the ground, sometimes moving in a succession of leaps.

Drinking is not an obvious feature of the behaviour of Australian Magpies, except during the summer months. In south-western Australia, in a habitat with long, dry summers, magpies were seen to bathe only infrequently, in pools left by rain. In south-east Australia, on the other hand, this species was found to bathe frequently in summer in shallow water, wetting the entire body by submerging in the water, fluttering the wings and wagging the tail. Such bathing is followed by a period of intensive preening. Most preening is done with the bill, except for the head and neck, which are raked with the claws, the leg being brought up over the wing in the indirect method of scratching. Allopreening is not often seen, occurring between a female and her offspring, although in one study a male was reported as preening an incubating or brooding female. In other studies, including that by Brown and Veltman, the observers recorded that allopreening by adult magpies was conspicuously absent.

Early on sunny mornings, after a cold night, these birds may sun-bathe. Many reports describe Australian Magpies as lying

*The calls of the **Black Currawong** include a musical "kar-week, kar-week", a long drawn-out rolling croak, and an incessant chattering scream. Although vocalizations in this species have been little studied, they are probably equivalent to the "currawong" call of the Pied Currawong* (Strepera graculina). *This has been found to be used in territorial advertisement, as an alarm call, in communication between members of a pair, and in flight by members of the flocks that form outside the breeding period.*

[*Strepera fuliginosa fuliginosa*, Mount Field, Tasmania. Photo: Peter Fuller]

on the ground, face down, with the wings extended to the side or meeting in front of the head, and the feathers ruffled; others describe the birds as lying on their side. The sun-bathing Australian Magpies observed in Perth parks were leaning with the back against a brick wall warmed by the sun, the sun's rays striking the exposed belly. Individuals in this posture appear to be asleep, and often they did not move until the observers were close beside them.

Relatively few observations have been made of the maintenance behaviour of other members of this family, although some details are available for two of the currawongs. Pied Currawongs bathe by wading into shallow water no deeper than about 15 cm, squatting, and then shaking the wings and dipping the head and back several times beneath the surface; the entire process may be repeated in one session of bathing, the birds wading in and out of the water up to four times. This species has been observed also to bathe in water dripping from leaves of trees following rain. In Little Desert, in Victoria, a group of about 20 Grey Currawongs gathered to drink in a pool of water, where they also splashed their wings while remaining near the edge of the pool.

Bathing is usually followed by preening. Flocks of Pied Currawongs in Sydney, for example, preened in bouts lasting 5–10 minutes, first running the bill through the throat and breast feathers, and then through those of the wings and rump. An interesting aspect of the preening behaviour of this species has been recorded in which, during or after bathing, the individual rubs mud, moist soil or clay into its plumage. One was seen to preen with damp clay for a period of 30 minutes, picking up soil in its bill and rubbing this into the plumage every 20 seconds or so; it took four breaks, in which it bathed for 10–15 seconds. After preening with mud in this way, it sometimes flew to a tree and continued preening, but it did not always wash the clay from its plumage afterwards. Similar behaviour has been recorded for the Grey Currawong. At Kinglake, in east-central Victoria, a family party of this species consisting of two adults and a juvenile, after having bathed in water-containers, proceeded to scoop up wet clay in the bill and then apply this to the body. The juvenile emitted squawking calls until an adult placed clay in its bill, whereupon it, too, daubed itself. All three individuals continued to apply clay to the plumage for about half an hour.

Anting has been recorded for the Black-backed Butcherbird in New Guinea and for the Australian Magpie and the Pied Currawong in Australia. The last two species, at least, placed ants (Formicidae) directly on to the plumage, but little else is known of this behaviour among the Cracticidae.

The usual daily routine of the Australian Magpie entails an early-morning Carolling chorus, the group challenging and replying to nearby groups. This is followed by a period of foraging, and in the middle of the day the birds retreat to trees, where they rest and preen; they are not in a tight group at this time, but spread through adjacent trees. Late in the afternoon, they indulge in a further period of foraging, before finally going to roost at last light. They usually roost together, having one or more favourite trees for this purpose. For the race *dorsalis* in south-western Australia, Angus Robinson described a Dusk Song, a repeated Carolling given by one of the group males from a high exposed tree in the territory, between sunset and nightfall, before going to roost with the rest of the group.

Few details are available on the roosting behaviour of other cracticids. The Grey Butcherbird roosts at night in trees, and has been known to use exotic pine (*Pinus*) plantations for this purpose. In a suburb of Sydney, the members of a pair were found to roost together in the same tree during the breeding season, but they roosted separately at other times. Similarly, in suburban Brisbane, Pied Butcherbirds usually roost in a tree near the nest-site when breeding. More information is available on the Pied Currawong. In a study near Armidale, this species was found to roost communally in forest during the cooler months of the year. In winter, flocks left the roost-sites in the early morning, from 06:15 to 06:25 hours, and moved into nearby built-up areas, where they foraged for much of the day, returning to the roosting sites in the late afternoon, between 16:55 and 17:20 hours. Farther south, at a site north-west of Melbourne, again in winter, Pied Currawongs dispersed in small flocks from their forest roosts

Pied Currawongs *forage by gleaning on the ground, and on the trunks and branches of trees. They probe in crevices and under loose bark, sort through litter, and turn over stones and cow dung in search of arthropods, snails and small vertebrates. On the ground, currawongs run or hop, sometimes moving in a succession of leaps.* ***Australian Magpies****, which do most of their foraging on the ground, have relatively long legs and short tails. They walk slowly, looking for prey on the surface. Smaller prey is consumed immediately, but larger items are held, shaken and bashed against the ground, or held with the feet and torn apart.*

[Left: *Strepera graculina nebulosa*, Canberra, Australia. Photo: Tony Howard.

Right: *Cracticus tibicen tibicen*, Lamington National Park, Queensland, Australia. Photo: Marie Read]

With their relatively long wings and tail, butcherbirds are effective, manoeuvrable strikers and pouncers. Although it will sally in pursuit of flying insects, the ***Pied Butcherbird*** *finds most of its food by perching on a branch, and scanning the ground. On spotting a spider, insect or perhaps a small vertebrate, it will drop to the ground to catch it. Butcherbirds are like shrikes (Laniidae) in their manner of handling prey: large items may be wedged into a crevice, or impaled on a thorn or barbed wire before being torn apart; surplus food may be cached in crevices or on thorns. Note the absence of the adult's white collar in this juvenile Pied Butcherbird.*

[*Cracticus nigrogularis picatus*, Mitchell Falls, Australia. Photo: Don Hadden]

each morning between 07:00 and 10:00 hours and returned in the late afternoon between 17:00 and 17:30 hours, spending the intervening time in nearby open areas. The roosting site of a winter flock of this species in Sydney varied, and the flock sometimes separated, its members using two or more sites for sleeping overnight; in the late evening, the birds dived into the crowns of tall trees, from where they gradually moved down into denser foliage.

Just as they are very aggressive towards individuals of their own species that intrude upon them, so do the cracticids react very aggressively towards intruders of other species. In the case of group-living species such as the Australian Magpie, the intruder is mobbed by all members of the group, and sometimes, if it is an owl (Strigidae) or raptor, also by birds from nearby groups or a non-territorial flock. Australian Magpies will also join a mobbing attack initiated by another bird species. Similarly, with pair-living species, the pair and its neighbours mob an intruder. Mobbing is best known for the Australian Magpie, but it is performed also by butcherbirds and currawongs. When the intruder is first detected, alarm and rally calls (see Voice) are given in order to assemble the group, which then flies at the intruder, often moving above and behind it, swooping down and pecking at the back of its head and its back. Magpies will mob large birds such as owls, including the Morepork (*Ninox novaeseelandiae*), and large raptors, including the Wedge-tailed Eagle (*Aquila audax*), small birds, the Australasian Pipit (*Anthus novaeseelandiae*) being one such example, mammals such as possums (Diprotodontia), koalas (*Phascolarctos cinereus*) and domestic cats (*Felis catus*), and reptiles such as snakes and goannas (*Varanus*). P. J. Higgins and colleagues, in the *Handbook of Australian, New Zealand and Antarctic Birds*, list many of the species of intruder the mobbing of which by individual species of cracticid has been described, and D. N. Jones's book *Magpie Alert* has graphic descriptions of mobbing attacks by Australian Magpies on many species, including humans, possums and koalas left permanently blinded by such attacks.

Play behaviour is a common activity of the Australian Magpie, especially juveniles and immatures, and is well described in the studies by S. M. Pellis and by G. Kaplan. Play by the Black Currawong of Tasmania was briefly described by B. C. Mollison, but there is no relevant information on the other cracticids, although they are likely to indulge in similar behaviour. Young siblings of the Australian Magpie play with each other or with an adult. Social play increases in frequency until it reaches a peak 10–14 weeks after fledging. Most of this play is between two individuals, and usually involves chasing, mock fighting or the manipulation of objects, and tug-of-war. One individual solicits play by crouching, with the bill open, in front of another, or by crouching behind another and tweaking its tail feathers, or by chasing on foot or in flight. Bouts of play can last for up to ten minutes. Young Australian Magpies often pick up leaves or twigs and manipulate them, and this may lead to a chase or tug-of-war with a sibling. Pellis found that about one-third of play episodes involved chasing, one individual flying behind another and trying to grab its tail feathers so as to bring it down to the ground. Such chases involve much swooping up and down, and are probably good practice for the swooping attacks and chases that will later be used in territorial defence and anti-predator behaviour. More than half of all play episodes involve play-fighting, sometimes initiated by an adult male. The two individuals often lie on their side on the ground, wrestling, with the claws interlocked. The varied nature of play by the Australian Magpie is demonstrated by the many descriptions of this behaviour cited by Higgins and colleagues.

Voice

The butcherbirds, currawongs and Australian Magpie produce some of the most beautiful songs to be heard in the bush and forests of Australia and New Guinea. Only the vocalizations of the Grey and Pied Butcherbirds and the Australian Magpie have been studied in any real detail, those of the last-mentioned being the best known. Vocalizations of other *Cracticus* species, especially those from New Guinea, are not so well known. All have an extremely varied repertoire of sounds, including loud, long-distance harsh alarm calls, extended melodious songs, soft individual warbling song, and a variety of other calls, including distress calls, begging calls by juveniles, and various soft grunting sounds given in close contact by females and juveniles or by the members of a pair. Vocalizations, including song, are produced thoughout the year, some during the night in the breeding season by the Australian Magpie. Both sexes sing, the butcherbirds

with extended duets and antiphonal songs, and the Australian Magpie with long, complex bouts of group-singing when all group-members join in, this usually known as Carolling. Higgins and colleagues presented sonagrams of some vocalizations of all Australian cracticids, and the compilation of recordings by H. Plowright includes examples of the voices of this family. There appear to be no published studies in which the vocalizations within the family Cracticidae have been compared.

In an unpublished study of the Grey Butcherbird, G. P. Johnson identified three main types of vocalization. The first type was those given by a pair or family group during the day, at all times of the year, the second was those given by males at dawn during the breeding season, and the third type was a quiet warbling song given by males only. The group song is the Territorial Song, heard early in the morning and throughout the day, with an evening peak. It is loud and rollicking, containing some harsh cackling and some melodious warbling elements, often of a yodelling character. This song includes antiphonal singing and duetting, and involves males, females and other group-members; its main function is in territorial advertisement. The songs are not stereotyped, and Johnson's study explored their complexity. In the breeding season, males sing an early-morning Breeding Song, starting up to an hour before first light, and lasting for 13–47 minutes. This is also a very varied and complex song, with no harsh elements. Johnson suggested that the song serves to advertise the male's location and condition to females outside his own group as part of a system of extra-pair copulation. She identified a third major category of song which she called Whisper Song, heard most often after the breeding season and in autumn, usually in the middle of the day. The singer is the main male in the territory, and he delivers, always from a particular perch, a song much softer than the Territorial or Breeding Songs and continuing for long periods of up to an hour and a half. The song may include mimicry and phrases of Territorial and Breeding Songs, sung softly and continuously. Its significance is not clear. In her study, Johnson compared Grey Butcherbird vocalizations with those of the Pied Butcherbird, a larger species overlapping in distribution with the former in much of Australia. She identified the same basic types of vocalization, the main difference between the two species being in the beautiful and well-known territorial song of the Pied Butcherbird, given as a solo song or antiphonal duet, or in family chorus. The basic elements are long-drawn-out, pure, flute-like notes, and the song is a slow progression of flute-like notes, as if a flautist were improvising at random, but in fact a series of notes is produced in sequence by one or more singers; these are well illustrated in the recordings by D. Lumsdaine made at Mutawinji, in western New South Wales. The few descriptions and recordings of the voices of other butcherbirds in Australia and New Guinea indicate that these species, too, have complex, melodious songs, but they are not well known.

Johnson considered that the songs of the Australian Magpie are also of the three main types identified for the butcherbirds. Territorial Song is represented by the Carol, an extremely loud song, described by Kaplan as a long series of slurred, melodious, flute-like yodelling sounds, usually preceded by a warble from one individual, a dominant male or female. Carolling is often performed on the ground, and is thought to have several functions, including those of territorial advertisement, of group-bonding behaviour, in group disputes, and of signalling that a good food source has been located. A number of song variants described are Dawn Song, Dusk Song and Moonlight Song, short, relaxed carolling songs heard at different times of the day, particularly in the breeding season; the Moonlight Song, for example, is given by one individual, mainly on moonlit nights in the breeding season. These songs most likely belong to the Breeding Song type, but this requires further investigation. The Whisper Song type identified by Johnson appears to match the Warble Song described by Kaplan and the Autumn Song described by Angus Robinson. The Warble Song of adults is described by Kaplan as "soft, undulating, tuneful, melodious, with rich tones and overtones". Warbles are often given in a long sequence by a single individual, often from a preferred high perch. The song is heard particularly in autumn and early winter, and bouts of singing can last for longer than one hour. It is not loud and, although the bird sings from a high perch, it does not perch conspicuously. In the Rowley team's study, a tall tree in the garden was used as a singing perch for Warble Song by a male of the local group; he sang regularly for long periods, but it was always very difficult to see him and to identify him from his colour rings.

The basic alarm call of butcherbirds and Australian Magpies is a loud harsh squawk. A wide variety of alarm calls of different intensities is produced by Australian Magpies in response to different terrestrial and aerial predators. One of the most recognizable calls, named the Rally Call by Robinson, is a loud two-tone or three-tone call, carrying a long distance, and given during the mobbing of an aerial predator and during flight towards an intruder into the territory or near the nest: "The impelling tone of this call is such that all members of the group except odd very young birds, rally to the place of danger". Descriptions of this call of the Australian races by various authors refer to a two-tone call, but the Rowley team's experience of the subspecies *dorsalis* in Western Australia and that of Robinson and other sources quoted by him is that the Rally Call is more often of two short notes followed by a longer one. As with the Australian Magpie, the alarm calls of butcherbirds vary with the type of threat.

Studies by Brown and S. M. Farabaugh and by K. Sanderson and H. Crouch have demonstrated geographical variation in the alarm calls and song of the Australian Magpie, as well as individual variation in the Warble Song of the subspecies *tyrannicus*. Brown and colleagues analysed warbles made by 23 individuals from six territorial groups and a non-territorial flock, and found 893 different syllable types, few of which were shared by more than five birds, and 67% of which were specific to an individual. More syllables were shared with group-mates and neighbours than with more distant individuals. Mimicry occurs in the adult Warble Song, and includes imitation of many other bird species and mammals, and even of non-animal sounds heard frequently in the territory. A male in one of the study groups of the race *dorsalis* in Perth, in Western Australia, produced a very convincing rendition of the sound made by the siren of a police car, often heard in his territory near a major road.

Although, in general, the whole range of the vocalizations of the three currawongs is little studied, one call in particular is very well known. This is the Currawong Call of the Pied Currawong, probably its territorial advertisement, but also serving other functions. Wood's study of a nesting pair of this species found that it was employed as a means of advertising the territory, as an alarm when a nest predator came near, in expelling an intruder, and as communication between the members of the pair. It is uttered also in flight by members of the flocks that form outside the breeding season. The vocalization in question is a loud ringing call of

*The bill of the **Australian Magpie** has only a slightly hooked tip, and is relatively shorter and stouter than in other* Cracticus *species. It is used for probing in the ground. The bird's probing behaviour is clearly not random, and experiments have shown that it is able to hear the movements of beetles and their larvae, earthworms and other prey below the surface of the ground.*

[*Cracticus tibicen tibicen*, Geelong, Victoria, Australia.
Photo: Peter Fuller]

Perching and pouncing species like the ***Grey Butcherbird*** *need habitats, such as woodlands of* Eucalyptus *and* Acacia, *with an open understorey of grasses and other low vegetation, where prey like lizards can be more easily spotted. However, they readily adapt to similar man-made habitats like farms, parks and gardens. Grey Butcherbirds will sally from perches to take flying insects. They are also reported to take small flying birds, although more often they seize them from behind while they are foraging on the ground, killing them by spearing their heads with their powerful bills.*

[*Cracticus torquatus leucopterus*, Port Augusta, South Australia, Australia. Photo: Andy & Gill Swash/ WorldWildlifeImages.com]

two or three syllables, sounding like "curra-wong, curra-wong" or, in the case of Wood's breeding birds, "currah-currah-currong". It is probably variable within and between locations but, in the absence of detailed analysis, it is impossible to know if it is a single variable vocalization or something more complex. Johnson, in her comparison of cracticid vocalizations, identified a Breeding Song of the Pied Currawong, a song of two or three phrases, "ow-ooo, ow-ooo, ow-ooo", heard only in the breeding season, and unlike any other vocalizations given by this species. Bouts of singing are short, unlike those of the butcherbirds. The two other currawongs have an equivalent of the Currawong Call, frequently a noisy call, harsher and less ringing than that of the Pied Currawong, and often described as sounding like screams or croaks. Indeed, the Western Australian subspecies of the Grey Currawong, *plumbea*, is often referred to by the colloquial name of "Squeaker".

Finally, the two species of peltops in New Guinea are poorly known, but they appear to produce none of the ringing, melodious sounds of the other cracticids. Instead, various clicking and twittering sounds have been described for these species. Coates characterized the song of the Lowland Peltops as resembling the sound made by "winding a clock with a key".

Food and Feeding

The cracticids are predominantly predators of insects, other invertebrates, including earthworms (Oligochaeta), and small vertebrates, including frogs, small lizards and birds. Most members of the family eat seeds and fruits occasionally, while the diets of the currawongs include a much larger proportion of fruits, especially in the winter months, when insects are less active. Indeed, currawongs can at times become a pest in orchards and gardens (see Relationship with Man). The Pied Butcherbird and the Pied Currawong, as well as the two north-west Australian subspecies of the Grey Butcherbird, these last often separated under the name "Silver-backed Butcherbird" (see Systematics), have been recorded as feeding also on nectar of eucalypts and other flowering trees, such as those in the genera *Grevillea* and *Melaleuca*. Few of the species have been studied in detail, the exceptions being the Australian Magpie and the Pied Currawong. For most other cracticids, the best information available consists of anecdotal reports, as listed by Higgins and colleagues in the *Handbook of Australian, New Zealand and Antarctic Birds*.

The main foraging method of most butcherbirds involves simply perching in a tree or shrub and pouncing to the ground to catch insects or lizards, or sallying out from the perch to catch flying prey. These birds also move through the canopy, gleaning and snatching items from leaves and branches. The Black Butcherbird forages in the canopy of its rainforest habitat in New Guinea and northern Australia. Those living in the mangrove forests fringing the northern coast of Australia were recorded by R. E. Johnstone and Storr as foraging below the canopy on branches, tree trunks, prop-roots and the exposed mudflats, from which they seized crabs and small fish such as mudskippers (Gobiidae). Butcherbirds are also nest predators, and are extremely efficient at catching small birds, sometimes stalking them on the ground or taking them in the air. M. K. Tarburton recounted how a Pied Butcherbird dived into a tree and quickly swallowed three fledglings of a Willie Wagtail (*Rhipidura leucophrys*), after which it seized the tail of the attacking adult Willie Wagtail, manoeuvring the head into its bill, and killed it by crushing the head and neck.

Australian Magpies spend most of the time in feeding on the ground, and a large component of their diet is beetle larvae (Coleoptera) and underground insects. The probing actions of this species are clearly not random, and experiments by R. B. Floyd showed that the magpies were able to hear the sounds made by the insects, and to direct their probing at the source. A list of feeding observations made by A. B. Rose illustrates the opportunistic foraging of Australian Magpies: items taken included snails and slugs (Gastropoda), ants, beetles, earthworms, frogs, caterpillars, termites (Isoptera), grasshoppers (Orthoptera), lizards, a nestling turtle-dove (*Streptopelia*) and a snake.

Currawongs are the most omnivorous of the cracticids, with greater proportions of fruit and seeds in their diet, along with

In addition to perching and pouncing, and sallying, butcherbirds forage by moving through trees, gleaning and snatching. However, the prey of this ***Pied Butcherbird*** *is a snake, probably an olive whipsnake* (Demansia olivacea)*, a ground-living species, which the bird has probably carried into the tree to kill and dismember. Butcherbirds are efficient nest predators, well adapted to capturing and killing the adults at a nest, as well as the nestlings. While the Pied Butcherbird is a species of open woodlands, its congener the Black Butcherbird* (Cracticus quoyi) *is found mostly in closed canopy forests. The latter seems to vary its foraging behaviour according to its habitat. In the rainforests of New Guinea and northern Australia it may sometimes feed, like other butcherbirds, by pouncing on prey on the ground, but it mostly forages at heights of 8–30 m through the subcanopy and lower canopy. In mangrove forests, Black Butcherbirds hunt below the canopy on branches, trunks and prop-roots, and on the exposed mudflats from which they snatch crabs and small fish such as mudskippers. Rainforest was probably the original habitat of the ancestors of the butcherbirds, and species adapted to more open, arid habitats would have evolved as the climate became progressively drier.*

Although the diet of ***Australian Magpies*** *consists mainly of insects and other ground-living invertebrates, they will take any other prey they find at ground level, including rodents and other small mammals. The piece of wire that can be seen through this rodent's body suggests it may previously have been cached. Australian Magpies will eat carrion when available, as well as the insects and maggots found on carcasses.*

insects and small vertebrates. They are also well known as nest predators, especially in urban environments, and studies of Pied Currawongs indicate that, in particular, they take the nestlings of small birds to feed to their own nestlings. They forage by gleaning on the ground and on the trunks and branches of trees, probing in crevices and under loose bark, sorting through litter, and turning over stones and cow dung in order to obtain the insects beneath. They eat a wide range of fruits, from both introduced and native trees and shrubs, foraging both on the ground and in trees; the detailed study by Prawiradilaga demonstrated the importance of the fruits from introduced garden shrubs and trees in the cold Canberra winter, when insects are hard to find. The two subspecies of the Black Currawong living on the Bass Strait islands feed on invertebrates in the piles of giant kelp (*Macrocystis pyrifera*) that are driven on to the beaches at certain times.

New Guinea rainforests harbour two aerial foragers of this family, the Lowland Peltops and the Highland Peltops. These feed on flying insects, which they catch by sallying out from a high perch, sometimes snatching prey from foliage. There have been no detailed studies of the biology of these two, but they are reported as catching beetles, bugs (Hemiptera) and moths (Lepidoptera), which they take to a perch to prepare for consumption.

A very characteristic feature of the feeding behaviour of some cracticids is the shrike-like habit of impaling larger prey on a spike or wedging it in a crevice. They then tear pieces from it, either immediately or at a later time. This is a commonly seen habit of butcherbirds and currawongs, less often practised by Australian Magpies, and is not known for the two peltops species. In addition, Australian Magpies and currawongs cache surplus food, poking it into a grass clump or other suitable hiding place.

Breeding

The nest-sites and eggs of all Australian members of the Cracticidae have been described, as have those of the mainland New Guinea butcherbirds. Little is known of the breeding biology of the Tagula Butcherbird of the Louisiade Archipelago, off the south-east coast of New Guinea. A few nests of the peltops species have been found, but little more is known about these two New Guinea taxa.

The butcherbirds, the Australian Magpie and the currawongs build a bulky, untidy bowl of sticks and twigs, in which they lay a relatively small clutch of 2–5 eggs, clutch sizes tending to be smaller in New Guinea. The breeding habits of the Australian Magpie have been studied in considerable detail at several locations in Australia, and also in New Zealand, where the species has been introduced. For those other species which live close to towns and cities, such as the Pied and Grey Butcherbirds and the Pied Currawong, there is much anecdotal information and many nest records. Ann Robinson attempted to unravel the pattern of mating and extra-pair paternity among Pied Butcherbirds and provided some information on breeding, and Wood made detailed observations of nesting by Pied Currawongs. In general, the species of northern Australia and New Guinea are not well known.

Some species in this family live in groups with complex mating systems, high levels of extra-pair or extra-group mating, and their own unique forms of co-operative breeding. In its simplest form, co-operative breeding is characterized by the presence of breeding and non-breeding mature individuals in a group; the non-breeding members are sometimes called "helpers", and they may contribute to the reproductive effort of the breeding female by feeding the nestlings or caring for the fledglings after they have left the nest. Helpers are important also in the defence of the nest and the territory and in their role in attacking predators and intruders. This following account of the group mating and rearing patterns of the Australian Magpie is based on studies by Hughes and many colleagues in south-east Queensland and at Seymour, in Victoria; on observations by the Rowley team in Western Australia, some in collaboration with Hughes; and on the study by Carrick near Canberra, in the Australian Capital Territory.

A comparison of breeding groups of the Australian Magpie showed that, in south-eastern Queensland, most consisted of a simple pair, occasionally with a juvenile from the previous breeding season that had stayed on. The subspecies involved is *terrareginae*. Farther south, near Seymour, groups of the local race *tyrannicus* were much larger, containing 3–15 individuals, with an average of eight, and two to as many as five nests per territory, a situation known as "plural breeding". Similar large plural breeding groups occur in south-west Western Australia, where the subspecies *dorsalis* has been studied by several ornithologists, some having identified as many as five females nesting within an area of 1 ha. In Victoria, observations at nests established that adults of both sexes, as well as juveniles and subadults, helped to feed nestlings and fledglings that were not their own. Similar behaviour occurs in Western Australia, but it was not recorded in the introduced population of Australian Magpies studied by Veltman in New Zealand, where the race concerned, probably *tyrannicus*, forms groups smaller than those in Australia.

Genetic studies of the Victorian population suggest that non-breeding individuals sometimes did not feed young to which they were related, and it was found that the presence of helpers did not lead to increased production of fledglings by the group over the period of the study. These results are contrary to two of the suggested explanations for the occurrence of co-operative breeding, namely that the helpers assist in the rearing of close relatives, and thus receive a genetic benefit, and that their contributions increase the productivity of the group.

Within the complex plural breeding groups, some individual nesting females had a particular male partner which remained

close to the nest when the female was incubating or brooding, and which assisted in feeding the young. When groups had several nesting females, not all had a male partner; females breeding for the first time were often unassisted, and were rarely successful, whereas older females were capable of rearing a brood without help. A study of hormone levels in breeding and non-breeding adult and subadult males of the subspecies *dorsalis* in Western Australia, carried out by L. G. Schmidt and co-workers, found that androgen levels were similar in adult males whether classed as "breeding" or as "non-breeding", but subadult males in the presence of adult males in larger groups had depressed levels of androgens. This was interpreted as being a consequence of behavioural inhibition caused by the presence of dominant breeding males.

Extra-pair or extra-group copulations are now known to be common in many avian mating systems, although the 1956 study by Angus Robinson of the race *dorsalis* of the Australian Magpie referred to a despot male which, he assumed, mated with all the females in the group. Hughes and colleagues tested this assumption in a population of this subspecies in Perth, in Western Australia, and found a very high level of extra-group copulations, with 82% of nestlings fathered outside the group, most by unknown males from outside the study area. In the Victorian population of *tyrannicus*, the rate was 44%. The reason for this discrepancy is not yet fully explained, but one difference between the two study populations is that the Western Australian one has a much lower level of dispersal of young than the Victorian population; both young breeding females and young adult males in a group may be the offspring of one or two surviving breeding females. It may be that females improve their reproductive success by not breeding with close kin. Another suggestion is that females involved in extra-group copulations are seeking to mate with the best possible male, with "good genes", but the studies of the Victorian population do not support this idea.

With the other well-known group-living species, the Pied Butcherbird, groups studied by Ann Robinson rarely contained more than one breeding female. Some of the other group-members were immigrants, and some were surviving offspring of previous years which stayed with the group for at least two years. Most individuals in the group help to feed the nestlings, but their presence does not appear to lead to greater production of fledglings, although there may be some benefit to the breeding female in that her total effort in feeding nestlings is reduced. Significant numbers of extra-group copulations occurred, as well as cases of intraspecific brood parasitism, in which the sitting female was not the mother of one or more of the fledglings from her nest. This study gives a fascinating glimpse of the mating patterns found in Pied Butcherbirds, but much more work will be required in order to provide a greater understanding of this species, visible differences between the males and females of which are, at most, slight. The nature of the social system of the Pied Butcherbird became apparent only when individually marked birds were studied.

Breeding and mating systems of other butcherbirds and the two peltops species are little known. There are a few observations of more than two individuals attending a nest, or of birds nesting very close together, but no other of these species has been investigated in detail. The breeding behaviour of Pied Currawongs has been sufficiently well studied to establish that this species breeds in pairs in a defended breeding territory, and observations of its two congeners, the Black and Grey Currawongs, suggest that they are similar in behaviour.

Among Australian cracticids with an extensive distribution, the timing of breeding varies considerably, being influenced mainly by latitude and the seasonal distribution of rainfall for any particular population. In general, butcherbirds, Australian Magpies and currawongs breed in spring and early summer. Most clutches are laid in September–October, with some early nests in August in warmer areas; clutches laid in November or December are usually replacements after earlier failure, or second attempts after successful rearing of a first brood.

In a study of the subspecies *dorsalis* of the Australian Magpie in south-western Australia, where regular winter rainfall is at its peak in June and July, a total of 286 clutches was monitored over a nine-year period. It was found that the first clutches were laid in the second or third week of August, with a peak in the fourth week, and the last clutches were laid at the end of October. Despite annual variation in the timing and quantity of rainfall, the start of breeding was very constant. In years with little rainfall in September and October, however, few late nests were found; on the other hand, in years when rainfall in these months was above average, some females attempted a second clutch after a late failure, and some even attempted a second brood after the

While most cracticids will eat seeds and fruits occasionally, currawongs include a much larger proportion of fruits in their diet, especially in winter, when insects are less readily available. In autumn, flocks of ***Black Currawongs*** *move down from the cool temperate woodlands and heathlands where they breed, and may enter orchards and suburban gardens. Similarly, Pied Currawongs* (Strepera graculina) *descend in flocks on native and introduced fruiting trees and shrubs. In cities such as Sydney and Canberra, where they once occurred only as non-breeding visitors, fruiting garden plants have enabled Pied Currawongs to become resident.*

[*Strepera fuliginosa fuliginosa*, Tasmania. Photo: Drew Fulton]

first had fledged. Information on re-laying after failure and the laying of a second clutch after a first has fledged is not available for other cracticid species because of the lack of studies of individually marked birds.

In cooler Tasmania, egg-laying by Black Currawongs is usually later, from late October, and in the high country of the Australian Alps, in south-eastern Australia, Pied Currawongs start laying one or two months later than at the lower altitude of Canberra. Breeding by the Pied and Grey Butcherbirds and the Grey Currawong of the arid parts of Australia has been recorded in most months following adequate rainfall. Available records for New Guinea butcherbirds and the two peltops species, as summarized by Coates, suggest that most breeding occurs in the middle to late dry season, mainly September–October, with some earlier and later nests from August to late December.

Breeding displays of cracticids are neither elaborate nor conspicuous, as would be expected for a male and female living together in a pair or group throughout the year. With such aggressive, territorial species, the frequent extra-group copulations are likely to be rushed and surreptitious. Perhaps for this reason, few detailed accounts of courtship or pre-copulatory displays exist, although there are many fragmentary observations, these summarized by Higgins and colleagues. The most comprehensive account of breeding displays is that of Wood, based on observations at nests of the Pied Currawong. He describes an Advertisement Posture, seen in the breeding season, when an individual of either sex lands near the nest, droops both wings and cocks its tail, holding this posture for 30–60 seconds, during which the bird does not crouch. In the Food-begging Display, the female gives the food-begging call of the juvenile while the male is in view; if she approaches him for food, she partly spreads her wings and quivers them quickly six to eight times while calling, sometimes with the tail held cocked. In the Solicitation Display, given by either sex, the currawong crouches, quivering both wings while looking at the individual of the opposite sex; this is similar to Food-begging, but no begging call is given. Sometimes the neck is extended, with the bill pointing upwards, and occasionally the tail is wagged sideways.

Wood described in detail one copulation of the Pied Currawong. At the start of the sequence, the male flew into the nest tree, where the female was perched a few metres above the nest. She dropped down through the tree, gliding over the nest and landing below it; as she did so, the male gave a short series of wing-quivering bouts, the Solicitation Display. When the female landed below the nest, she assumed the crouched Solicitation posture, with the head tilted back and the bill raised. She looked towards the male and bobbed her tail vertically, for about 90 seconds, in eight to ten bouts, while the male maintained the Solicitation pose, with the head not raised but the body feathers ruffled. The male flew to within 25 cm of the female, on the same branch, and immediately began to quiver his outstretched wings; at the same time the two touched bill tips 12–14 times, the female then cocked her tail, exposing her vascular cloaca, and the male mounted her briefly. The whole sequence, from the male's flight into the nest tree until copulation was complete, lasted about five minutes. Similar food-begging, wing-quivering solicitation has been described for the Pied Butcherbird and the Australian Magpie.

Nests have been described for all cracticids except the Tagula Butcherbird. The rest of the butcherbirds, the Australian Magpie and the currawongs all build a bulky, untidy nest, a flattened bowl of sticks and twigs, well lined with grass, shredded bark, casuarina needles, wool, vine tendrils, and similar soft material. Australian Magpies commonly incorporate into the nest fencing wire, lengths of electric cable, generally with bright plastic covering, or lengths of plastic string or rope, if such materials are available. This has been reported also for butcherbirds. Currawongs and Australian Magpies usually place the nest in a fork in the outer canopy of a tall tree, whereas butcherbirds tend to build in lower trees and saplings. Nests of the two peltops species are small and compact, and are generally placed in a horizontal fork in the outer canopy.

The nest is built by the female, with or without with assistance from the male. In the case of the Australian Magpie, the female alone builds, the male sometimes remaining nearby, but not in close attendance. Studies of the breeding behaviour of the Pied Currawong revealed that, in some instances, the male may help to gather material and even build the outer framework, but the female lines the nest. Observations of the better-known butcherbirds, the Pied and Grey Butcherbirds, indicate that males may help with nest-building.

The eggs of cracticids are more or less oval in shape, and variable in colour and markings both within and among species.

*Standing water can be relatively rare in the open, semi-arid habitats used by **Pied Butcherbirds**, so they make the most of sources such as drinking troughs and puddles of rainwater. They drink warily, peering around them after lifting the bill to swallow. They can, however, become very tame where they are fed regularly. Clearance of forests for agriculture has created new foraging habitat for Pied Butcherbirds, and together with the provision of water for livestock and irrigation, this has enabled them to extend their range, at the same time as urbanization is causing them to decline elsewhere.*

[*Cracticus nigrogularis*, Queensland, Australia. Photo: William Osborn/ naturepl.com]

Some cracticids live in groups, with complex mating systems and co-operative breeding. While little is known of the breeding behaviour of the two Peltops *species, their arrangements appear to be simpler. The* ***Lowland Peltops*** *is territorial, and the pair is present in the territory all year round. There are reports of additional birds, probably the single offspring of the previous year, helping out at the nest. In the family as a whole, courtship displays have been described for a few species. As might be expected of birds that stay together as a pair or group throughout the year, the displays are not elaborate, consisting, for example, of juvenile food-begging calls made by the female, and wing-quivering solicitation by both sexes.*

[*Peltops blainvillii*, Kiunga, New Guinea. Photo: Pete Morris]

Those of the Australian Magpie are pale blue or green in colour, sometimes with darker blotchy markings at the blunter end. The base colour of currawong and butcherbird eggs ranges from dirty white to grey, various tones of olive and brown, with darker blotchy markings at the large end. The eggs of peltops are poorly known, but are reported to be yellowish-white with a reddish tinge, and with dark blotches at the blunter end. Clutches are small, and exhibit little variation. Most species lay from two to five eggs, with a mean clutch size of three in Australia. New Guinea species tend to lay smaller clutches, and complete clutches of only one egg have been reported for *Peltops*. There is little information about the time intervals between the laying of each egg, in part because many cracticid nests are situated high up in trees. For the more accessible nests of butcherbirds, there are some reports of the eggs being laid at intervals of about two days.

Only the female incubates. While she is sitting, her male partner spends a lot of time close to the nest, either perched in the nest tree or one nearby, or feeding on the ground close to the nest. He may take food to his sitting partner. There are also times when the male is absent; from his observations of breeding Pied Currawongs, Wood interpreted this as indicating that the male was on excursions in search of extra-pair copulations. Incubation periods are not well known for most species of this family. The exceptions are the Pied Butcherbird, the Pied Currawong and the Australian Magpie, for which they are 20–23 days, and the few records for other members of the family seem to fall in this same range.

Nestlings of Australian Magpies and currawongs are naked on hatching, and down develops within one week. Butcherbirds, when they hatch, may be naked or covered with sparse down. All have acquired a juvenile plumage when they leave the nest; subsequently, butcherbirds and currawongs achieve adult plumage at about one year, but Australian Magpies may not gain full adult plumage until they are three or four years old. Other aspects of growth and development are little studied. Studies of the Pied Butcherbird, the Pied Currawong and the Australian Magpie indicate that the young leave the nest permanently after about one month, although for a few days before that time they may leave for short periods and sit on nearby branches. When they finally depart, their wings and tail are not fully grown, and they are capable only of scrambling, fluttering flight. They remain out of sight for about a week, perched inconspicuously in a tree, giving away their position by loud begging when an adult approaches with food.

Among group-living species, the male and female, and sometimes one or more helpers, once the eggs have hatched, begin to carry food to the nest. For the first week, the breeding female broods the nestlings almost continuously; she takes food delivered to the nest by others, and passes it on to the chicks. Later, when the nestlings have some covering of feathers, she leaves the nest from time to time in order to forage, and food is then delivered directly to the nestlings by the male and any helpers that may be present. In the case of the Pied Currawongs observed by Wood, once the female left the nest for extended periods, the male and female contributed more or less equally to the provisioning of the nestlings. In the group-living species so far studied, namely the Australian Magpie and the Pied Butcherbird, the contribution to brood-feeding made by individual group-members is very variable. Group sizes vary, as do the age and sex of the group-members and their individual relationship to the breeding female. Although observations at nests of Australian Magpies and Pied Butcherbirds have established that other group-members do help to feed nestlings, an understanding of which members help in this way, and why, is still a long way off. A great deal more investigation of the relationships among group-members, the paternity of the nestlings and the contributions of the different individuals is required.

Attempts to explain the contributions of helpers recognize that there has to be some benefit to the helper so as to balance the costs both of finding food for the nestlings and possibly of its own foregone reproduction. This benefit could be indirect, if the helpers are feeding nestlings with which they share genes, perhaps via their own mother, a so-called "kin benefit", or it could be direct, providing some tangible benefit to the helper, and also to the senior group-members that allow the helper to stay. From studies of Australian Magpies and butcherbirds hitherto, helpers appear to have little effect on the reproductive success of an individual breeding female that is assisted, and extra-group copulations reduce the degree of relationship between the helper and the nestlings. It is possible that other males in a group may share paternity of a brood, and thus feed their own offspring, but this has not been clearly demonstrated. Helpers may reduce the amount of work done by the breeding female or compensate for the absence of a male from the territory

when he is seeking extra-group copulations, but the studies to date are not sufficient to establish this.
